PREFACE

Generations of veterinary practitioners, students, nurses, farmers and pet owners have relied on *Black's Veterinary Dictionary* as a primary reference on animal health and husbandry matters. The 22nd edition has been comprehensively revised and expanded; it covers the widest spectrum of veterinary data available in a single volume. Much new information on animal health, husbandry and welfare topics, and signs of diseases and their treatment, has been added. Many entries reflect the numerous developments that have taken place since the 21st edition was published; they range from advances in medication to descriptions of newly identified conditions; from the resurgence of old scourges such as TB in cattle to the emergence of diseases such as Schmallenberg virus. The risk of exotic diseases such as heartworm being imported following the relaxation of travel arrangements for dogs and cats has been reflected by new entries. Popular breeds of dog and cat, and the inheritable conditions to which they might be susceptible, are described. Notes are included on many new species being farmed or kept as companion animals.

Dr G. R. Duncanson, BVSc, DProf, MSc(VetGP), FRCVS, D. McK. Fraser BVM&S, CertWel. MRCVS, A.D. Malley FRCVS, MVB, BA and S. Nicholas Clayton, BVSc, MRCVS, have all made extensive suggestions and contributions; many more colleagues have given advice. We are very grateful for their input.

E.B., A.A. 2015

Note: The use of small capitals, for instance, ANTIBODY, in the text, refers the reader to the entry of that name for additional information.

VetBooks.ir

VetBooks.ir

Black's Veterinary Dictionary, first published in 1928, owes its existence to the late Professor William C. Miller, who was also responsible for the 1935 edition. When on the teaching staff of the Royal (Dick) Veterinary College, Edinburgh, he saw the need for such a book and modelled it on *Black's Medical Dictionary*. Professor Miller held the chair of animal husbandry at the Royal Veterinary College, London, and completed a distinguished career by becoming Director of the Animal Health Trust's equine research station at Newmarket. Editorship from the 1953 to 1995 editions was in the hands of Geoffrey P. West MRCVS, veterinary writer and journalist.

A

Ab
(See ANTIBODY.)

Abamectin
An AVERMECTIN used in cattle as an ectoparasiticide and endoparasiticide.

Abaxial
Away from the axis. Term often used in describing parts of bones. Opposite of AXIAL.

Abdomen
The part of the body in front of (below in quadrupeds) the spine between the thorax (see CHEST) and the PELVIS. (For a description of abdominal organs, see under appropriate headings.) As birds and reptiles have no demarcation between the thorax and abdomen (no diaphragm) it is inappropriate to use these terms in these Orders.

Abdomen, Diseases of
(See under STOMACH, DISEASES OF; INTESTINES, DISEASES OF; DIARRHOEA; LIVER, DISEASES OF; PANCREAS, DISEASES OF; KIDNEYS, DISEASES OF; BLADDER, DISEASES OF; PERITONITIS; BLOAT; COLIC; ASCITES; HERNIA.)

Abdomen, Injuries of
These include injuries to the abdominal walls, to the alimentary tract and to the organs within the abdomen. Trauma may result in damage to the liver, spleen, kidneys, or urinary bladder. Apparently small external wounds of the abdominal wall may be far more serious than their appearance suggests. Radiographs and ultrasound can be useful in diagnosis.

Diagnosis An exploratory LAPAROTOMY may be necessary to establish the internal effects of such wounds, and also the cause of internal haemorrhage, free intra-peritoneal gas, peritonitis, etc.

Obtaining a sample by PARACENTESIS may be useful, although the hollow needle may be blocked by omentum. Use of a catheter and peritoneal lavage has been effective in detecting early intra-abdominal traumatic lesions, rupture of internal organs, etc. in dogs and cats.

When a stake or other pointed object has caused a large wound in the abdominal wall, the bowels may protrude through the opening, and if the incision be extensive, evisceration may take place. When only the wall of the abdomen has been damaged, there may be severe bruising, and haemorrhage into the tissues (See HAEMATOMA).

If exposure of the abdominal contents has taken place, or if the organs have been themselves damaged, there is risk of SHOCK, haemorrhage, infection, and PERITONITIS; the latter may cause great pain and usually proves fatal. For this reason the injured animal should receive promptly the expert services of a veterinary surgeon or else be humanely destroyed. Simple WOUNDS or bruises of the abdominal walls are treated in the same way as ordinary wounds.

Aberdeen Angus Cattle
An old breed also called Angus. It was developed in Scotland and known since the 18th century with the herd book started in 1862. They were locally known as 'doddies' or 'hummlies'. They are usually all black but can be all red. The cattle are naturally polled and occasionally have white udders. They are a relatively small animal but it means that the crosses have minimal DYSTOKIA. They are hardy and able to fatten off pasture and are often sold as Aberdeen Angus beef which attracts a price premium. A few crosses with FRIESIAN CATTLE have shown SPASTIC calves.

Abiotrophy
A degenerative condition of an organ or tissue leading to dysfunction or loss of function. Usually inherited and often involving brain or other nerve tissue. (See LYSOSOMES – Lysosomal storage disease.)

Abizzia spp.
A group of rapidly growing African trees being exploited as a forestry crop. The seed pods have caused poisoning in goats and cattle. Clinical signs include tachycardia, anorexia, ruminal stasis, anaemia, dyspnoea and recumbency. Affected animals always show methaemglobinaemia.

Ablation
Removal of an organ, or part of an organ, by surgery.

Ablepharia
The lack of eyelids – a normal condition in snakes.

Abnormalities, Inherited
(See GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.)

Abnormal Pigment Deposition in the Eye
An abnormal increase in the ocular pigment which eventually results in an impeding of the drainage of fluid in the eye and causes GLAUCOMA. It is recorded in a few breeds and mainly CAIRN TERRIERS.

A

VetBooks.ir

Abomasum

Abomasum is the so-called 4th stomach of ruminating animals; more correctly, the 4th compartment of the ruminant stomach. It is also called the 'true' or 'rennet' stomach, and the 'reed'. It is an elongated, pear-shaped sac lying on the floor of the abdomen, on the right-hand side, and roughly between the 7th and 12th ribs.

Abomasum, Displacement of

(See STOMACH, DISEASES OF; TYMPANITIC RESONANCE IN CATTLE.)

Abortifacient

A substance causing abortion.

Abortion

The premature expulsion of the fetus and fetal membranes. The termination of pregnancy. In farm animals it represents one important aspect of INFERTILITY. Some of the causes of abortion in farm animals are shown in the tables below:

Cows

Infections

Viruses
- BVD/MD (bovine virus diarrhoea/mucosal disease); bovine herpesvirus 1 (infectious bovine rhinotracheitis/infectious pustular vulvovaginitis)

Chlamydophila
- *C. abortus* (Epizootic abortion)

Rickettsiae
- *Coxiella burnetii* (Q fever)
- *Ehrlichia phagocytophilia* (tick-borne fever)

Bacteria
- *Arcanobacterium pyogenes (formerly Actinomyces pyogenes, previously Corynebacterium pyogenes)*
- *Salmonella dublin, S. typhimurium*
- *Bacillus licheniformis*
- *Brucella abortus;* also *B. melitensis*
- *Listeria ivanovii, L. monocytogenes*
- *Leptospira hardjo* and other serovars
- *Campylobacter fetus* subspecies *fetus*
- *Besnoitia*

Fungi
- *Aspergillus fumigatus*
- *Mortierella wolfii*

Protozoa
- *Neospora caninum*
- *Toxoplasma gondii*
- *Trichomonas fetus*

Non-infectious causes

Claviceps purpurea (ergot in feed)
Stress
Recessive lethal gene
Malnutrition
Haemolytic disease
Vitamin A deficiency
Iodine deficiency

Ewes (female Goats [does])

Infections

Viruses
- Border disease/Thogoto virus

Chlamydophila
- *C. abortus* (formerly *Chlamydia ovis* and *Chlamydophila psittaci*) (Enzootic abortion)

Rickettsiae
- *Ehrlichia phagocytophilia* (tick-borne fever)
- *Coxiella burnetii* (Q fever)

Bacteria
- *Arcanobacterium pyogenes* (formerly *Actinomyces pyogenes* previously *Corynebacterium pyogenes*)
- *Brucella abortus*, now called *Taylorella equigenitalis*; *B. ovis*; *B. melitensis*
- *Campylobacter fetus* subspecies *fetus*
- *Campylobacter jejuni*
- *Bacillus licheniformis*
- *Salmonella dublin, typhimurium, montivideo, S. abortus ovis* and others
- *Listeria monocytogenes*
- *Arizona* spp.

Fungi
- *Aspergillus fumigatus*

Protozoa
- *Toxoplasma gondii*

Non-infectious causes

Stress (e.g. chasing/savaging by dogs; transport)
Near-starvation
Pregnancy toxaemia
Claviceps purpurea (ergot in feed)
Iodine deficiency

Sows

Infections

Viruses
- African swine fever virus
- Aujeszky's disease
- Smedi
- Swine fever virus

Bacteria
- *Erysipelothrix rhusiopathiae* (swine erysipelas)
- *Brucella abortus suis* (not in UK)
- *Pasteurella multocida* (occasionally)
- *E. coli*
- *Leptospira pomona* (not in UK) *grippotyphosa, canicola, icterohaemorrhagiae*

Protozoa
- *Toxoplasma gondii*

Non-infectious causes

Malnutrition, e.g. vitamin A deficiency
(See also CARBON MONOXIDE.)

Mares

Infections

Viruses
- Equine herpesvirus 1 (Equine rhinopneumonitis)
- Equine viral arteritis

VetBooks.ir

Bacteria
Aeromonas hydrophilia
Salmonella abortus equi
Brucella abortus (rarely)
Haemophilus equigenitalis (contagious equine metritis)
Leptospira spp. (sometimes in association with equine herpesvirus 1)
Listeriosis

Non-infectious causes

Twin foals
Plant poisoning (e.g. by Locoweed)
In thoroughbred mares, following an abortion there was reduced reproductive efficiency but subsequent pregnancy and foaling outcomes could not be predicted.

Bitches

Infections

Brucella canis (not UK)
Canine herpes virus
Neospora caninum
Streptococcus spp.
Toxoplasma gondii

Non-infectious causes

Hormonal imbalance
Trauma

Queens

Infections

Chlamydophila psittaci
Feline herpesvirus
Feline immunodeficiency virus
Feline infectious peritonitis
Feline leukaemia virus
Feline panleukopenia virus

Non-infectious causes

Nutritional deficiencies
Progesterone deficiency

Rabbits (does) Abortion is uncommon in rabbit does, but physiological resorption of fetuses can occur before 20th day of gestation. Expulsion of premature aborted fetuses occurs after 24th day of gestation. Prolonged gestation (more than 35 days) is usually due to a small litter of large fetuses which can be expelled or retained and mummified or macerated.

Abortion, Contagious

(See BRUCELLOSIS.)

Abortion, Enzootic, of Ewes and Goats

This disease occurs in all parts of Britain, as well as overseas.

Cause *Chlamydophila abortus* (formerly *Chlamydia ovis* and *Chlamydia psittaci*), which is ingested by mouth from infected material. It can remain latent for long periods in non-pregnant sheep until they become pregnant again. (See CHLAMYDOPHILA.)

Diagnosis Necrotic placentitis is indicative, smears stained by Ziehl-Neelsen show many organisms. A competitive ELISA (cELISA) test is stated to be 100 per cent effective in testing for antibodies against abortion-causing strains of *C. abortus.* Paired serology of aborted ewes can assist, and COMPLEMENT fixation test can be used.

Signs Abortion occurs during the last 6 weeks, and usually during the last 2 or 3 weeks, of the normal period of gestation. Stillbirths and the birth of weak full-term lambs also occur. The placenta is thickened and necrotic. Most infected ewes who do not become ill have a thick, infected vaginal discharge for a week or more. Infertility is temporary, since ewes usually lamb normally the following season.

Enzootic abortion is a zoonosis (see ZOONOSES)**; pregnant women must avoid all contact with infected sheep**.

Prevention Replacement sheep should be obtained from blood-tested disease-free flocks. Vaccines are available; antibiotics (oxytetracycline) given to the whole flock can reduce the level of abortions if given early in an outbreak. Vaccination should be administered to non-pregnant sheep; it is ineffective during an abortion outbreak.

Abortion, Epizootic

Chlamydial abortion in cattle.

Abrachiocephalus

Fetal anomaly without head or arms.

Abrachius

The absence of forelimbs (arms).

Abrasion

A superficial wound of skin or mucous membrane caused by trauma, chaffing, rubbing, etc.

Abscess

Localised lesion comprising of pus, surrounded by inflamed tissue. A tiny abscess is known as a PUSTULE, and a diffused area that produces pus is spoken of as an area of CELLULITIS. Abscesses in cats are usually of this type and may not always 'point' (see below)

An acute abscess An acute abscess is the most common form in most species. It forms rapidly, comes to a head (points) and bursts, or else becomes reabsorbed and disappears.

VetBooks.ir

Causes The direct cause of an acute abscess is either infection with bacteria, or the presence of an irritant in the tissues.

The organisms that are most often associated with the formation of abscesses include staphylococci and streptococci *Arcanobacterium pyogenes; Pasteurella pyocyanea* and, in cats, *Fusobacterium necrophorum* (see BACTERIA).

When bacteria have gained access they start to multiply, and their TOXINS may damage surrounding tissue.

White blood cells (leukocytes) – in particular, those called neutrophils – gather in the area invaded by the bacteria and engulf them. The area of invasion becomes congested with dead or dying bacteria, dead or dying leukocytes, dead tissue cells and debris all of which are converted into a liquefied mass (pus) by the action of LYSOZYMES.

Signs Inflammation, (redness, warmth, swelling, and pain); and sometimes fever may occur. When abscesses are deep and so cannot be detected by palpation, measurement of body temperature, diagnostic imaging and blood tests (to identify changes of morphology and leukocyte proportions) may be required.

An acute abscess is said to point when it has reached the stage when the skin covering it is dead, thin, generally glazed, and bulging. If slightly deeper, the skin over the area becomes swollen, is painful, and 'pits' on pressure. When the abscess bursts, or when it is evacuated by lancing (at the site of bulging or pitting), the pain disappears, the swelling subsides, and the temperature falls. If all the pus has been evacuated, the cavity rapidly heals; if, however, the abscess has burst internally into the chest or abdomen, then pleurisy or peritonitis may follow. When an abscess is deeply seated so as to be out of reach of diagnosis by manipulative measures, its presence can be confirmed by blood tests.

Treatment LANCING is the treatment of choice. It is best to leave the opened abscess uncovered to encourage drainage. Hot fomentations, or application of a poultice, may afford relief. Antibiotics may be employed once drained or as the sole means of treating multiple or deep-seated abscesses. They may be injected into a cavity with or without following aspiration of the pus. A cold or chronic abscess takes a long time to develop, seldom bursts (unless near to the surface of the body), and becomes surrounded by large amounts of hard fibrous tissue. The pus can be solid ('inspissated') or semisolid ('caseated'). Some can be lanced.

A cold or chronic abscess It takes a long time to develop, seldom bursts (unless near to the surface of the body), and becomes surrounded by large amounts of fibrous tissue.

Causes Abscesses due to TUBERCULOSIS, ACTINOMYCOSIS, Staphylococci, and Caseous abscess formation in the lymph nodes of sheep, are the most common types of cold or chronic abscesses. They may arise when an acute abscess, instead of bursting in the usual way, becomes surrounded by dense fibrous tissue. The neutrophils of rabbits, birds, and reptiles do not contain many lysosymes (so are more properly described as heterophils) and the pus in their abscesses is less liquefied – caseated - and inspissated to such an extent that drainage is not achieved by lancing and total excision is the preferred form of treatment.

Signs Swelling may be noticeable on the surface of the body (as in actinomycosis), or it may show no signs of its presence until the animal is slaughtered (as in the case of many tuberculous abscesses and in lymphadenitis of sheep). If it is present on the surface, it is found to be hard, cold, only very slightly painful, and does not rapidly increase in size.

Treatment This may involve surgery to remove the abscess, and/or the use of antibiotics, depending upon the nature of the abscess and its location.

Abyssinian

A breed of short-haired cat similar in appearance to those depicted in illustrations from ancient Egypt. It is favoured for its quiet vocalisation. Familial renal amyloidosis has been found in this breed and it is also prone to MYASTHENIA GRAVIS and HIP DYSPLASIA. DNA tests are available for PROGRESSIVE RETINAL ATROPHY and ERYTHROCYTE PYRUVATE KINASE DEFICIENCY. The breed was the first to have its genome sequenced.

Acacia Poisoning

Acacia poisoning has been recorded in cattle and goats. Signs include ataxia, excitation and prostration.

Acampsia

The inflexibility of a limb; rigidity, ankylosis.

Acanthosis Nigricans

A chronic condition of the skin, the primary form mainly found mainly in short-haired dogs, especially Dachshunds. The secondary form is seen in obesity, nutritional and endocrine disorders. The skin becomes thickened with loss of hair and excessive black pigmentation, and is velvety to the touch. The condition often starts in the axillae (armpits) but the abdomen has also been seen as the primary location. The primary disease cause is unknown and it is not usually curable. It and the

VetBooks.ir

secondary form may respond to corticosteroids (local and injection), after the removal of secondary infections.

Acapnia
Acapnia is a condition of diminished carbon dioxide in the blood.

Acardia
The congenital absence of the heart.

Acardiacus
A parasitic twin without a heart, utilising the circulation of its twin.

Acardius
A parasitic twin without a heart, utilising the circulation of its twin.

Acaricide
A parasiticide effective against mites and ticks.

Acarus
A forage mite only accidentally parasitic.

Acaudal, Acaudate
The absence of a tail.

Accidental Self-Injection, Needle Stick Injury
This has led to human infection with BRUCELLOSIS, ORF, Q FEVER and TUBERCULOSIS (TB).

Accidental self-injection with an oil-based vaccine is painful and dangerous; it requires **immediate** medical attention.

If the accident involves IMMOBILON, the effects can be reversed by an immediate self-injection of Revivon (diprenorphine hydrochloride). A veterinary surgeon who had no Revivon with him died within 15 minutes of accidental self-injection, when a colt made a sudden violent movement. Even a scratch with a used needle can cause collapse. All involved in a procedure with the drug should be aware of the location of the antidote and that of the product leaflet. (See DIPRENORPHINE HYDROCHLORIDE; ETORPHINE; IMMOBILON/REVIVON.) Tuberculin testing can reactivate latent infection in humans. Certain other products such as tilmicosin can be dangerous if much is injected. Thus the 'Warnings' section on a data sheet or product marketing authorisation should always be read before using a new product. Prescribers and suppliers of veterinary medicines should at all times make sure that those using the products are suitably competent, and make them aware of the potential risk.

Accidents
Any part of the animal may be injured in an accident. Often the damage is obvious, such as a broken limb. Serious internal injury may not be immediately apparent. Road traffic accidents are the commonest cause of accidents to dogs and cats. Care must be taken in handling injured animals, as mishandling may make the injury worse. (See also ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION; FRACTURES; BLEEDING; RABBITS-HANDLING; INTERNAL HAEMORRHAGE; BURNS AND SCALDS; SHOCK; EYE, DISEASES AND INJURIES OF.)

First-aid for owners: how to carry an injured cat with a suspected limb fracture. A dog may be carried similarly if not too large. An alternative for a bigger dog is to draw it gently on to a coat or rug, ready for lifting into the back of a car for transport to a veterinary surgeon. Photo, Marc Henrie / Pedigree Petfoods.

Accommodation
(See EYE.)

Acemann
A potent anti-viral substance extracted from the fleshy leaves of aloe vera. It has the additional property of enhancing the immune system especially lymphocytic function.

Acephalobrachia
A development anomaly in which head and arms are absent, the same as ABRACHIOCEPHALUS.

Acephaly
The absence of a head.

VetBooks.ir

Acepromazine, Acetylpromazine (Acp)

Acepromazine (Acetylpromazine) is a phenothiazine-derived tranquilliser. Given by injection before anaesthesia, it enables low doses of barbiturates to be used: 1 to 3 mg per kg bodyweight, given by mouth a quarter of an hour or more before food, may be used for the prevention of travel sickness in small animals. In equines, also used for relaxation of the penis; should be used with care.

Acepromazine lowers blood pressure, and so is contraindicated in accident cases. Noradrenaline (norepinephrine) is recommended for reversing any fall in blood pressure.

Acetabulum

Acetabulum is the cup-shaped depression on the PELVIS with which the head of the femur forms the HIP-JOINT. DISLOCATION of the hip-joint sometimes occurs as the result of 'run-over' accidents, and FRACTURES of the pelvis involving the acetabulum frequently result from the same cause.

Acetaminophen

(See PARACETAMOL.)

Acetic Acid

Acetic acid is used as a treatment for alkalosis, which may be caused by urea poisoning. Acetic acid may form naturally in pig mash feeds allowed to stand, or in silage and fermented hay, when it can cause illness or even death. It is one of the normal breakdown products of cellulose digesting bacteria in the rumen. It is a VOLATILE FATTY ACID produced in carbohydrate digestion in ruminants.

Acetonaemia, Ketosis

This, and ketosis, are names given to a metabolic disturbance in cattle and sheep. It may be defined as the accumulation in the blood plasma, in significant amounts, of KETONE BODIES. The disorder may occur at any time, but is commonest in winter in dairy cows kept indoors when receiving a full ration of concentrates. The condition is uncommon in heifers and occurs less frequently before the 3rd calving. It can be seen in cows in the 1st month after calving and is most commonly apparent at 3 weeks.

Cause The disturbance is caused by the cow's demands for carbohydrate exceeding that available from the feed or where KETONE BODIES are produced more rapidly than they are utilised. Whenever the glucose level in the blood plasma is low, as in starvation or on a low-carbohydrate diet, or when glucose is not utilisable, as in diabetes, the concentration of free fatty acids in the plasma rises, as may fatty acid levels. This rise is roughly paralleled by an increase in the concentration of ketone bodies, which provide a 3rd source of energy. In other words, unless fat is metabolised at the same speed as it is mobilised, the liver will become fatty. The moderate ketosis which occurs under a variety of circumstances is to be looked upon as a normal physiological process supplying the tissues with a readily utilisable fuel when glucose is scarce.

By contrast, the severe forms of ketosis met with in the lactating cow and the diabetic cow, and characterised by high concentrations of ketone bodies in the blood and urine, are obviously harmful pathological conditions where the quantities of ketone bodies formed grossly exceed possible needs. Secondary ketosis can occur following any condition that reduces feed intake without a comparable reduction in milk yield.

Signs The cow shows rapid weight loss, reduced appetite and favours roughage to concentrates. Rumen activity is reduced and faeces become harder. The animal is markedly dull, with a dull coat and reduced milk yield. The breath has a sickly sweet smell of acetone, which may also be detected in the milk and urine. Sometimes nervous signs are present, with the animal licking walls, head rope and other objects, and over-excitement. Most animals recover with treatment.

Diagnosis Rothera's test on milk; urine may be used but can cause false positives.

First-Aid Treatment consists in giving about half pint (500 ml) of glycerine or propylene glycol, diluted in water, or a preparation containing sodium propionate, all by mouth.

The feeding of cut grass or flaked maize, the addition of a little molasses to feed, and exercise all aid recovery. Injections of dextrose and/or corticosteroids are used under veterinary control. Vitamin B_{12} is used by some clinicians. A very few resistant cases defy all treatment; the cow improves up to a point but does not feed properly and dies in 10 to 20 days.

Prevention In the 2nd half of a lactation, the diet of a dairy cow should contain a greater proportion of home-grown foods with a lower digestibility than that in the diet fed during peak lactation.

At the beginning of the dry period, the cows should be fit but not fat (condition score 2.5 to 3). The cows should be kept in this condition during the dry period by a diet of relatively poor-quality forage or heavy stocking and should be given a vitamin/mineral supplement. Production rations should be introduced in the last 2 weeks of the dry period and contain both the forage and concentrate

VetBooks.ir

elements to be fed after calving. Cattle should not be 'steamed up' but should receive up to 3 kg (6½ lb) (dry) of the milking ration.

After calving, the quantity of production ration fed should be steadily increased as the milk production increases. For high-yielding cows the production concentrate ration should contain 16 to 18 per cent crude protein with a high metabolisable energy. The carbohydrate in the ration should be readily digestible. The inclusion of some ground maize may be particularly helpful in ketosis-prone herds, since some of the starch escaping rumen fermentation is digested and absorbed as sugars. Production concentrates should contain a balanced vitamin and mineral supplement.

Cows must **not** be given excessive amounts of straw. Concentrates can be fed between meals from out-of-parlour feeders, as a constituent of a complete diet, or layered in silage. High-yielding cows should not be penned for a long time in yards, but be given ample opportunity for exercise.

After the first 10 to 12 weeks of lactation, the feeding routine of the high-yielders can be modified. The home-grown forage can be slowly increased in the ration with a corresponding decrease in the more expensive highly digestible carbohydrates if the cow's performance is not affected. This changeover must be a gradual process.

Acetone

A ketone with characteristic smell found in small amounts in some samples of normal urine, and in greater quantities during the course of diabetes mellitus, acetonaemia, pneumonia, cancer, starvation, and diseases of disturbed metabolism.

Acetonuria is the excretion of ketones in the urine.

Acetylcholine

Acetylcholine is a neurotransmitter, an important link in the transmission of nerve impulses between the nerves themselves (at the synapses) and between the nerve and the muscle. Paralysis results if the body's ability to produce acetylcholine is affected by shock, injury or certain drugs, such as curare. Pharmaceutical preparations of such compounds are used in anaesthesia to produce muscle relaxation, which facilitates surgical procedures.

In the healthy animal, acetylcholine is destroyed by the enzyme cholinesterase as soon as the nerve impulse has passed. When this reaction is prevented, as in poisoning by organophosphorous insecticides, convulsions follow. Excessive salivation is an important sign in dogs so poisoned.

Acetyl Coenzyme-A (Acetyl Co-A)

An enzyme which carries acetyl groups into the energy cycle (KREB'S CYCLE; TRICARBOXYLIC ACID CYCLE) and also precedes lipid formation.

Acetylcysteine

It is also known as N-acetylcysteine or N-acetyl-L-cysteine. It is a nutritional supplement and a pharmaceutical drug. It is used as an antidote to PARACETAMOL (ACETAMINOPHEN) poisoning, a mucolytic agent and when deficient to supplement sulphur-containing amino acids (provides CYSTEINE)

Acetyl Promazine

(See ACEPROMAZINE.)

Acetylsalicylic Acid

(See ASPIRIN.)

Achalasia of the Oesophagus

Absence of progressive peristalsis and failure of the lower oesophageal sphincter to relax. It has been reported as an inherited condition in Boston terriers, English springer spaniels, smooth fox terriers, wire-haired fox terriers, German shepherd dogs and Rhodesian ridgebacks.

Acheiria

A congenital absence of one or both hands (forefeet).

Acheiropodia

The congenital absence of hands or feet.

Achilles Tendon

A group of tendons which insert on the calcaneus near the point of the hock. The tendon is made up of the tendons of the gastrocnemius, soleus, superficial digital flexor, semitendinosus, and biceps femoris muscles.

Achondroplasia
(adjective, Achondroplastic)

Achondroplasia is a form of dwarfing due to disease affecting the long bones of the limbs before birth. It is noticed in some calves of certain breeds of cattle such as the Dexter, in some breeds of dogs, and in lambs. (See GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.)

Achorion

(See RINGWORM.)

Achromotopsia

A deficiency of pigmentation tissue that can result in day blindness or partial or total colour blindness. (See also CONE DEGENERATION.)

Achromotrichia

The absence or loss of pigment from the hair. It occurs following freeze branding in animals such as cattle, and horses.

VetBooks.ir

Acid-Fast Organisms

Acid-fast organisms are those which, after staining with carbol-fuchsin dye, retain their colour after immersion in strong acid solutions; the non-acid-fast group are decolourised by the acid. The test usually used is ZIEHL-NEELSEN.

The important acid-fast bacteria are:

Mycobacterium tuberculosis, which causes tuberculosis in humans and other primates;
M. bovis, which causes tuberculosis in cattle and some other mammals;
M. microtis, which is a pathogen of mice and shrews;
M. piscium, which causes tuberculosis in fish;
M. avium, which causes tuberculosis in birds and a variant var. *paratuberculosis* (*johnei*), which causes Johne's disease in ruminants and the camelids;
M. leprae, which causes leprosy in humans, primates and armadillos.

Many mycobacteria are saprophytic and are found in soil, water, decaying vegetation, etc.

Acid-Fast Stain

A positive stain obtained by using the ZIEHL-NEELSEN test.

Acidifiers

These are organic acids used in the diet as growth enhancers; their use increased following the European ban on the use of antibiotics in growth promoters. They are either short chain monocarboxlic acids (formic, acetic, proprionic, butyric) or carboxylic acids (lactic, malic, tataric, and citric). They act on acid-sensitive bacteria. A Bulgarian study showed that 4 per cent citric and 4 per cent tartaric acids in the feed of cattle completely inhibited *E. coli*, *Proteus* spp., *Pseudomonas* spp., *Salmonella enteritidis*, *Listeria monocytogenes* and *Staphylococcus aureus*. Their effect is caused by decreasing the internal pH of the microbes to a level at which it inhibits or eventually kills them.

Acidosis

A condition of reduced alkaline reserve of the blood and tissues, with or without an actual fall in pH. Sudden death may occur in cattle from acidosis after gorging on grain, or following a sudden introduction of cereal-based concentrates. A subacute form (SARA – subacute ruminal acidosis) is now commonly seen in 20-22 per cent of newly calved high yielding dairy cows. It is a common complication of diarrhoea, particularly in young animals. (See also BARLEY POISONING.) Sheep may similarly be affected. Rabbits, having a limited ability to excrete hydrogen ions, are particularly susceptible to metabolic acidosis.

Acids, Poisoning by

Strong acids are intensely destructive of animal tissue. If accidentally consumed, the effects are immediate and drastic.

Signs Excessive salivation, great pain, and destruction of the mucous membrane lining the mouth (which causes the unfortunate animal to keep its mouth open and protrude its tongue) are seen. After a short time convulsive seizures and vomiting occur, and general collapse follows; while if a large amount of acid has been taken, death from shock rapidly supervenes.

Treatment Alkaline demulcents should be given at once and in large quantities; bicarbonate of soda given in gruels or barley-water or milk is quite useful. These neutralise the acids into harmless salts, and soothe the corroded and burnt tissues. (See ACETIC ACID; HYDROCYANIC ACID (HCN).)

Aciduria

Aciduria is the excretion of acid urine. It may occur as a result of feeding a specialised diet to reduce the formation of urinary calculi (stones) in the dog and cat. Also in dairy cows it can follow DCAD.

Acinus

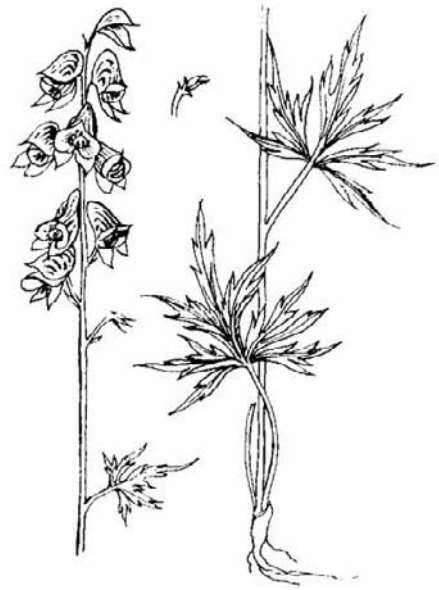
Acinus is the name applied to each of the minute sacs of which secreting glands are composed.

Acleistocardia

A congenital patent foramen ovale in the heart (hole in the heart).

Acne

(compare FURUNCULOSIS)



An inflammation of sebaceous glands or hair follicles. In the horse, a contagious form of acne is sometimes due to infection with *Corynebacterium ovis*. Acne often accompanies canine distemper, and is seen on the chin of the cat. It is not comparable with human acne.

Aconite

(*Aconitum napellus*) Also known as monkshood, it is a poisonous plant cultivated in gardens, but also growing wild in the cooler mountainous parts of both hemispheres. It is frequently cultivated in gardens in Britain for its decorative appearance. All parts of the plant are poisonous, the parts above the ground being often eaten by stock (see ACONITE POISONING). Aconite owes its poisonous properties to an alkaloid (aconitine), mainly found in the tuberous root, but present in smaller amounts in other parts of the plant. Aconitine is irritant in large doses, but smaller

VetBooks.ir

doses have a sedative and paralysing effect on the sensory nerves.

Aconite (*Aconitum napellus*). The flowers are either blue or yellow, and each has a petal which is in the shape of a helmet or hood; hence the name 'monkshood' which is often applied to the plant when growing in gardens. Height: 65 cm to 2 m (2 to 6 ft).

Aconite Poisoning

Aconite poisoning is apt to occur when herbivorous animals gain access to gardens.

In pigs poisoning sometimes occurs through eating the horseradish-like roots.

Signs The chief signs shown are general depression, loss of appetite, salivation, inflammation of the mucous membrane of the mouth and jaws, grinding of the teeth; pigs are nauseated and may vomit; and horses become restless and may be attacked with colic. Animals walk with an unsteady gait, and later become paralysed in their hindlimbs. The animal becomes unconscious, followed by convulsions and death.

Treatment An emetic must be given to the pig, dog and cat to induce vomiting, and a stomach-tube may be passed in the large herbivorous animals that do not vomit. Stimulants, such as strong black tea or coffee, should be given by mouth.

Acoprosis

Absence or scantiness of faeces in the intestines.

Acorea

The absence of the pupil of the eye.

Acormus

The lack of a trunk; a fetal abnormality consisting of a head and extremities without a trunk.

Acorn Calves

A congenital problem most commonly seen in calves from suckler cows fed on an unsupplemented silage diet. Affected calves have domed heads, other facial deformities, and stunted limbs.

Acorn Poisoning

(See under OAK POISONING.)

Acoustic Nerve

(See AUDITORY NERVE.)

Acp

(See ACEPROMAZINE.)

Acral Mutilation Syndrome

An inherited syndrome resulting from sensory neuronal degeneration with associated self-mutilation of the extremities seen particularly in German short-haired pointers and English pointer puppies from three months old.

Acral Pruritic Node

An intensely itchy thickened area of skin usually found over the dorsal aspect of the carpus in dogs. It is extremely difficult to control as continual chewing by the dog interferes with healing. It may be behavioural in origin or have an underlying pathological cause.

Acrania

The congenital absence of cranium, partial or complete.

Acreminiumzeae

A naturally occurring mould producing pyrrocidines that disrupts the ability of *Aspegillus* and *Fusarium* spp. to infect ripening maize kernels thereby preventing mycotoxicosis caused by these moulds.

Acromegaly

A condition caused by excess of the growth hormone STH, produced by the anterior lobe of the pituitary gland, leading to enlargement of the extremities and to overgrowth of connective tissue, bone and viscera. (See also SOMATOTROPIN.)

Acromicria

Congenital shortness or smallness of the extremities.

VetBooks.ir

Acropachia

Also known as hypertrophic osteopathy, or Marie's disease, it is a condition in which superfluous new bone is laid down – first in the limbs and later in other parts of the skeleton. It may accompany tumours and tuberculosis in the dog.

Acrosome

A cap over the anterior part of the head of spermatozoa; it contains enzymes which aid penetration of the ovum.

ACTH

ACTH is the abbreviated form of ADRENOCORTICOTROPHIN. (See also CORTICOTROPHIN.)

Actinobacillosis, Wooden Tongue

Actinobacillosis is a disease of cattle similar in some respects to ACTINOMYCOSIS, and sometimes mistaken for it.

Generally only 1 or 2 animals in a herd are affected at one time.

It is most commonly seen as hard and painful swellings, often with ulcerated areas on the tongue, hence the common name 'wooden tongue'. It may also be seen as swellings on the lips, cheeks, jaw, and at the base of the horn. Pneumonia or infection of the liver or alimentary canal may lead to death in untreated cases. The disease occurs also in sheep and occasionally in pigs and foals. Skin lesions can occur in goats and camelids.

Cause Actinobacillosis is due to infection with *Actinobacillus lignièresi*. Infection occurs through injuries, abrasions, etc. of soft tissues, including tongue and subcutaneous tissues and when lymph nodes are affected through invasion along the lymph vessels. Abscesses form.

Lesions may also involve the lungs, rumen, omasum, abomasum, and reticulum.

Actinobacillus seminis was discovered in a sheep in Australia. The infection, sometimes subclinical, has since been recognised in several countries including the UK, and causes polyarthritis.

Signs With *Actinobacillus lignièresi* when the tongue is affected the animal has difficulty in mastication and swallowing and there is usually a constant dribbling of saliva from the mouth. When lymph nodes in the throat are affected, the swelling and pressure caused may have little effect or may make swallowing and breathing difficult; if the lesion is in the skin and superficial tissues only, it may attain to a great size without causing much trouble. If the saliva is examined there may be found in it small greyish or greyish-yellow 'pus spots', in which the organism can be demonstrated by microscopic methods. Later, the saliva may become thick, purulent, and foul smelling.

Treatment Antibiotics are often effective, such as streptomycin for a minimum of five days. In intransigent cases, intravenous sodium iodide is used.

Pigs The disease has been recorded both in the UK (very rarely) and overseas, caused by *Actinobacillus equuli* (*Bacterium viscosum equi*) causing sudden deaths with dehydration, multifocal subcutaneous haemorrhages throughout the carcase, epicardial and endocardial haemorrhages, congested oedematous lungs, congested liver, multiple spots on kidney surface and multifocal embolic infarcts in the renal cortex. *Actinobacillus suis* has been recorded occasionally; it causes septicaemia in piglets and lesions in various organs. *Actinobacillus pleuropneumoniae* (formerly *Haemophilus pleuropneumoniae*) causes pleuropneumonia in pigs.

Horses *Actinobacillus equuli* causes septicaemia and internal lesions in foals (see under FOALS, DISEASES OF).

Precautions The disease can be transmitted to man. Accordingly, care must be taken over washing the hands, etc., after handling an animal with actinobacillosis.

Actinobacillus equuli

A Gram-negative rod-shaped bacterium that is a commensal on the mucosal membranes of adult horses. It causes fatal septicaemia in newborn foals; the infection is directly from the mare via the mouth or respiratory tract. It can cause sudden deaths in pigs. (See ACTINOBACILLOSIS.)

Actinobacillus pleuropneumoniae

A Gram-negative rod-shaped bacterium formerly called *Haemophilus pleuropneumoniae*. It has at least 13 strains and is recognised worldwide. It mainly affects growing pigs but in naïve herds, adults and baby pigs are affected. The main signs are respiratory (a cough) with poor growth, often initiated by stress. It is part of the PORCINE REPRODUCTIVE RESPIRATORY SYNDROME complex. Post-mortem examination shows pleuropneumonia. Diagnosis can be by bacterial isolation from lung, serotyping of strains, and monitoring slaughter. Treatment is with antibiotics including CEPHALOSPORINS and TILMICOSIN. Prevention is by reducing stress at management changes and vaccination.

Actinomycosis, Lumpy Jaw

This has been recorded in very many species of animals, including man, dogs, pigs, birds and reptiles.

The lesions produced bear a considerable resemblance to those of actinobacillosis (see above), and

VetBooks.ir

are often indistinguishable from them, but typically actinomycosis affects the cheeks, pharynx and especially the bone of the jaws (it is known as 'lumpy jaw' in cattle), while actinobacillosis is more likely to attack soft tissues only.

Cause *Actinomyces bovis*. This anaerobic bacterium is present in the digestive system of cattle, and it is probable that it can only become pathogenic by invading the tissues through a wound. It is common during the ages when the permanent cheek teeth are cutting the gums and pushing out the milk teeth.

The liver is sometimes affected, while actinomycosis and actinobacillosis have both been found in lungs and bronchi.

Yellow sulphur granules are found in the lesions.

Actinomyces (Corynebacterium) pyogenes is a major cause of abscesses and suppurative conditions.

Signs The swelling in bone and other tissue, mainly composed of dense fibrous tissue, may reach a considerable size causing interference with mastication, swallowing, or breathing, depending on the situation of the lesion. In most cases when the mouth or throat is affected, there is a constant dribbling of saliva in varying amounts from the mouth. In the earlier stages this saliva is normal in its appearance, but later becomes offensive.

Actinomycosis of the bone of the upper and lower jaws produces an increase in the size of the part and a rarefication of its bony structure, the spaces becoming filled with the proliferation of fibrous tissue which is characteristic of the disease.

When the udder is affected, hard fibrous nodules may be felt below the skin, varying in size from that of a pea to a walnut or larger, and firmly embedded in the structure of the gland itself. These swellings enclose soft centres of suppuration which, on occasions, may burst either through the covering skin, or into an adjacent milk sinus or duct. The milk from such animals should not be used for human consumption because of the danger of the consumer contracting the disease.

Treatment Antimicrobials (penicillin, streptomycin, sulphonamides) may be effective. In intransigent cases, intravenous sodium iodide and/or potassium iodide by mouth may be used.

Precautions The disease can be transmitted to man; hygienic precautions are necessary after handling infected animals.

Activated Water

Electrically charged sodium and chlorine ions in water produced by electrochemical means was supplied to pigs in Germany. This resulted in a 5 per cent increase in daily liveweight gain and improved feed conversion.

Active Medicine, Active Treatment

This is a medicine or pharmaceutical product which has proven biological activity against particular disease organism(s) or causes or is active in specific diseases or certain disorders that are generalised or related to specific organs.

Acuaria Uncinata

This roundworm, now called *Echinaria uncinata* has caused outbreaks of disease in geese, ducks, and poultry. The life-cycle of this parasite involves an intermediate host, *Daphnia pulex*, the water flea. On post-mortem examination of affected birds, worms may be found in nodules scattered over the mucous membrane of the oesophagus and proventriculus. Mortality may be high. Dosage with fenbendazole is normally effective.

Acupuncture

The centuries-old Chinese technique of needle insertion at certain specified points on the surface of the body has become a part of Western veterinary medicine for treatment, analgesia, and resuscitation. Acupuncture can produce the morphine-like natural substances called ENDORPHINS which are, in effect, analgesics.

Adaptations have been made, such as the use of lasers instead of needles. Ultrasonics and heat have also been applied to the points.

Acupuncture is commonly used to relieve painful conditions; also in treating poor circulation, tissue damage, and smooth muscle dysfunction. However, it is not a panacea and must be applied by experts.

Success has been reported for the use of injections of sterile saline at acupuncture points in treating intractable pain in horses. The injections were repeated at weekly intervals for up to 8 weeks.

In China, acupuncture has been used for surgical analgesia in animals and man.

Acute

A disease is called acute – in contradistinction to 'chronic' – when it appears rapidly, and either causes death quickly or leads to a speedy recovery. Very rapid onset or death is termed 'peracute'. (See also under DEATH, CAUSES OF SUDDEN; CHRONIC, PERACUTE, SUBACUTE.)

Acute Phase Proteins

(See PROTEIN, ACUTE PHASE.)

Adactyly

A congenital abnormality in which there is the complete absence of the digits.

VetBooks.ir

Adamantinoma
A tumour affecting the jaw and composed of cells that normally produce dental enamel.

Adder
The common viper (*Vipera berus*). About 50 cm (20 in) in length, it has dark markings on a paler ground. If disturbed, this snake may bite farm or domestic animals. The bite is dangerous especially in juveniles and particular if the animal is bitten on the head or forequarters. An antiserum is available: veterinarians require a Special Treatment Certificate.

Addison's Disease, Hypoadrenocorticism
Addison's disease (hypoadrenocorticism) is caused by failure of the ADRENAL GLANDS to produce adequate amounts of corticosteroids. It may be caused by congenital defects in, injury to, or disease of the cortex of the gland, when it is known as primary hypoadrenocorticism. Secondary hypoadrenocorticism results from excessive or prolonged dosage of an animal with cortisone products, which depresses the natural production of the hormone.

Signs In the dog or cat, where it most commonly occurs, the animal may be lethargic, depressed and weak; diarrhoea and vomiting may be seen. In severe cases left untreated, death may result. Diagnosis is by ACTH stimulation test.

In cattle, it is associated with a high incidence of aborted, weakly or still-born calves.

Treatment The condition responds rapidly to administration of hydrocortisone or other appropriate corticoid product to restore levels of cortisol in the blood; numerous formulations are available. (See also HYPERADRENOCORTICISM in ferrets.)

Additives
Substances incorporated in a pre-mix added to animals' feed, often for a purpose other than nutrition. They are mainly growth promoters, enhancers of feed conversion, or, commonly, used to provide vitamins or minerals necessary for a healthy diet. In addition to minerals and vitamins, biological substances and certain dyes such as xanthins (for coloration of rainbow trout) are permitted additives. Other additives that are available on prescription include certain ANTHELMINTICS and coccidiostats for the control of parasites in farm animals. The use of antibiotics as growth promoters, permitted to a limited extent to date, has now been phased out in the EU. However prescribed antibiotics can be used for animals to treat diseases.

Very strict controls apply to the preparation and use of medicated feeds with the principal aim of ensuring that consumers are not put at risk from medicinal residues in food animals. The legislation is contained in Veterinary Medicines Regulations which are revised annually. A guidance note is issued by the Veterinary Medicines Directorate under the heading 'Medicated feeding stuffs and specified feed additives' and the Feeding Stuffs (Zootechnical Products) Regulations 1999. All UK compounders, whether commercial or home mixers, must register with the Royal Pharmaceutical Society or the Department of Agriculture for Northern Ireland. Keepers of exotic animals often have great difficulty in balancing the nutritional requirements of their charges and make use of additives of vitamins and minerals. Specialised formulations are available.

(See also under ANTIBIOTIC; GROWTH PROMOTERS; HORMONES IN MEAT PRODUCTION.)

Adenitis
Inflammation of a lymph gland.

Adenofibroma
Adenofibroma is a fibrous tumour enclosing neoplastic glandular tissue.

Adenoma
A TUMOUR composed of epithelial tissue, often gland-like in appearance. It may sometimes be found in positions where glandular tissue is not normally present. A malignant form is the adenocarcinoma.

Adenomatosis
The formation of numerous adenomatous growths in an organ. (See PORCINE INTESTINAL ADENOMATOSIS; PULMONARY ADENOMATOSIS.

Adenopathy
Swelling of the glands, particularly the lymph glands.

Adenosine
Adenosine is a purine which is part of the structure of certain genes controlling the formation of amino acids. Adenosine triphosphate and diphosphate are important in the contraction of muscles.

Adenosine Diphosphate (ADP)
A compound produced from the hydrolysis that is important in the metabolisation of energy. It is involved in the process by which potential ('stored') energy is transformed into kinetic ('usable') energy.

Adenosine Monophosphate (AMP)
Also called adenylic acid: a nucleotide adenosine 5-phosphate. It is used in energy production and synthesis of nucleotides.

VetBooks.ir

Adenosine Triphosphate (ATP)
A nucleotide adenosine 5-triphosphate which can be converted to ATP and AMP. It is found in all cells.

Adenovirus
This is a contraction of the original term 'adenoidal-pharyngeal conjunctival agents'. (See VIRUSES.)

ADH
(See ANTIDIURETIC HORMONE.)

Adhesion Factor, Bacterial
(See BACTERIAL ADHESIVENESS.)

Adhesions
Adhesions occur by the uniting or growing together of structures or organs which are normally separate and freely movable. They are generally the result of acute or chronic inflammation, and in the earlier stages the uniting material is fibrin, which later becomes resolved into fibrous tissue.

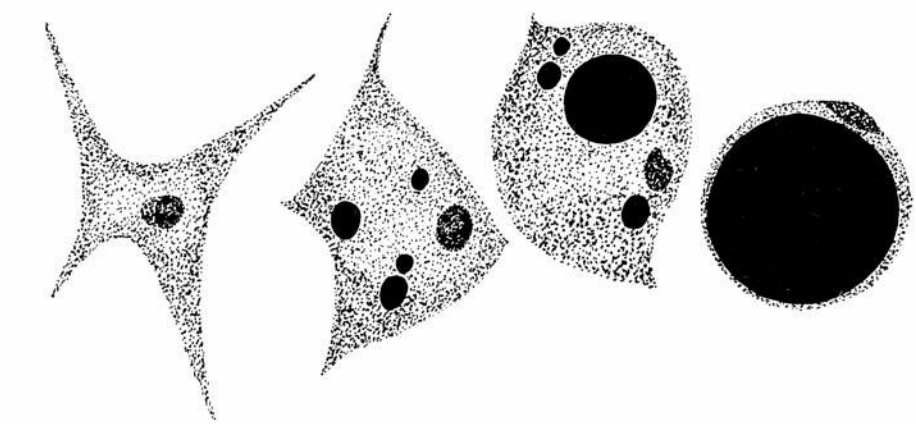
Treatment Surgical division of these adhesions is often necessary especially in the abdominal cavity, the ocular fornix and in adhesions of the walls of the vagina following injuries received at a previous parturition. (See PLEURISY; PERITONITIS.)

Adipocytes
Another name for FAT CELLS or lipocytes and they are of two types containing brown or white fat.

Adipose Tissue
Here fat is stored as an energy reserve; globules of fat form within connective tissue cells. When additional fat is stored, each cell eventually becomes spherical, its nucleus pushed to one side.

During demanding muscular exercise, or when food is insufficient, or during a debilitating disease, the cells release the fat into the bloodstream and resume their normal shape. (See also LIPOMA.)

Adjuvant
A substance added to a vaccine, in order to stabilise the product and enhance the immune response.



Ad Lib Feeding
Abbreviation for *ad libitum feeding*. This is a labour-saving system under which pigs or poultry help themselves to dry meal, etc., and eat as much as they wish. It is also used in dairy cattle and for intensive beef production. (See also DRY FEEDING.)

ADP
(See ADENOSINE DIPHOSPHATE.)

Adrenal Glands, Suprarenal Glands
These are two small organs situated at the cranial extremities of the kidneys, and are endocrine glands consisting of a cortex and medulla.

Function The cortex secretes hormones which are called steroids or corticosteroids. These include glucocorticoids, notably cortisol, concerned with the regulation of carbohydrate metabolism; and mineralocorticoids (which regulate sodium and potassium levels in body fluids), e.g. aldosterone. The cortex also secretes androgens; the medulla secretes adrenalin and noradrenalin.

Surgical removal of the adrenal glands (adrenalectomy) has been carried out in the treatment of CUSHING'S SYNDROME in the dog – survival being possible through hormone implants. Otherwise, removal of the adrenals usually leads to death within a matter of weeks.

Typical fat cell formed by intake of fat globules. (Reproduced with permission from R. D. Frandson, *Anatomy and Physiology of Farm Animals*, Lea & Febiger, 1986, after Ham and Leeson, *Histology*, J. B. Lippincott Co.)

VetBooks.ir

Atrophy The commonest cause of adrenal atrophy in the western world has been said to be corticosteroid therapy. Hyperadrenocorticism in ferrets differs from that in humans, dogs, and cats, in that adrenocortical sex steroids, rather than cortisol, play an important role in the pathogenesis.

Adrenalin, Adrenaline; Epinephrine

Adrenalin (adrenaline) is the 'fight or flight' hormone from the adrenal glands (see above).

Its chief action is that of raising the tone of all involuntary muscle fibres, stimulating the heart, constricting the walls of the smaller arteries, and producing a rise in the blood pressure. It is used for checking capillary haemorrhage in wounds, and for warding off shock or collapse by raising the blood pressure. It can be used to treat acute allergies.

Adrenocorticotrophin (ACTH), Corticotrophin

A naturally occurring hormone produced by the anterior lobe of the pituitary gland.

ADV

Abbreviation for Aleutian Disease Virus (See ALEUTIAN DISEASE.)

Aedes

(See under FLIES.)

Aelurostrongylosis

A form of PARASITIC BRONCHITIS caused by the Genus *Aelurostrongylus* of ROUNDWORM. *A. abstrusus* in the cat, *A. falciformis in badgers and A. pridhasmi* in wild milk. Treatment is with AVERMECTINS or BENZIMADAZOLE products.

Aelurostrongylus

A lungworm of cats. (See ROUNDWORMS.)

Aerobe

A micro-organism which needs oxygen for its growth and multiplication. (See also ANAEROBE.)

Aeromonas

Aeromonas shigelloides is associated with chronic diarrhoea in cats. (See also FURUNCULOSIS.) *Aeromonas salmonicida* is implicated in furunculosis, a skin disease of salmon. A vaccine against the disease is available.

Aerosol

A liquid agent dispersed in air in the form of a fine mist. If aerosols, for insecticidal and other purposes, are used over a long period, e.g. by a continuous evaporator, thought must be given to the effect of the chemicals used on (a) the health of the livestock; (b) organochlorine or other residues left in the carcase to the detriment of people eating meat and; (c) the health of the stockmen.

Aerosols as a Mode of Infection Viruses excreted by animals suffering from an infectious disease may be transmitted to other animals (or man) as an aerosol. ('Coughs and sneezes spread diseases.')

Salmonella, Brucella and other infections of veterinary surgeons through aerosols has occurred during uterine irrigation, calving interventions and embryotomies in cows.

Aerotropism

The tendency of micro-organisms to group themselves about a bubble of air in culture media.

Aetiology, Etiology (US)

Aetiology is the cause of a disease, or the study of such causes.

AFB

Abbreviation of AMERICAN FOULBROOD. (See also BEES.)

Affenpinscher Dogs, Affenpinschers

A small (toy) breed of terrier. It has a wiry coat and while it loses its hair, it does not have a moult. They are usually black but can be grey, red, black and tan and belge (mixed black, white and red hairs), and weigh 2.0 kg to 6.0 kg (6.5 lb to 13.2 lb). They may be territorial over food and toys. It is suspected that CHIARI-LIKE MALFORMATION and SYRINGOMYELIA may be inherited. They can suffer HIP DYSPLASIA, TRACHEAL COLLAPSE and CATARACTS.

Afferent

Conducting towards a central or specific site or organ. Used for nerves, nervous activity, arterioles, alimentary tract, kidney etc. Efferent is the conducting away from a central or specific site or organ. (See EFFERENT.)

Afghan Hound

A tall breed of dog with a silky coat. Inherited cataract caused by a recessive gene has been reported in the breed.

Aflatoxins

Toxins produced by fungi, e.g. *Aspergillus flavus*: they cause poisoning in animals eating contaminated feed materials. The toxins have been found mainly in groundnut meal, but sunflower and cottonseed can also be affected. The Feeding Stuffs Regulations 2000 require those products, and copra, palm kernel, maize and feeds derived from them, to be screened for the presence of toxins. Under the Feeding Stuffs Regulations 2000 the maximum permitted level of aflatoxins is 0.2

VetBooks.ir

mg/kg of feed materials with more than 12 per cent moisture.

In cattle, aflatoxins may give rise to a reduced growth rate and lower milk yield. Aflatoxins are excreted in the milk. In pigs, jaundice may be seen; post mortem, the liver has a leathery appearance. Adult pigs may show bile duct carcinoma.

Aflatoxicosis in poultry is characterised by haemorrhages, anorexia, decreased efficiency in food utilisation, pathological changes in the liver, kidneys and bile ducts, and death. The problem can be prevented by storing grain with 13 per cent of moisture or less which is uneconomic in many countries. The litter may also be a source of toxins and consequently it is important to keep the moisture in the litter to a minimum by ensuring that the ventilation of the house is adequate and that the waterers are operating correctly.

Fish are extremely susceptible to aflatoxins. As one of the precautions taken to keep animal feeds free of dangerously high levels of aflatoxins, trout have been used for testing. In young trout (as in pigs), aflatoxin poisoning is likely to result in cancer of the liver. (Mature cock fish become fully resistant.) Equally, care has to be taken with commercial dry trout feeds, to ensure that aflatoxin level is below 0.5 parts per billion; otherwise malignant tumours are apt to develop, and later liquid-filled cysts may grow to a remarkable size.

As the long-term effect is cancer of the bile ducts, animals without gall-bladders, e.g. horses and deer, are less likely to be affected. (See also MYCOTOXICOSIS; CIRRHOSIS.)

AFRC

AFRC is the abbreviation for the Agricultural and Food Research Council. This body was replaced in 1994 by the Biotechnology and Biological Sciences Research Council. (See BBSRC.)

Africander

Cattle in origin about ¾ Brahman and ¼ British beef breed. (See also under CYTOGENETICS.)

African Horse Sickness

(See HORSE-SICKNESS, AFRICAN.)

African Swine Fever

(See SWINE FEVER, AFRICAN.)

Afrikaner

A synonym for Brahman or Zebu cattle.

Afterbirth

(See PLACENTA.)

Afterbirths, Infected

Infected placentas may be a source of infection to other animals. (See SCRAPIE; BRUCELLOSIS; ABORTION, ENZOOTIC.)

Agalactia

Partial or complete absence of milk, or milk flow, from the udder. It can be the result of diseases including infections especially with pyrexia or of pain in the udder or elsewhere or 'emotional' problems such as weaning. Where this is due to a failure of milk 'let down', oxytocin may be prescribed. (See SOWS' MILK, ABSENCE OF; COW'S MILK, ABSENCE OF.)

Agalactia, Contagious

This is a disease of goats especially, and sheep less commonly, characterised by inflammatory lesions in the udder, eyes, and joints. It is not found in the UK, but is chiefly encountered in France, Switzerland, the Tyrol, Italy, the Pyrenees, North Africa and India.

Cause *Mycoplasma agalactiae*. The disease often occurs in the spring and the summer, and disappears with the advent of the colder weather. The infection may be carried by flies or the hands of the milkers and by the litter in a shed becoming contaminated, while the fetus may be infected before birth.

Signs Fever, mastitis and a greatly reduced milk yield. The milk becomes yellowish-green and contains clots. In addition to the udder, both joints and eyes may be involved; a painful arthritis, and conjunctivitis followed by keratitis (with resultant temporary blindness) may worsen the animal's condition.

Emaciation and death within 10 days may occur in very acute cases; otherwise recovery usually follows within a few weeks, though the former milk yield will not have been regained.

Male animals may have orchitis as well as arthritis.

Inflammation of the lymph nodes may occur, and lesions may be found also in abdominal organs and tissues, and in the chest.

Treatment Isolation of the affected animals and strict segregation of the in-contacts should be carried out.

Agar

Agar is the gelatinous substance prepared from Ceylon moss and various kinds of seaweed. It dissolves in boiling water, and, on cooling, solidifies into a gelatinous mass at a temperature slightly above that of the body. It is used extensively in preparing culture-media for use in bacteriological laboratories, and also in the treatment of chronic constipation in dog and cat.

Agar-Gel Immunodiffusion Test (AGID)

A test used in diagnosis of, e.g., equine infectious anaemia. (See also COGGINS TEST.)

VetBooks.ir

Agastria
The congenital absence of the stomach.

Agene Process
The bleaching of flour with nitrogen trichloride. The use of such flour in dog foods gave rise to HYSTERIA, CANINE.

Agenesis
The absence of an organ as a result of the lack of the primordium in the embryo.

Agenosomia
A condition of the fetus in which the genital organs are absent or poorly developed and the intestines protrude from an incompletely-formed abdominal wall.

Ages of Animals

Horses By the time it has reached 17 years, which generally means about 14 years of work, a horse's powers are on the wane. Many at this age are still in possession of their full vigour, but these are generally of a class that is better looked after than the average, e.g. hunters, carriage-horses, or favourites. On an average, the feet of the horse are worn out first, not the arteries as in man and, consequently, horses with good feet and legs are likely to outlast those inferior in this respect, other things being equal. After the feet come the teeth. The cheek teeth have a long reserve crown of over 7 cm (2 ¾ in) when they are five years old. The occlusal surfaces are worn down by grinding at approximately 2.5 cm (1 in) in 10 years. Therefore, the 30-year-old horse has lost many of its teeth by this age and requires a special diet to maintain its body weight. It often happens that the upper and lower rows of teeth do not wear in the normal way; the angle of their grinding surfaces alters until the chewing of the food becomes less and less effective, and the horse loses condition. Tooth rasping may remedy this.

Instances are on record of horses attaining the age of 35, 45 and 50, and one of a horse that was still working when 63 years old. These, however, are very exceptional. The average age at which a horse dies or is euthanased lies somewhere between 20 and 25 years.

Cattle The great majority of bullocks are killed before they reach 3 years of age, and in countries where 'prime beef' is grown they are fattened and killed between 1 and 3 years. In the majority of dairy herds, few cows live to be more than 8 or 10 years of age as they are less productive. Pedigree bulls may reach 12 or 14 years of age before being discarded but they are not usually kept that long. Records are in existence of cows up to 39 years old, and it is claimed that one had 30 calves. Productive suckler cows may be kept longer than dairy animals.

Sheep Here again the requirements of the butcher have modified the age of the animal at death. Wether lambs are killed at ages ranging from 4 to 9 months (Christmas lambs), and older fat sheep up to 21 months. Ewes, on average, breed until they are from 4 to 6 or 7 years, when they too are fattened and slaughtered for mutton. Exceptionally, they reach greater ages, but unless in the case of pure breeding animals, each year over 6 reduces their ultimate value as carcases. Mountain ewes usually only have four lambings while on the hills. Rams are killed after they have been used for 2 or 3 successive seasons at stud – that is, when they are 3 or 4 years of age, as a rule.

Pigs In different districts the age at which pigs are killed varies to some extent, according to the requirements of local trade. Pigs for pork production are killed at about 3½ to 4 months; bacon and commercial pigs are killed between 6 and 7½ months, and only breeding sows and boars are kept longer. Ages of up to 12 years have been recorded for sows.

Dogs and cats These are the only domesticated animals which are generally allowed to die a natural death. The average age of the dog is about 12 years, and of the cat 9 to 12, but instances are not uncommon of dogs living to 18 or 20 years of age, and of cats similarly. (See also BREEDING OF LIVESTOCK; DENTITION.)

Elephants Their normal lifespan in the wild is 65 to 70; some working elephants are employed up to a similar age and then retired.

Agglutination
Agglutination is the clumping together of cells in a fluid. For example, bacteria will agglutinate when a specific antiserum is added to the suspension of bacteria. Similarly, the blood serum of one animal will cause the red blood cells of another to become agglutinated.

Agglutination is explained by the presence in the serum of a protein (agglutinin) which combines with an agglutinable substance, or agglutinogen, possessed by the organisms.

Agglutination is made use of in the Agglutination Test, which depends upon the principle that in the blood serum of an animal harbouring in its body disease-producing organisms (though it may show no signs), antibody levels in serum can be evaluated using various agglutination test methods.

Aggressiveness, Aggression
Aggression can be an acquired trait in animals such as those used as guard dogs, but often it can be a

VetBooks.ir

natural protective response, as in nursing bitches, cows, sows, etc. A survey of UK dog owners showed about a fifth showed aggression to other dogs on walks but usually most did not show signs in other situations. In some cases aggression can be the result of infirmity – pain and lack of mobility causing an animal to protect itself (e.g. large dogs with arthritis). A low protein (17 per cent) or medium protein (25 per cent) diet supplemented with tryptophan may lower territorial aggression. Many different methods are employed to reduce aggressive behaviour, including retraining under the guidance of a behaviourist, the use of behaviour-modifying drugs, neutering, or a combination of all three remedies. Owners and others should always be aware that an allegedly reformed animal may revert to aggressive behavioural activity at any time. (See also ENCEPHALITIS; MENINGIOMA; RABIES; BENZOIC ACID POISONING; EQUINE VERMINOUS ARTERITIS; 'VICES' AND VICIOUSNESS; CHLORINATED HYDROCARBONS; MUSCLES, DISEASES OF - MUSCULAR RHEUMATISM; OVARIES, DISEASES OF; HYPERAESTHESIA; BOVINE SPONGIFORM ENCEPHALOPATHY; LISTERIOSIS; ANAPLASMOSIS; ACETONAEMIA; GRASS SICKNESS; HEARTWATER.)

AGID
(See AGAR-GEL IMMUNODIFFUSION TEST.)

Aglossia
The congenital absence of the tongue.

Aglossostomia
The congenital absence of the tongue and mouth opening.

Agnathia
The congenital absence of the lower jaw (MANDIBLE)

Agonist
A type of drug which gives a positive response (e.g. contraction or relaxation of a muscle fibre, or secretion from a gland) when its molecule combines with a receptor. The latter is a specific structural component of a cell, on its membrane, and usually a protein.

Antagonist (The opposite of agonist) A drug which blocks the attachment of any other substance at the receptor, so preventing any possible active response.

Partial agonist A drug which produces a positive response at the receptor (*), but only a weak one. However, since it occupies the receptor it prevents any full agonist from binding so that, in the presence of agonists, partial agonists may act as antagonists.

Many drugs are now classified according to their major action, e.g. *β blockers, H_1 and H_2 receptor antagonists.

β receptors are present in the heart and smooth muscle of the bronchioles, uterus and arterioles supplying skeletal muscle. Drugs which are selective β1 (heart) or β2 (elsewhere) are now available. For example, CLENBUTEROL HYDROCHLORIDE is a specific β2 agonist; it is used as a bronchodilator to treat respiratory conditions in horses, dogs and cats, but in cattle, it acts as a growth promoter, and so is prohibited in the EU.

Agriculture and Horticulture Development Board (AHDB)
A levy board organisation combining various other bodies including the British Pig Executive (BPEX), DairyCo and the English Beef and Lamb Executive (EBLEX), Their address is AHDB, Stoneleigh Park, Kenilworth, Warwickshire, CV8 2TL. Telephone: 0247 669 2051; email: info@ahdb.org.uk; website: www.ahdb.org.uk.

Agyria
Lack of gyri (folds) on the brain which is normal in lower mammals, birds, reptiles, amphibians and fish

AHDB
(See AGRICULTURE AND HORTICULTURE DEVELOPMENT BOARD.)

AHS
Abbreviation of AFRICAN HORSE SICKNESS (See HORSE-SICKNESS, AFRICAN.)

AHVLA
(See ANIMAL HEALTH AND VETERINARY LABORATORIES AGENCY.)

AHWBE
(See ANIMAL HEALTH AND WELFARE BOARD FOR ENGLAND.)

AI
1. ARTIFICIAL INSEMINATION
2. AVIAN INFLUENZA

Air
Atmospheric air contains by volume 20.96 per cent of oxygen, 78.09 per cent of nitrogen, 0.03 per cent of carbon dioxide, 0.94 per cent of argon, and traces of a number of other elements – the most important of which are helium, hydrogen, ozone, neon, xenon, and krypton, as well as variable quantities of water vapour. (See SMOG.)

Air that has been expired from the lungs in a normal manner shows roughly a 4 per cent change

VetBooks.ir

in the amount of the oxygen and carbon dioxide, less of the former (16.96 per cent) and more of the latter (4.03 per cent). The nitrogen remains unaltered.

The importance of fresh air to animals is immense. (See VENTILATION; RESPIRATION; OZONE; SLURRY; CARBON MONOXIDE.)

Airedale Terrier

A large, black-and-tan, wiry-coated breed. Entropion and cataract are inherited, probably as autosomal dominant traits, while cerebellar hypoplasia, deformed vertebrae (spondylitis deformans), and inflamed eyes and skin depigmentation (uveodermatological syndrome) may be inherited by mechanisms not completely known.

Air Ionisation

This has been used in poultry hatcheries to reduce airborne fluff produced by day-old-chicks and thereby the overall bacterial population of the environment.

Air Passages

(See BRONCHUS; NOSE AND NASAL PASSAGES; TRACHEA.)

Air Sac

Part of the respiratory system, particularly in reference to birds and some reptiles.

Air Sacculitis

Inflammation of the air sacs in birds.

Air Transport

In horses, heart rate and behaviour indicated that it was less stressful than road transport, as resting values occur during the flight. (See TRANSPORT STRESS.)

Akabane Virus

First isolated from mosquitoes in Japan; antibodies detected in cattle, horses and sheep in Australia. A cause of abortion in cattle, and of birth of abnormal calves. The virus, a member of the Bunyavirus group, is teratogenic.

Some calves are born blind and walk with difficulty; some have the cerebrum virtually replaced by a water-filled cyst.

(See also Arthrogryposis under GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.)

Akita inu Dogs

(See JAPANESE AKITA DOGS.)

Alabama Rot

A disease, first recorded in the USA in the 1980, associated with greyhounds but later found in other breeds. A similar disease has been recorded in Britain since 2012. First seen as a slowly-healing ulcer usually of legs or face, then depression, loss of appetite and vomiting, quickly turning into acute kidney failure often with AZOTURIA. The cause is unknown but it has been suggested that it might be the result of *E. Coli* toxin. There is a high mortality but early aggressive veterinary treatment can save the affected animal.

Alanine

An amino acid that enables energy to be stored in the nervous system (including the brain) and muscles.

Alanine Aminotransferase (ALT)

An enzyme involved in amino acid transfer. Liver damage results in high levels in the circulating blood. It is used as a measure of liver damage in dogs and cats.

Alaskan Malamute

A breed of dog developed from the husky. Dwarfism (chondrodysplasia) is inherited in some litters. Day blindness may also be inherited and CONGENITAL HAEMOLYTIC ANAEMIA occurs. Factor VII haemophilia and cases of hip dysplasia have been reported.

Albendazole

A benzimidazole anthelmintic, which has a good efficacy against most gastrointestinal helminths (except *Trichuris* spp.), lungworms and some tapeworms. At a higher dose, it is efficacious against liver fluke.

Albinism

Albinism is a lack of the pigment melanin in the skin – an inherited condition.

Albumen

The white of an egg.

Albumins

A group of water-soluble proteins which are moderately soluble in salt solutions and coagulated by heat. They include plasma albumin (mainly produced in the LIVER) and binds in the blood with water, CATIONS, HORMONES, BILIRUBIN, THYROXINE, drugs, etc. It is also the protein of the 'white' of eggs. (See PROTEINS; CONALBUMIN; ALBUMINURIA.)

Albuminuria

The presence of albumin in the urine: one of the earliest signs of NEPHRITIS and cystitis. Its presence can be demonstrated by laying a small amount of SULFOSALICYLIC ACID on the surface of a urine sample in a test tube or by use of a

VetBooks.ir

commercial dipstick test kit. (See URINARY BLADDER, DISEASES OF).

Alcohol Poisoning

Acute poisoning is usually the result of too large doses given *bona fide*, but occasionally the larger herbivora and pigs eat fermenting windfalls in apple orchards; or are given or obtain, fresh distillers' grains, or other residue permeated with spirit, in such quantities that the animals become virtually drunk. In more serious cases they may become comatose.

Aldosterone

This is a hormone secreted by the medulla of the adrenal gland. Aldosterone regulates the electrolyte balance by increasing sodium retention and potassium excretion. (See CORTICOSTEROIDS.)

Aldrin

A persistent insecticide; a chlorinated hydrocarbon used in agriculture and formerly in farm animals. Its persistence has prevented its veterinary use. Signs of toxicity include blindness, salivation, convulsions, rapid breathing. (See GAME BIRDS, MORTALITY.)

Aleukaemic Leukaemia

(See MULTICENTRIC LEUKAEMIA.)

Aleutian Disease

First described in 1956 in the USA, this disease of Mustelidae (mink, ferrets) caused by Aleutian Disease Virus (ADV), a parvovirus, which also occurs in the UK, Denmark, Sweden, New Zealand and Canada.

Mink

Signs The disease is characterised by the development of antigen/antibody complexes which produce signs including: failure to put on weight or even loss of weight; thirst; the presence of undigested food in the faeces – which may be tarry. Bleeding from the mouth and anaemia may also be observed. Death usually follows within a month.

Ferrets In these animals antibodies, and so antigen-antibody complexes, are less readily formed.

Signs include: loss of weight; malaise; chronic respiratory infection; and paresis or paraplegia. Bleeding from the mouth and anaemia may also be observed. Death usually follows within a month and cardiomyopathy and lymphoma may be seen on necropsy. The disease can be confused with the later stages of rabies.

Diagnosis In ferrets diagnosis is complicated by their failure to produce large amounts of antibodies and so screening of populations for carriers is difficult. Counterimmunoelectrophoresis, immunofluorescent antibody and ELISA tests on blood and saliva (difficult to obtain) are used.

Alexin

(See COMPLEMENT.)

Alfadalone

(See ALFAXALONE.)

Alfalfa

American name for LUCERNE.

Alfaxalone, Alphaxalone; Alphaxolone

Previously used in combination with alfadalone, but not recently. It is a neurosteroid general anaesthetic in veterinary practice under the trade name Alfaxan. It is licensed for use in both dogs and cats and is also used off-licence in rabbits.

Algae

Simple plant life of very varied form and size, ranging from single-cell organisms upwards to large seaweed structures. Algae can be a nuisance on farms when they block pipes or clog nipple drinkers. This happens especially in warm buildings, where either an antibiotic or sugar is being administered to poultry via the drinking water. Filters may also become blocked by algae.

The colourless *Prototheca* species are pathogenic for both animals (cattle, deer, dogs, pigs) and man. (See MASTITIS IN COWS – Algal mastitis.)

The non-toxic algae of the *Spirulina* group are used in the feed of some ornamental fish and human health supplements. *S. platensis* (originally found in Lake Chad) is being investigated as a feed ingredient for animals. *Nalila salina* (originally from Lake Uroumich, northern Iran) is rich (12 per cent of dry matter) in natural carotenoids.

Algae Poisoning

Toxic freshwater algae, characteristically blue-green in colour, are found in summer on lakes in numerous locations, particularly where water has a high phosphate and nitrate content derived from farm land. Formed by the summer blooms of cyanobacteria, they can form an oily, paint-like layer several cm thick. Deaths have occurred in cattle and sheep drinking from affected water; photosensitivity is a common sign among survivors. Dogs have also been affected.

The main toxic freshwater cyanobacteria are strains of the unicellular *Microcystis aeruginosa*, and the filamentous forms *Anabaena flos-aquae*, *Aphanizomenon* and *Oscillatoria agardhii*.

VetBooks.ir

Signs vary according to the dominant cyanobacterium present. *Anabaena flos-aquae*, for example, can form alkaloid neuromuscular toxins which can produce signs within half an hour; these being muscular tremors, stupor, ataxia, prostration, convulsions, sometimes opisthotonus and death. Dyspnoea and salivation may also be seen.

Mycrocystis strains produce a slower-acting peptide toxin, which may cause vomiting and diarrhoea, salivation, thirst, piloerection, and lachrymation. Survivors may show LIGHT SENSITISATION, with inflamed white skin and oedema of ears and eyelids.

Poisoning by algae has been recorded in dogs that have been in the sea off Denmark. In the USA, a colourless alga is reported to have caused dysentery, blindness and deafness, and sometimes ataxia and head-tilting.

In Victoria, Australia, 17 sheep died and many others showed signs of light sensitivity after drinking from a lake affected by a thick bloom of *M. aeruginosa*. The deaths were spread over six months after removal from access to the lake.

Poisoning in cattle was suspected in the UK after a spell of hot weather in East Anglia caused an algal bloom in field ponds and 50 per cent of the cows in a herd suddenly showed nervous signs. BSE was ruled out as the cause.

Alimentary Canal

(See DIGESTION, ABSORPTION AND ASSIMILATION.)

Alkali

A substance which neutralises an acid to form a salt, and turns red litmus blue. Alkalis are generally the oxides, hydroxides, carbonates, or bicarbonates of metals.

Varieties Ammonium, lithium, potassium and sodium salts are the principal alkalis, their carbonates being weak and their bicarbonates weaker.

Uses In poisoning by acids, alkalis in dilute solution should be administered at once. (See ACIDS, POISONING BY; STOMACH, DISEASES OF; DISINFECTION; DETERGENTS; LAUNDRY DETERGENT POD POISONING.)

Alkaline Phosphatase (ALKP, ALP)

An enzyme found on the membrane surfaces of cells. Increased levels occur in serum when there is increased LIVER activity such as in HEPATITIS or in diseases including obstructive JAUNDICE, bone diseases where there is increased bone breakdown (OSTEOCLAST activity) such as in HYPERTHYROIDISM, or bone cancer. It can also rise in some other types of cancer. The liver and bone tissues develop distinct isoenzymes.

Alkaloids

Alkaloids constitute a large number of the active principles of plants and all possess a powerful physiological action. Like alkalis, they combine with acids to form salts, and turn red litmus blue. Many alkaloids are used in medicine, and their names almost always end in 'ine' – e.g. atropine, morphine, quinine, etc.

Aconitine, *Aconine* } from monkshood (*Aconitum napellus*).
Arecoline, from areca nut (*Areca catechu*).
Atropine, from belladonna, the juice of the deadly nightshade (*Atropa belladonna*).
Caffeine, from the coffee plant (*Coffea arabica*) and from the leaves of the tea plant (*Thea sinensis*), also found in the kola nut, guarana, and species of holly, etc.
Cocaine, from coca leaves (*Coca erythroxylon*).
*Digitoxin** , *Digitalin** } from foxglove (*Digitalis purpurea*).
Ephedrine, from various species of *Ephedra*.
*Ergotoxin** , *Ergometrine* } from ergot (*Claviceps purpurea*).
Hyoscyamine, from henbane (*Hyoscyamus niger*).
Hyoscine or *Scopolamine*, *Morphine* } also from henbane.
Codeine, *Thebaine*, *Heroin* } from opium, the juice of the opium poppy (*Papaver comniferans*).
Nicotine, from tobacco leaves (*Nicotiana tobaccum*).
Physostigmine or *Eserine* } from Calabar beans (*Physostigma venenosum*).
Pilocarpine, from jaborandi (*Pilocarpus jaborandi*).
Quinine, from cinchona or Peruvian bark (*Cinchona*, and *Cinchona rubra*).
*Santonin**, from wormwood (*Artemesia pauciflora*).
Sparteine, from lupins (*Lupulinus*, sp.) and from broom (*Cytisus scoparius*).
Strychnine, from *Nux vomica* seeds (*Strychnos nux vomica*).
Veratrine, from cevadilla seeds (*Cevadilla officinale*, or *Schoenocaulon officinale*).

Those marked * are neutral principles.

A first-aid antidote for poisoning by an alkaloid is strong tea.

Alkalosis

A pathological condition due to accumulation of base (alkali) or loss of acid from body fluids without a related loss of base. It is characterised by a decrease in hydrogen ions and a rise in pH. It is the opposite of acidosis and is seen clinically less commonly.

VetBooks.ir

ALKP
(See ALKALINE PHOSPHATASE.)

Allantoin
A product of PURINE metabolism and is present in the urine of most mammals except man, primates and DALMATIAN DOGS.

Allantois
The outer of two fluid-filled sacs that surround the developing embryo. It is a sac extending from the hind gut of the early embryo and containing urine-like fluid which helps to protect the embryo. The allantois fuses with the chorion to become part of the PLACENTA. Occasionally the fetal ureter, instead of being connected to the placenta, becomes connected to the allantoic sac, which becomes dilated with fetal urine to a stage where it can depress appetite by compressing the rumen, a condition is called hydroallantois. The abdomen of the cow becomes pear-shaped and the only cure for the condition is to abort the fetus. (See also PERVIOUS URACHUS.)

Alleles, Allelomorphs
Alleles (allelomorphs) are genes which influence a particular development process, processes, or character, in opposite ways, and can replace one another at a particular locus on a chromosome. They result from a previous mutation, and the original gene and its mutated form are called an 'allelomorphic pair'. Another definition is: one of a pair or series (multiple alleles) of genes occupying alternatively the same locus. (See also GENETICS, HEREDITY AND BREEDING.)

Allergen
The chemical entity responsible for the development of allergic disease; usually a foreign protein.

Allergic Conjunctivitis
A form of conjunctivitis ('RED EYE') mainly seen in dogs often caused by airborne allergens, or resulting from changes in their environment or their immune status. It commonly also occurs with RHINITIS resulting in SNEEZING or other allergic signs. It is becoming increasingly common. (See also ALLERGY; EYE, DISEASES AND INJURIES OF.)

Allergic Dermatitis
Allergic dermatitis is another name for dermatitis caused by an allergy. For example, 'Queensland Itch' is seen in horses in Australia, where it is a result of hypersensitivity to the bites of insects. In the United Kingdom midges are responsible for the development of Sweet Itch; in Japan it follows bites of the stable-fly. It is intensely itchy in character. Treatment involves the use of antihistaminics and prevention of access of biting flies responsible for the development of the condition: susceptible animals should be kept indoors during the periods of midge activity; if outside, appropriate horse rugs should be used.

Causes in dogs are more complex and include fleas, fungi (particularly house dust) and others for which many diagnostic tests have been developed. Allergic dermatitis in cats is usually related to infestation with fleas so treatment involves disinfestations and, possibly, the use of STEROIDS. (See also ECZEMA.)

Allergic Nasal Granuloma
An allergic rhinitis particularly seen in JERSEY CATTLE. It results in the animal rubbing its nose, often damaging the nose, sneezing, nasal discharge and often acute DYSPNOEA. It is seen in warm moist weather and appears to be allergy to pollen or fungal spores. Some animals also suffer MILK ALLERGY.

Allergy
A specific sensitivity to e.g. a plant or animal product, usually of a protein nature. In the dog and cat, sensitivity occurs most commonly from bedding, carpeting, rubber products, household cleaners, plants and some skin dressings; in pigs, soya-bean protein antigens.

The three main signs are itching, self-inflicted damage as a result, and redness; sometimes oedema of the face, ears, vulva or extremities, or skin weals.

Many foodstuffs have caused allergy in the dog, e.g. cow's milk; horse, ox, pig, sheep and chicken meat; eggs. True food allergies are less common in cats but can be distressing. Allergy may commonly arise in large animals following the bites of flies, sandflies, stable-flies, and sometimes bee or wasp stings. Pollens can produce skin changes as can avianised vaccines, horse serum, antibiotics, and synthetic hormone preparations

(See also ATOPIC DISEASE; ECZEMA; ANAPHYLACTIC SHOCK; ANTIHISTAMINES; LIGHT SENSITISATION; LAMINITIS; REAGINIC ANTIBODIES.)

Allograft
A piece of tissue, or a complete organ, transplanted from one animal to another of the same species. (See SKIN GRAFTING TRANSPLANTATION.)

Allopurinol
1. The treatment of choice for LEISHMANIASIS in dogs. Given by mouth, it is well absorbed from the gastrointestinal tract and excreted by the kidneys.
2. It is also used in dogs to treat UROLITHIASIS.

Aloe
Cape aloes are an anthraquinone laxative with an intensely bitter taste. Aloe vera is a popular

VetBooks.ir

ingredient in skin preparations and the juice is reputed to be of benefit in cases of eczema.

Alopecia

Absence of hair from where it is normally present. It has to be differentiated from loss of hair due to mange, ringworm, lice infestation, and eczema or other causes. For example, the result of hormone imbalance, dietary deficiencies, trauma (e.g. burns) or selenium poisoning. A temporary alopecia is occasionally seen in newborn animals, and also in the dams of newborn animals. The female rabbit dam plucks fur to create alopecic areas to provide nesting material. Senile alopecia occurs in all species. In the gerbil, alopecia is seen on the top of the head and around the base of the tail. Alopecia in dogs, with symmetrical hair loss from trunk, neck and end of tail, may sometimes be due to a deficiency of the growth hormone SOMATOTROPIN. The age group affected is 1 to 4 years. Highly pigmented skin may be a feature, and treatment with growth hormone has proved successful. A deficiency of iodine or of thyroxine (HYPOTHYROIDISM) may produce usually symmetrical hair loss on the flanks and extending to the limbs. This type of canine alopecia usually responds to thyroid therapy. In male dogs of 5 years and upwards, alopecia may be accompanied by an attraction for other males, and usually responds to castration but not to hormone therapy. A Sertoli-cell tumour of the testicle also causes alopecia and feminisation. Symmetrical bare patches, accompanied by other signs, are a feature of Cushing's disease.

ALP

(See ALKALINE PHOSPHATASE.)

Alpaca

A subspecies of SOUTH AMERICAN CAMELID now farmed in the UK and elsewhere for its fine wool; not reared for meat. Individuals can live for up to 20 years. There are two main types – the Suri (long fine fleece) and the Huaccaya (thick and more dense fibres). They are susceptible to infections already present in Britain. Clostridial vaccination is advised. Cryptosporidiosisi, coccidiosis and *E. coli* infections have been recorded. Exposure to the sun following shearing may cause dermatitis; fly strike is unusual. A dermatosis is zinc responsive. When contented alpaca make a humming noise, but scream if upset. They spit or empty their stomach contents when annoyed. Foot trimming is important and they can develop split nails. Attention to the teeth is important particularly reducing the canines in males, which are used in fighting.

HAEMONCHOSIS results in ANAEMIA usually without diarrhoea. In Britain and Europe several cases of BOVINE TUBERCULOSIS have occurred, usually in the lungs, and some cases were 'open' allowing the spread of infection.

In New Zealand parturition is known as 'unpacking'.

In 2010 there were over 30,000 in the UK.

Alpha (α)-2 Adrenergic Agonists

These are SYMPATHOMIMETIC AGENTS. (See IMIDAZOLINE COMPOUNDS.)

Alphachloralose

A narcotic used for the destruction of rodents, pigeons, etc. It acts by lowering the body temperature. Accidental poisoning in dogs and cats can occur with seizures, muscle tremors, hyperaesthesia, hypothermia, salivation, myosis, stupor, coma and ataxia. Signs occur about two hours after ingestion and may last for 24 to 48 hours. Animals should be kept warm; emetics may be given to conscious animals in the early stages and a stomach pump can be used in unconscious animals.

Alphavirus

Viruses of arbovirus group A and equine encephalitis viruses bear this name.

Alphaxalone, Alphaxolone

(See ALFAXALONE.)

Alsatian

(See GERMAN SHEPHERD DOG.)

ALT

(See ALANINE AMINOTRANSFERASE.)

Alternative Medicine, Alternative Treatment

These are medicines and treatments which do not possess the same evidence base as CONVENTIONAL MEDICINE. It includes many practices including herbal medicine, homeopathy, and acupuncture. (See COMPLEMENTARY MEDICINE.)

Altitude

Animals unaccustomed to high altitudes can be adversely affected by them. Like humans, animals suffer hypoxia. Testicles of cats, rabbits and rats atrophy with resulting fertility problems. Hens and geese lay infertile eggs or cease laying. Ascites caused by high altitudes has been reported in all types of poultry. Acclimatisation to high altitudes results in the formation of more and smaller red blood cells so that oxygen-binding capacity is increased. (See also 'MOUNTAIN SICKNESS'.)

Altrenogest

A prostaglandin analogue used for the synchronisation of oestrus in mature sows (Regumate

VetBooks.ir

Porcine) and the suppression of prolonged oestrus in mares (Regumate Equine).

Aluminium Toxicity
In the rat, research in South Africa has shown that aluminium toxicity might be due to (experimental) porphyria. In Israel it has been shown that rats given aluminium salts, and then examined under ultra-violet light, show fluorescence of eyes, long bones, brain and peri-testicular fat. In rats at least, therefore, aluminium cannot be regarded as a harmless element.

Alveld
A disease of lambs in Norway, associated with the eating of bog asphodel *Narthecium ossifragum.* Signs are photosensitisation and jaundice; it is thought to be due to poisoning by microfungi present on the plant.

Alveolitis
Inflammation of an alveolus. (See EXTRINSIC ALLERGIC ALVEOLITIS.)

Alveolus
(plural, Alveoli)
A tooth socket in the jaw. The term is also applied to the minute divisions of glands and to the air sacs of the lungs.

'Alzheimer's Disease' in Cats
A condition in geriatric cats that closely resembles the human disease. Signs include disorientation, compulsive behaviours, disturbed sleep patterns and incontinence. Histologically, changes to the brain and blood resemble those in the human disease. (See also DEMENTIA.)

Amaurosis
Impaired vision or even loss of sight, resulting from disease of the optic nerve, brain, or spinal cord.

Amblyopia
Diminution of vision.

Amelia
An information bulletin published by the Veterinary Medicines Directorate. The title is an acronym for Animal Medicines European Legislation Information and Advice.

Amelia
Complete absence of one or more limbs.

American Box Tortoises
(Americans call tortoises turtles.) A ban on the importation into the UK of tortoises from Mediterranean countries led dealers and pet shops to seek an alternative, and the choice was *Terrapene carolina*. Care of these animals is rather specialised and a vivarium is necessary. They are terrestrial animals, but occasionally immerse themselves in water although they are poor swimmers. Their recommended diet includes earthworms, mushrooms, beans, beansprouts, cucumber, grapes, banana and some leafy vegetables usually with a vitamin and mineral supplement. Specialist advice on husbandry is available from keepers' societies.

American Cocker Spaniel
A breed smaller than the English spaniel and with longer hair. Cataract DISTICHIASIS and ENTROPION are all probably inherited dominant traits. Other inherited mainly recessive conditions may include haemophilia (factor IX and X deficiencies), patellar luxation and prognathia. Other conditions apparently inherited include cleft primary an secondary palates, ECTROPION, PATENT DUCTUS ARTERIOSUS, primary glaucoma, RETINAL DYSPLASIA, SPONDYLITIS and umbilical hernia.

American Foulbrood (AFB)
This is a NOTIFIABLE DISEASE of BEES in the UK. In July 2011, American foulbrood (caused by Paenibacillus bacterium) was detected in an apiary in Perthshire, Scotland. The infected hive was destroyed and movement restrictions placed on bees and equipment from the apiary concerned. There is no permitted treatment for the disease in the UK.

American Pit Bull Terrier
A dog which was bred from the STAFFORDSHIRE BULL TERRIER and was often intended for fighting. It is banned in UK under the Dangerous Dogs Act 1989.

American Quarter Horse
A breed derived mainly from dams of Spanish origin, for a long time bred by American Indians, and from Galloway sires brought by the early settlers. 'It was Barb blood spiced with a Celtic infusion and refined with a dash of Eastern blood that fashioned the Quarter Horse.' (R. M. Denhardt.) The horse was named as it was used to race over a quarter of a mile, i.e. it is a horse bred for racing very short distances.

American Saddleback Horses
The famous American breed is renowned for is smart carriage. It has a high-stepping show horse. Black is the main colour.

Amine
An organic compound containing ammonia (NH_3).

VetBooks.ir

Amino Acetonitrite Derivatives (AAD)

A group of anthelmintics discovered in 2000 and introduced in 2009. The first AAD (monepantel), a liquid drench, was used in 2010 in UK sheep for treatment and control of parasitic gastroenteritis.

Amino Acids

Amino acids are the 'building blocks' into which proteins can be broken down, and with which proteins can be constructed.

Amino acids contain carbon, hydrogen and oxygen, together with an amine group (NH_2).

The quality of a protein, in terms of its value as an animal feed, depends upon its content of essential amino acids. These are lysine, methionine, tryptophan, leucine, isoleucine, phenylalanine, threonine, histidine, valine and arginine.

LYSINE is a particularly important amino acid for growth and milk production, and is one of those prepared synthetically and added to some livestock feeds.

The pig and rat require, for rapid growth: lysine, tryptophan, leucine, isoleucine, methionine, threonine, phenylalanine, valine and histidine. The chick needs glycine in addition to these. The cat needs TAURINE.

Aminoglycosides

A group of bactericidal antibiotics produced from *Streptomyces* species including streptomycin, neomycin, framycetin and gentamicin.

Aminonitrothiazole

A drug used against BLACKHEAD OF TURKEYS; it is not currently used in the EU.

Aminotransferase

An enzyme which catalyses transfer reactions involving amino acids.

Amitraz

An ectoparasiticide for the treatment of lice and tick infestation and mange in dogs. It has been used in farm animals. It must not be used on chihuahuas, nor on cats or horses. It is sold under a variety of trade names.

Ammonia (NH_3)

A few drops of ammonia on a piece of cotton-wool held a few inches from the nostrils have a good effect in reviving animals which have collapsed. (Inhalation of concentrated ammonia can prove fatal.) Ammonia fumes from litter may adversely affect poultry. (See DEEP LITTER FOR POULTRY; also QUATERNARY AMMONIUM COMPOUNDS.)

An excess of ammonia in the rumen has been cited as a cause of hypomagnesaemia in spring following massive applications of nitrogenous fertiliser. (See also UREA.)

Ammonia poisoning Hydrolysis of urea to ammonia in the rumen may occur very rapidly in cattle receiving excessive amounts of urea. If more ammonia reaches the blood and then the liver than the latter organ can detoxify, then ammonia poisoning will result. (See UREA.)

Several cows died after being fed straw which had been treated with ammonia for 5 days only and came direct from the treatment box. (It is recommended that the treatment should be for 10 days, with a 2-day interval before the product is fed to livestock.) Laryngeal oedema and emphysema of the lungs were caused. The level of ammonia in the atmosphere of animal housing must not exceed 14 ppm. Higher levels cause discomfort, especially in the case of birds, and continuous exposure can lead to ulceration of the cornea. A similar hydrolysis occurs in stale litter in rabbit hutches and releases ammonia in sufficient quantities to affect the animals quite seriously, as rabbits are very susceptible to the chemical. Due to its acidity, the use of peat moss as litter in rabbit trays and on the floor of hutches may counteract the effect of this hydrolysis.

(See also LITTER, OLD.)

Amnion

The innermost of the 3 mammalian fetal envelopes. It is continuous with the skin at the umbilicus (navel), and completely encloses the fetus but is separated from actual contact with it by the amniotic fluid, or the 'liquor of the amnion', which in the mare measures about 5 or 6 litres (9 to 10 pints). (See PLACENTA.)

This 'liquor amnii' forms a kind of hydrostatic bed in which the fetus floats, and serves to protect it from injury, shocks, and extremes of temperature. It allows free, though limited, movements and guards the uterus of the dam from the spasmodic fetal movements which, late in pregnancy, are often vigorous and even violent.

At birth it helps to dilate the cervical canal of the uterus and the posterior genital passages, forms part of the 'waterbag', and, on bursting, lubricates the maternal passages. (See PARTURITION.)

Amoebic Encephalitis

Amoebic encephalitis due to *Acanthamoeba castellani* was found after the euthanasia of a 4-month-old puppy. Fits and hyperkeratosis of the foot pads suggested that the cause was the distemper virus, but *A. castellani* was recovered from an area of suppurative necrosis in the brain.

(In human medicine, several species of this amoeba are recognised as an important cause of

VetBooks.ir

granulomatous encephalitis.) (Pearce, J. R. & others, *JAVMA* **187**, 951.)

Amoxycillin
An antibiotic resembling ampicillin, but its action is quicker and it is excreted more rapidly. Amoxycillin is often used in combination with clavulanic acid, which makes it more effective by blocking the effect of penicillinase, by which ampicillin is destroyed. It is used in most species except horses.

AMP
(See ADENOSINE MONOPHOSPHATE.)

Amphistomes
Synonym for Paramphistomes. (See PARAMPHISTOMIOSIS.)

Amphotericin B
An antimycotic preparation which is produced from species of *Streptomyces* bacteria. It combines with ergosterol in the fungal cell membrane making it porous and may thereby contribute to the fungal cell death. It is used to treat avian gastric yeast infestations in caged birds, but in UK it often had to be imported with an appropriate import certificate.

Ampicillin
A semi-synthetic penicillin, active against both Gram-positive and GRAM-NEGATIVE bacteria. It is not resistant to penicillinase, but can be given by mouth (except in camelids and horses).

Ampoule
A small glass container having one end drawn out into a point capable of being sealed so as to preserve its contents sterile. It is used to contain solutions of drugs for hypodermic injection, while many vaccines and other biological products are also distributed in ampoules. A potential hazard of glass embolism has been recognised in human medicine, and the wisdom of allowing glass particles to settle, before filling a syringe, has been stressed.

Amprolium
A drug used for the prevention and treatment of coccidiosis in turkeys, guinea fowl and chickens.

Amputation
Removal of a limb. If a long bone of dog, cat, rabbit, other small mammal, bird or reptile has been shattered into several pieces (COMMINUTED or COMPOUND FRACTURE), or chronically infected or cancerous, amputation is usually the only humane course to take (other than euthanasia). Amputation is considered kinder than leaving the animal a permanent cripple, perhaps suffering some degree of pain for the rest of its life. A three-legged dog or cat can be expected to revise its technique of balance and movement, and to become not merely nimble but fast as well; and to demonstrate a capacity for enjoying life. After amputation of a hind limb in a pet rabbit, its ear on the same side will need regular cleaning as it uses the hind limb for this purpose. Tail amputation may also be performed in dogs and cats for similar reasons as for limbs. Cats may take some time to learn to balance again after tail removal, especially when climbing and jumping.

Amyelencephalia
Congenital absence of the brain and spinal cord.

Amyelia
The congenital absence of the spinal cord.

Amygdala
A distinct almond-shaped part of the brain's limbic system, involved with smell and behaviour.

Amylase, Amylopsin
A starch-splitting enzyme. (See DIGESTION, ABSORPTION AND ASSIMILATION.)

Amyloidosis
The deposition of an insoluble starch-like protein (amyloid) which affects the functioning of the tissues in which it is deposited. It may be associated with inflammatory conditions or chronic infections.

Anabolic
Relating to anabolism, which means tissue building, and is the opposite of catabolism or tissue breakdown.

An anabolic steroid is one derived from testosterone in which the androgenic characteristics have been reduced and the protein-building (anabolic) properties increased in proportion. Examples are nandrolone and ethylestrenol. These are used in cases of malnutrition, wasting diseases, virus diseases, and severe parasitism.

Synthetic anabolic steroids have been used as growth-promoter implants in commercial beef production, but this is prohibited in the UK and EU. They are also prohibited in competition animals. It has been found that anabolic steroids can give rise to changes in the liver and its functioning in both animals and man; with, in some instances, tumour formation. Changes in the sexual organs may follow misuse. (See STILBENES.)

Anadidymus
A developmental abnormality in which the lower extremities of two fetuses are joined together.

VetBooks.ir

Anadromy

An anadromous fish is one that spends most of its adult life in the sea but returns to fresh water to spawn. Salmon are anadromous.

Anaemia

A reduction in the number and/or size of the red blood corpuscles or the haemoglobin in the blood. It is a sign rather than a disease, and it is important to establish the cause (obvious only in the case of acute external haemorrhage due to trauma), so that a prognosis and suitable treatment can be given.

The animal may be suffering from a chronic loss of blood due to internal bleeding, e.g. from the urinary or digestive tracts; and the owner of a cat, for instance, may fail to notice the presence of blood in the urine, and so not bring the animal for treatment until other signs of illness have become obvious.

Anticoagulants, such as Warfarin, may cause internal haemorrhage and hence anaemia.

An iron-deficient diet (and one lacking also the trace elements cobalt and copper, which aid the assimilation of iron) is another cause of anaemia; likewise a deficiency of folic acid, vitamin B_6 and vitamin B_{12}.

Both external and internal parasites (lice, fleas, ticks, liver flukes, roundworms and tapeworms) can cause anaemia.

Parasites of the bloodstream are an important cause, and include trypanosomes, piroplasms and rickettsiae. (See also FELINE INFECTIOUS ANAEMIA.)

For an incompatability between the blood of sire and dam, see haemolytic disease (under FOALS, DISEASES OF).

Aplastic anaemia means a defective, or a cessation of, regeneration of the red blood cells; it may be drug-induced. (See also RETICULOCYTES.) (In human medicine, the drugs involved have included chloramphenicol, phenylbutazone, and rarely penicillin and aspirin; deaths have resulted.)

Bracken poisoning, exposure to X-rays or other forms of irradiation are other causes; also salicylates (including aspirin).

In auto-immune haemolytic anaemia the animal forms antibodies against its own red cells.

Heinz-body haemolytic anaemia (see HEINZ BODIES) may result from kale poisoning in cattle, and from paracetamol or methylene-blue poisoning in cats; sometimes also from lead poisoning.

Signs Pallor of the mucous membranes, loss of energy and of appetite, and PICA. Dogs and cats may feel the cold more than usual, and seek warm places. In some cases fever is present, and liver enlargement. The heart rate may increase.

Treatment In the smaller animals especially, vitamin B_{12} or liver extract is often a valuable method of treatment. Where cobalt or copper or iron are lacking, these must be supplied. Lice or ticks and fleas should be destroyed, and treatment against internal parasites undertaken if they are the cause. Blood transfusions are useful provided donor and recipient are compatible. Anaemias due to specific causes have specific treatments. (See also PIGLET ANAEMIA; FELINE and EQUINE INFECTIOUS ANAEMIA; CANINE BABESIOSIS; HEARTWORM; ROUNDWORMS; FLUKES AND FLUKE DISEASE.)

Anaerobe

(adjective, Anaerobic)

The term applied to bacteria having the power to live without oxygen. Such organisms are found growing freely, deep in the soil, as, for example, the tetanus bacillus.

Anaesthesia, General

The use of general anaesthetics to produce loss of consciousness and sensation for operations on animals dates back to 1847, when several veterinary surgeons first used ether. Chloroform was also first used in 1847. Both have now been superseded by safer anaesthetic agents. A wide choice is now available. The choice, dosage and means of administration will be influenced by such considerations as the species, size and habitat of the individual, as well as by the procedure to be undertaken and the availability of equipment. Unconsciousness, abolition of reflexes and muscle relaxation are the key requirements of anaesthesia. In overdose, respiratory paralysis occurs due to depression of the respiratory control centres in the medulla. General anaesthesia can be induced by inhalation of a volatile or gaseous anaesthetic, or by intravenous or intramuscular injection. Inhalation anaesthetics are often administered via an endotracheal tube. Anaesthetic agents are often used in combination with a premedicant, such as acepromazine or an alpha-2 agonist drug.

'Balanced anaesthesia' is the use of smaller doses of a combination of two or more drugs to achieve the various stages of anaesthesia, thus avoiding the disadvantages of using large doses of any one drug. Muscle relaxants may also be used to facilitate certain procedures. If the animal is a food animal, care must be taken to observe any precautions indicated by the drug manufacturer to avoid drug residues accumulating in meat or milk. In all cases, the manufacturers' recommendations as to dosage must be followed.

Endotracheal anaesthesia, Closed-circuit anaesthesia

This technique depends upon the introduction into the trachea of a tube which is then connected

VetBooks.ir

to an anaesthetic machine. The tube is passed via the mouth following an injectable anaesthetic, such as a barbiturate, propofol, alfaxalone, ketamine, etc., and is then used as the route for administration of an inhalant anaesthetic mixture. The method ensures a clear airway throughout the period of anaesthesia, and thus obviates the danger of laryngeal obstruction (e.g. by the tongue falling backwards), which sometimes causes death. The method has several other advantages, e.g. it permits an unobstructed operation field during lengthy major operations especially of the head and neck, achieves better oxygenation, facilitates an even level of anaesthesia, and permits use of respiratory monitors and of positive pressure ventilation of the lungs in the event of respiratory failure. As an alternative to general anaesthesia, EPIDURAL ANAESTHESIA (involving the injection of a local anaesthetic into the spinal canal) is used for some surgical procedures in large animals that are easy to restrain, and may be used to provide extra analgesia during general anaesthesia. (See ANAESTHESIA, GENERAL - 'BALANCED ANAESTHESIA' above.)

Cattle Most procedures are performed under local anaesthesia. Where general anaesthesia is indicated, after premedication with, for example, xylazine, and induction of anaesthesia with ketamine, isoflurane or secroflurane is administered via an endotracheal tube. Endotracheal intubation is recommended in order to preserve a clear airway, and to prevent inhalation of regurgitated rumen contents.

Horses General anaesthesia is normally induced by intravenous injection of ketamine and diazepam after premedication with xylazine, romifidine or detomidine and maintained by inhalation of isoflurane or sevoflurane, administered through an endotracheal tube. Ketamine must not be used as sole anaesthetic in the equine. The use of thiopental, via intravenous catheter, also requires premedication. Great care must be taken that the recumbent anaesthetised horse does not suffer muscle or nerve damage, caused by the pressure of its own weight, while unconscious.

Sheep No anaesthetic drugs have a market authorisation for sheep and so must be used according to the 'cascade'. Ketamine, propofol and alfaxalone given by slow intravenous injection have all been used for induction of anaesthesia. Isoflurane may be given by inhalation.

Goats Alfaxolone, propofol, ketamine and isoflurane, and sevoflurane have also been suggested for such procedures as the disbudding of kids. Xylazine (usually diluted) can be used but hypothermia needs to be prevented. For long procedures anaesthetised goats should be intubated. Again, no preparations are licensed for this animal.

Dogs and cats A wide choice is available. Propofol, alfaxalone and thiopental by intravenous injection rapidly induce general anaesthesia in action. Ketamine, given by intravenous or intramuscular injection, is another choice, but it must never be used alone without adequate premedication. When given to cats, it is often used with metomidine to prevent excitability on recovery. Propofol, an intravenous anaesthetic for dogs and cats, is very commonly used for minor outpatient procedures and CAESAREAN SECTION. Recovery is generally smooth but retching, sneezing, and pawing of the face may be seen.

Monkeys Ketamin is often used given by subcutaneous, intramuscular, or intravenous injection after suitable premedication. Tiletamine/zolazepam (Zoletil) is a similar drug combination which has proved useful. Isoflurane is suitable for maintenance of anaesthesia. The choice usually depends on the ease and safety of restraint in individual animals

Rabbits, rats, mice, guinea pigs Inhalation anaesthetics such as isoflurane and sevoflurane are safe and effective; but rabbits should be sedated first. Injectable anaesthetic combinations, such as fentanyl-fluanisonle and midazolam, or ketamine and xylazine, may be used.

Birds Isoflurane is the most suitable. Intramuscular injections of ketamine with or without xylazine may be useful when anaesthetic machines are not available. Restraint must be carefully considered so that the movement of the sternum is not impaired.

Reptiles Small reptiles may be anaesthetised by inhalation of isoflurane or sevoflurane. Large lizards, tortoises and snakes are best induced by intravenous propofol, intubated and maintained with isoflurane or sevoflurane. Positive pressure is usually required as reptiles seldom breathe spontaneously under anaesthesia. Ketamine by intramuscular injection is also used but recovery may be prolonged. Due to the ectothermic nature of reptiles, maintenance of the animal's optimal temperature and a patent airway are essential until the animal is breathing spontaneously.

Fish Phenoxyethanol, benzocaine or tricaine mesilate, dissolved in the water, are commonly used for both exotic and farmed fish. Exotic fish species vary in their tolerance to these substances; water temperature and quality also affect their

VetBooks.ir

efficacy. Clean oxygenated water should be available to aid recovery.

Camelids A combination of xylazine, ketamine and butorphenol by intramuscular injection may be used for short time surgery.

Pigs A combination of xylazine, ketamine and butorphenol by intramuscular injection may be used.

Anaesthesia, Local and Regional

For many minor operations and diagnostic procedures, local anaesthetics are used in preference to general anaesthesia. They act by blocking conduction along the nerve fibre, producing loss of sensation and/or muscle paralysis. Drugs used include lidocaine (lignocaine), procaine, ropivacaine and bupivacaine. The method and site of administration can be targeted according to the specific procedure to be carried out.

Perineural anaesthesia is used when the precise location of the nerves serving the area to be anaesthetised is known. For example, when disbudding calves, the area may be anaesthetised by injecting the agent above the corneal nerve between the eye and the base of the horn bud.

A field block can be used for anaesthetising large areas. A series of injections is made along a line (including skin, subcutaneous structures and sometimes muscle) to remove sensation from the tissue along that line. An example would be desensitising of the flank for CAESAREAN SECTION and RUMENOTOMY. Regional anaesthesia results from perineural or epidural anaesthesia. To anaesthetise a limb, a tourniquet is applied above the part of the limb to be anaesthetised and the drug given intravenously; lidocaine is the agent of choice. This technique is termed intravenous regional anaesthesia (or sometimes Bier's block). Loss of sensation lasts until the tourniquet is released. The precautions applying to the use of tourniquets must be observed (See under TOURNIQUET). Surface anaesthesia is useful for facilitating certain procedures. It may be applied to a mucous surface by spray. For example, a cat's throat may be sprayed with lidocaine before introducing an endotracheal tube. To facilitate introduction of a venous catheter, the skin of smaller species can be anaesthetised by applying an anaesthetic cream, after shaving the area. The cream is protected by a waterproof dressing; the anaesthetic may take up to an hour to work.

Local anaesthetics may also be administered in eye drops. The cornea of an animal can be anaesthetised by local anaesthetics (e.g. tetracaine or proxymetacaine) sufficiently to perform minor procedures such as cauterisation of a shallow ulcer. The use of regional anaesthetic in small animals is usually as an adjunct to general anaesthesia. Epidural anaesthesia results when a local anaesthetic is injected into the space surrounding the spinal cord – the epidural space. This produces a loss of sensation in the tissues served by the spinal nerves. The specific area affected depends on the site of injection. In the caudal epidural space, anaesthesia of the perineal area results; the technique is used e.g. in difficult calvings.

Epidural anaesthesia applied to the lumbosacral epidural space may be used for operations on the recumbent animal. Intra-articular anaesthesia, by injection into a joint, is mainly used diagnostically to identify a joint that is causing pain. Local anaesthetics must not be used indiscriminately since poisoning can result, and affect the brain and heart. Signs of poisoning include sudden collapse, or excitement, vomiting and convulsions.

Anaesthetics, Legal Requirements

The Protection of Animals (Anaesthetics) Act 1966 made it obligatory to use an anaesthetic when castrating dogs, cats, horses, asses and mules of any age.

Castration Only a veterinary surgeon, using an anaesthetic, is permitted to castrate any farm animal more than 2 months old; with the exception of rams for which the maximum age is 3 months and in goats only use of rubber rings under seven days old can be done by stockpersons.

The use of rubber rings or similar devices for castrating bulls, pigs, goats and sheep, or for docking lambs' tails, is forbidden unless applied during the 1st week of life. The Act of 1966 also requires that an anaesthetic be used when dehorning cattle; and also for disbudding calves unless this be done by chemical cautery applied during the 1st week of life.

An anaesthetic must be used for any operation, performed with or without the use of instruments, which involves interference with the sensitive tissues or the bone structure of an animal. (See also DOCKING.)

Anaesthetics, Residues in Carcases

Dogs and cats have shown severe signs of poisoning after being fed on meat from animals humanely slaughtered by means of an overdose of a barbiturate anaesthetic, or chloral hydrate.

Anagen

The period of active hair growth by the hair follicle. (Compare TELOGEN)

Anakatadidymus

A congenital anomaly wherein twins are divided above and below but joined in the middle.

VetBooks.ir

Anal
Relating to the ANUS.

Anal Abscess
A common, if technically incorrect, term to denote an anal sac that has become infected and has fistulated to the exterior.

Anal Atresia
(See ATRESIA ANI.)

Analeptics
Drugs that stimulate the central nervous system (See STIMULANTS).

Anal Fistulae
(See under ANAL SACCULITIS and ANAL FURUNCULOSIS.)

Anal Furunculosis
A condition of the dog, particularly common in GERMAN SHEPHERD DOGS, in which discharging sinuses develop around the anus, allegedly caused by friction of the heavy tail on soiled skin, but perhaps follows the trapping of faecal matter in the folds of the anal MUCOUS MEMBRANE. Surgery may be required to assist resolution of this painful condition.

Analgesics
Drugs which cause a temporary loss of the sense of pain without a loss of consciousness, i.e. analgesia.

Analgesics include non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin, carprofen, flunixin, meloxicam, paracetamol and phenylbutazone. (They are contraindicated if animals that have heart, kidney or liver disease and some are particularly toxic in particular species, e.g. paracetamol in cats.)

Opiates are analgesics, the most effective of which is MORPHINE. (See also BUPRENORPHINE HYDROCHLORIDE; DETOMIDINE; ACUPUNCTURE.)

Anal Glands, Anal Sacs
Dogs, cats and other species (including the family Mustelidae) possess two sacs on either side of the anus into which open numerous APOCRINE and SEBACEOUS GLANDS, which produces a malodorous fluid, a PHEROMONE. (See also under ANUS.)

Anal Sacculitis
The ANAL GLANDS may not always empty properly and swell, cause pain and become infected. This is presented by the animal pressing and dragging the PERINEUM along the ground. There is often licking of the affected part and crying. Pressure and friction may result in formation of fistulas on one and both sides of the anus - ANAL ABSCESS or ANAL FISTULA.

Anamnesis
Anamnesis is the past history of a particular patient.

Anamnestic Response
The rapid rise in antibody level in a previously immunised animal in response to a 'booster' dose of the same vaccine. The immune system has 'remembered' what to do.

Anaphrodisia
Impairment of sexual appetite.

Anaphylactic Shock, Anaphylaxis
The reaction to a foreign protein which sometimes follows bee or wasp stings, injections of an antibiotic or antiserum, etc., after the patient has become hypersensitised to the substance. There is often a rapid fall in blood pressure; anaphylactic shock can prove fatal. (See also ANTIHISTAMINES; HYPERSENSITIVITY; WARBLES.)

Anaplasmosis
This is an infectious disease of cattle, characterised by anaemia and caused by a parasite of the red blood cells, *Anaplasma marginale*.

This parasite is found in Africa, Asia, Australia, Southern Europe, South America, and the southern States of the USA. *A. centrale* (in cattle) and *A. ovis* (in sheep and goats) are other species.

Signs The disease resembles Texas fever; frequently anaplasmosis coexists with babesiosis, but pure infections may also occur. It is characterised by acute anaemia, fever, jaundice, and degeneration of the internal organs; haemoglobinuria does not occur as the rate of red-blood-cell destruction is not fast enough to produce free haemoglobin in the circulating blood. Young animals appear to be resistant, and cases in calves under 1 year old are rare. In older animals the disease may be acute or chronic, and in the former case they may die within 2 to 3 days after the appearance of the first signs. The disease starts with a high temperature of 40.5° C to 41.5° C (105° F to 107° F) and after a day or two anaemia and icterus appear. In the acute illness, aggressiveness and abortion are other signs.

Transmission is by ticks, e.g. *Boophilus*, *Rhipicephalus*, *Hyalomma*, *Ixodes*, *Dermacentor*, and *Haemaphysalis*. Infection is passed through the egg to the next generation of ticks. Tabanid flies and mosquitoes are carriers.

Animals which recover from anaplasmosis are in a state of premunition, and remain carriers for long periods, probably for life.

In the South African States the less serious *A. centrale* has been found to give protection against the serious *A. marginale*, and both there and in

VetBooks.ir

other countries successful results follow its use as an immunising agent. In other areas where Texas fever and anaplasmosis frequently occur together, cattle are often immunised by blood of a bovine infected with *A. centrale*, which produces a mild infection, and with a mild form of *Babesia bigemina*. Treatment of anaplasmosis is by oxytetracycline injections.

Anasarca
Anasarca is a condition of oedema, particularly of the tissues below the skin. The fetus can become anasarcous from a genetic predisposition, most frequently seen in Ayrshire cattle, and can lead to abortion. Otherwise the fetus can become larger than the birth canal, so that a CAESAREAN SECTION is needed to deliver the calf.

Anastomosis
The means by which the circulation is carried on when a large vessel is severed or its stream obstructed. In anatomy the term is applied to a junction between two or more arteries or veins which communicate with each other. It is also a term for the surgical repair of a tubular organ such as the intestine.

Anatoxin
A toxin rendered harmless by heat or chemical means but capable of stimulating the formation of antibodies.

Ancephaly
The absence of the nose and olfactory centre of the brain.

Anchor Worm
(*Lernaea cyprinacea*) An exotic parasite of goldfish now to be found in some indoor ornamental pools in the UK. The worms can penetrate the fish's skin. Their removal needs to be done under anaesthesia.

Ancona Chickens
A breed originating in Ancona, Italy and present in Britain since the late 19th century. They produce white or blue-tinted eggs depending on the genetics, laying about five per week. The plumage is mottled black with white tips to the feathers. The combs are single and red and they are lopped in the females. The legs are not feathered. The standard cocks weigh towards 3 kg (6 lb) and the hens up to 2.5 kg (5 lb). They are a useful backyard or pet hen.

Anconeal Process
Part of the elbow joint, being a projection of the ULNA. In several breeds of dog it may not develop properly

Ancylostoma
(See HOOKWORMS.)

Andalusian Horses
These horses were bred in south west Spain from the old Iberian horses and Arab imports. They made good war horses, particularly favoured by the Romans, and now are popular as riding mounts. In Spain they are used in bull-fighting. They are normally bay, black and grey.

Androgen
Any steroid hormone that promotes male characteristics. (See HORMONES.)

Androgynous
The female pseudohermaphrodite.

Androgyny
Female pseudohermaphroditism, usually of hormonal origin.

Androstenedione
This hormone is produced in the ADRENAL GLANDS, ovaries and testicles as an intermediate step in the production of OESTRADIOL AND OESTRONE and testosterone.

Androstenone
A metabolite of androsterone which contributes to BOAR TAINT.

Androsterone
An androgenic hormone excreted in the urine.

Anedeous
The absence of genital organs.

Anencephaly
A defect in which an animal is born without a brain. This may be congenital or from exposure to a teratogenic substance during the dam's pregnancy.

Anephrogenesis
A congenital lack of kidney tissue.

Anergy
Failure or suppression of the cellular immune mechanism. This may occur in e.g. human brucellosis, and in other chronic diseases. Anti-anergic treatment with levamisole has been found successful in some patients. (R. D. Thorne, *Veterinary Record*, **101**, 27.) (See also IMMUNOSUPPRESSION.)

Aneuplody
The presence of an irregular number of chromosomes (not an exact multiple of the

VetBooks.ir

haploid number). It may arise through faulty cell division.

Aneurin
A synonym for THIAMIN.

Aneurysm
A dilatation of an artery (or sometimes of a vein or the heart) following a weakening of its walls. The result is a pulsating sac which is liable to rupture.

Aneurysms occur in the abdomen, chest and brain, and may result from a congenital weakness of the blood vessel, from disease of its lining cells, from injury, etc.

Causes Sudden and violent muscular efforts are regarded as the chief factors in the production of aneurysms, and as would be expected, the horse is more subject to this trouble than any of the other domesticated animals.

'Verminous aneurysm' is a misnomer for verminous arteritis of horses caused by immature strongyle worms. (See EQUINE VERMINOUS ARTERITIS.)

Angeln Cattle
A dairy breed originally from Schleswig-Holstein mentioned first in the 1600s. They are red in colour and a founding breed within the DANISH RED. The 305-day lactation produces 7,579 kg (16,700 lb), at 4.8 per cent butterfat.

Angiogenesis
A method of treating a tumour by depriving it of its blood supply.

Angiography
A radiographic technique which enables the blood-flow to and from an organ to be visualised after injection of a contrast medium.

Angioma
A TUMOUR composed of a large number of blood vessels. They are common in the livers of cattle. (See also HAEMANGIOMA.)

Angiosarcoma
(See HAEMOSARCOMA.)

Angiostrongylus
(See HEARTWORM.)

Angitis
Inflammation of a blood vessel, lymph vessel, or bile duct.

Angleberry
An old name for WARTS.

Anglo-Nubian Goats
A breed also called Nubian, developed from goats from the Middle East and North Africa. They may be of any colour and have a 'Roman nose' and long pendulous ears. They are a dairy breed but can be used for meat. Bucks weigh about 80 kg (175 lb) and does 60 kg (135 lb) with a minimum height at the withers of 90 cm (35 in) for bucks and 75 cm (30 in) for does. The average yield is about 4 kg (9 lb) milk daily with 4.8 per cent butterfat and 3.5 per cent protein.

Angora
The name of breeds of rabbit which produce angora wool and goats that produce mohair fibre.

Angora rabbits show a variety of colours; the wool is removed very easily by plucking.

Angora Goats
A breed of goats that produce mohair wool. They have a single coat rather than the usual double coat of goats; this grows as ringlets and is shorn twice yearly, usually in January and late summer. It weighs 4 kg to 6 kg (9 lb to 14 lb); that from the male is heavier.

Angora Rabbits
Breed of rabbits that produce angora wool. They show a variety of colours; the wool is removed very easily by plucking.

Angora Wool, Angora Fibre
This is produced from the PELAGE of the Angora rabbit. They show a variety of colours, the wool is removed very easily by plucking. The hair of Angora goats is called mohair.

Angus Cattle
(See ABERDEEN ANGUS CATTLE.)

Anhidrosis
A failure of the sweat mechanism. This occurs in horses especially, but also in cattle, imported into tropical countries with humid climates.

At first, affected horses sweat excessively and their breathing is distressed after exercise. Later, sweating occurs only at the mane; the skin becomes scurfy; and breathing becomes more laboured. Heart failure may occur.

Anhydraemia
A lack of fluid in the blood and a low serum yield. It can result from dehydration or other causes.

Anhydride
An oxide which can combine with water to form an acid.

Anhydrous
Containing no water.

VetBooks.ir

Animal and Plant Health Agency (APHA)

A combined agency formed on October 1st 2014 from the ANIMAL HEALTH AND VETERINARY LABORATORIES AGENCY (AHVLA), the Food and Environment Research Agency and Plant Health Agency.

Animal Behaviour

As a guide to animal welfare, see AGGRESSIVENESS; ANAESTHESIA, GENERAL; ANALGESICS; ETHOLOGY; ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION; HOUSING OF ANIMALS; TRANSPORT STRESS.

Animal Boarding Establishments Act 1963

This requires that the owner of a boarding establishment shall obtain a licence from the Local Authority, and that this licence must be renewed annually. The applicant has to satisfy the licensing authority on certain personal points, and that the 'animals will at all times be kept in accommodation suitable as respects construction, size of quarters, number of occupants, exercising facilities, temperature, lighting, ventilation and cleanliness'. The Act also requires that animals boarded 'will be adequately supplied with suitable food, drink, and bedding material, adequately exercised, and (so far as necessary) visited at suitable intervals'. Isolation facilities and fire precautions are covered by the Act, which empowers the Local Authority to inspect both the boarding establishment and the register which must be kept there. A copy of the licence and its conditions must be suitably displayed.

Animal By Products (Amendment) (England) Order 2001

(See DISEASES OF ANIMALS (WASTE FOOD) ORDER 1973.)

Animal By-Products Regulations 2003

The Regulation prevents the feeding of catering waste to farm animals and enacted legislation of The Animal By-Products Regulation (EC) 1774. 2002 that came into force on May 1st 2003. A UK national ban (SI 2001.1704) had previously come into operation on 24th May 2001 following the onset of the FOOT-AND-MOUTH DISEASE outbreak. This includes the prevention of the feeding of SWILL to pigs. Poultry litter and also compost and anaerobic digestion residues should not be used as bedding for animals.

Animal Data Centre

This is located at the National Centre for Animal Statistics, Westside, Newton, Stocksfield, Northumberland NE43 7TW.

Animal Food

(See CONCENTRATES; DIET AND DIETETICS; RATIONS FOR LIVESTOCK; PROTEINS; POISONING; VITAMINS; ADDITIVES; PET FOODS; also DOGS' DIET; CAT FOODS, etc.)

Animal Health Act 2002

This consolidated the Diseases of Animals Acts 1950, 1953 and 1975, 1981. (See also ANIMAL WELFARE ACT 2006).

Animal Health and Veterinary Laboratories Agency (AHVLA)

This was formed from the merger of Animal Health (formerly State Veterinary Service) with the Veterinary Laboratories Agency on 1 April 2011. The address is the Animal Health Corporate Headquarters, Block C3, Government Buildings, Whittington Road, Worcester WR5 2LO. Telephone: 01905 763355; website: http://www.defra.gov.uk. It is now known as the ANIMAL AND PLANT HEALTH AGENCY (APHA). (See VETERINARY INVESTIGATION CENTRES.)

Animal Health and Welfare Board for England (AHWBE)

A body created in April 2011 to drive policy for farm animals, equine and companion animal health and welfare. It is composed of stakeholders and 5 DEFRA representatives.

Animal Health and Welfare (Scotland) Act 2006 Part 2

The Act under which prosecutions for cruelty neglect or lack of proper care in the case of vertebrate animals are taken in Scotland. Part 1 updates part of the Animal Health Act 1981 in relation to Scotland.

Animal Health Schemes

(See under HEALTH SCHEMES FOR FARM ANIMALS.)

Animal Health Trust (AHT)

A charity that is one of the world's leading centres for research into animal health. Its Equine Research Station is renowned for its studies of the physiological and anatomical factors affecting performance, and the small animal centre has particular expertise in eye problems of the dog and cat. AHT research has led to breakthroughs in anaesthesia and in the development of vaccines against equine flu and canine distemper. The address is: Animal Health Trust, PO Box 5, Newmarket, Suffolk CB8 7DW.

Animal Husbandry

Animals, Housing Of

(See HOUSING OF ANIMALS.)

Animals (Scientific Procedures) Act 1986

This replaced the Cruelty to Animals Act 1876. The 1986 Act makes it illegal to supply animals, other than those purpose-bred in Home-Office-designated breeding establishments, for use in experimental procedures involving dogs, cats, and other animals. The Act requires all laboratories in the UK where animals are used in research to appoint a veterinary surgeon to be responsible for the care and welfare of their experimental animals.

On 1 January 1990 it became illegal to sell or supply pet or stray animals for use in scientific experiments.

The Act also represents the culmination of the efforts of three organisations – the British Veterinary Association (BVA), the Committee for the Reform of Animal Experimentation (CRAE), and the Fund for the Replacement of Animals in Medical Experiments (FRAME) – to reform animal experimentation legislation. The new Act is firmly rooted in BVA/CRAE/FRAME proposals sent to the Home Secretary in 1983, and represents an effective compromise between the welfare needs of animals, the legitimate demands of the public for accountability, and the equally legitimate requirements of medicine, science and commerce.

The legislation gives the Home Secretary the power and the responsibility to judge the scientific merit of the work s/he authorises and for which s/he will be answerable to Parliament.

Animal Transport

(See TRANSPORT STRESS.)

Animal Welfare Act 2006

The main Act in England and Wales under which prosecutions may be made for cruelty, neglect or lack of proper care to all vertebrate animals. There is a 'duty of care' to all owned animal species. The Act stipulates that animals should be provided with a suitable living environment and diet, and requires that animals are allowed to exhibit normal behaviour patterns and should have protection from pain, suffering, injury and disease. There is provision for action to be taken when the circumstances of an animal or animals is unlikely to improve. A person commits an offence if an act or failure to act results in an animal suffering and that it is unnecessary suffering. Subsidiary legislation may differ between England and Wales. (See FARM ANIMAL WELFARE COMMITTEE; 'FIVE FREEDOMS' FOR FARM ANIMALS.)

Animal Welfare Codes

(See WELFARE CODES FOR ANIMALS.)

Anionic Proteins

(See ORIFICES, IMMUNITY AT.)

Anions

A negatively charged ion which is attracted to the positive electrode (anode) of the battery. They can combine with CATIONS to make compounds such as acids, alkalis and salts. They are important when producing DIETARY CATION-ANION BALANCE.

Aniridia

The congenital absence, complete or partial, of the iris.

Aniseed

It is incorporated in herbal remedies of dogs and cats, acting as a carminative and mild expectorant.

Anisomelia

Inequality between the two limbs.

Ankylosis

The condition of a joint in which the movement is restricted by union of the bones or adhesions. (See JOINTS, DISEASES OF.)

Anodontia

The absence of teeth.

Anodynes

Anodynes are pain-relieving drugs.

Anoestrus

Anoestrus is the state in the female when no oestrus or 'season' is exhibited. It is a state of sexual inactivity. In most mares, for example, anoestrus occurs during the winter months, when daylight is reduced, ambient temperatures are low and, in the wild state, food is scarce. In these circumstances the pituitary gland does not release the gonadotrophins FSH and LF (see HORMONES) so that neither follicles nor *corpora lutea* develop in the ovaries.

Similar circumstances apply with cattle. Fear, hunger, cold and pain may all result in anoestrus. (See also OESTRUS.)

VetBooks.ir

Anophthalmia
Absence of eyes: a congenital condition. It is seen unhatched chicks resulting from being in a 'hot spot' in the incubator.

Anopia
The lack of one or both eyes. Also called ANOPHTHALMIA.

Anorchism
The congenital absence of one or both testes.

Anorexia
The lack or loss of appetite. Appetite is mainly physiologically dependent in memory and associations from the sight, small or thought of food. (See APPETITE – Diminished appetite.)

Anostosis
The defective development of bone with a failure to ossify.

Anotia
The congenital absence of ears.

Anovaria, Anovarism
Absence of ovaries. This is seen in 'WHITE HEIFER DISEASE'.

Anoxia
Oxygen deficiency. Cerebral anoxia, or a failure in the oxygen supply to the brain, occurs during nitrite and prussic-acid poisoning; in copper deficiency in cattle; and in the thoroughbred 'barker foal'. Anoxia is a method of slaughter allowed under the Welfare of Animals (Slaughter or Killing) Regulations 1995 (as amended). (See also ANAESTHESIA, GENERAL.)

Antagonism
Drug antagonism occurs when two incompatible medicines are mixed or administered. Bactericidal antibiotics that act on multiplying organisms (e.g. penicillins) may have no effect if used with bacteriostatic antibiotics that prevent multiplication (e.g. tetracyclines).

Ante-Mortem
Before death. An ante-mortem inspection is the name for an examination of the live animal which is used in conjunction with the findings of a post-mortem inspection, or autopsy. Under the Welfare of Animals (Slaughter or Killing) Regulations 1995, ante-mortem inspections are carried out on animals after their arrival at an abattoir and before they are stunned.

Ante-Natal Infection
Infection of the fetus before birth. Examples of this may occur with the larvae of the dog hookworm, *Ancylostoma caninum*, and with the larvae of other roundworms. (See *Toxocara*.) Toxoplasmosis is another example of an infection which may occur before birth.

Ante-Partum Paralysis
Ante-partum paralysis is a condition in which the hindquarters of the pregnant animal suddenly become paralysed. It is fairly common in the cow, has been seen in the sheep and goat, but is rare in the mare. It appears from 6 to 25 days before parturition, and is liable to affect animals in almost any condition – those that are well kept as well as others.

Signs The condition suddenly appears without any warning. The pregnant animal is found in the lying position, and is quite unable to regain her feet.

Treatment As a rule, the nearer to the day of parturition that the paralysis appears, the more favourable will be the result. Those cases that lie for 2 or more weeks are very unsatisfactory. The condition usually disappears after parturition has taken place, either almost at once or in 2 or 3 days. As a consequence, treatment should be mainly directed to ensuring that the animal is comfortable, provided with plenty of bedding, is turned over on to the opposite side 3 or 4 times a day if she does not turn herself, and receives a laxative diet so that constipation may not occur. Mashes, green food, and a variety in the food stuffs offered, are indicated. When the paralysis has occurred a considerable time before parturition is due, it is often necessary to produce artificial abortion of the fetus and so relieve the uterus of its heavy encumbrance.

Anthelmintic Resistance
Routine use of an anthelmintic tends to establish resistance to its effects. Resistance to anthelmintics in sheep and goats has become a serious problem in Australia and is increasing in other countries including UK, where livestock are regularly dosed. It is also a problem in horses, although uncommon in cattle. Goats do not acquire age-related resistance to helminths and anthelmintic over-use can rapidly produce resistance. The development of resistance may be discouraged by changing the class of anthelmintic used for each year's dosing programme. Worming products are labelled with the following codes that identify their chemical type:

1-BZ Benzimidazoles, probenzimodazoles (white)
2-LV Imidazothiazoles, tetrahydropyrimidines (yellow)

VetBooks.ir

3-ML Avermectins, milbemycins (clear)
4-AD Amino-acetonitrile derivatives (orange)
5-SI Spiroindoles (purple)

Products with the same codes should not be used on the same animals in successive seasons. The aim of the veterinary practitioner must be to minimise the use of anthelmintic treatment. Anthelmintics should only be used when it is necessary to prevent clinical disease. In this way the rate of acquiring resistance will be reduced and drug efficacy preserved longer. To do this it is important that the number of worms in REFUGIA is increased. (Worms which are not in the animal and so are not subject to anthelmintic treatment are said to be in refugia.) After treatment there are always some resistant worms that survive. Once resistant worms are in the majority, anthelmintic resistance will rapidly develop. The selective treatment of only animals showing signs of infestation significantly increases the percentage of the worms in refugia.

It is now considered that where sheep, goats and camelids are continually exposed to worms it is beneficial for the animal to retain a few worms. This will not only assist the formation of immunity but also prolong the effectiveness of the available anthelmintics. The selective treatment of only those animals showing signs of worm infestation significantly increases the percentage of the worms in refugia.

Anthelmintics

Anthelmintics are medicines which are given to expel parasitic worms. There is a large range of substances and formulations from which to choose as wormers. Anthelmintic drugs include abamectin, albendazole, dichlorophen, dichlorvos, doramectin, fenbendazole, haloxon, ivermectin, levamisole, monepantel, moxidectin, nitroxynil, tetramisole, morantel tartrate and thiophanate. Niclosamide, praziquantel, and triclabendazole are used against tapeworms in the dog. (See also DRONCIT.) Fenbendazole and albendazole are broad-spectrum anthelmintics usually effective against inhibited fourth-stage ostertagia larvae in cattle, as are macrocyclic lactones and amino acetonitrile derivatives (Ads or AADs).

Certain criteria apply in the selection of anthelmintics. For example, will the drug in question kill worm eggs? Is it effective against immature worms? Is it effective against adult worms of the economically important species? Does the drug discolour or taint milk? Can it be given to pregnant, or emaciated, animals? In cows, for how long must the milk be discarded after administration?

Methods of dosing include drenching; injection in the feed and 'pour ons'. (See also WORMS, FARM TREATMENT AGAINST.)

Anthisan

The proprietary name for mepyramine maleate, an antihistamine compound, often applied topically. It is not licensed for veterinary use in the UK.

Anthoxanthum odoratum

(See SWEET VERNAL GRASS.)

Anthrax

Anthrax, a NOTIFIABLE DISEASE, is one of the most serious ZOONOSES. It is an acute, usually fatal, infection found in mammals; it is commonest among the herbivora. All cases of unexpected sudden death in cattle must be notified. Any animal that dies suddenly and unexpectedly without an obvious cause should be considered to be an anthrax suspect and investigated as such. In many countries, this sudden death should be reported to the local office of the government veterinary service for investigation. In England, Scotland and Wales this should be the local office of AHVLA, in Northern Ireland the duty veterinarian DARD, and in the Irish Republic, the duty veterinarian in DAFF. In the event of any difficulty making contact with these bodies, the owner/farmer should speak to their veterinary surgeon for advice. The premises concerned will be subject to restrictions and arrangements made for the affected carcase to be destroyed if the investigation does not rule out the suspicion of anthrax in that animal.

Cause The *Bacillus anthracis*. Under certain adverse circumstances, each rod-shaped bacillus is able to form itself into a spore. The spores of anthrax are hard to destroy. They resist drying for a period of at least 2 years. They are able to live in the soil for 10 years or more and still be capable of infecting animals. Consequently pastures that have been infected by spilled blood from a case that has died are extremely difficult to render safe for stock.

Earthworms may carry the spores from deeper layers of the soil up to the surface. Spores have been found in bone-meal, in blood fertilisers, in wool and hides and in feeds. (See also STREAMS.)

The bacillus itself is a comparatively delicate organism and easily killed by the ordinary disinfectants.

Method of Infection In cattle, infection nearly always occurs by way of the mouth and alimentary system. Either the living organisms or else the spores are taken in on the food or with the drinking water. Flies can spread the disease. Anthrax has been caused through inoculation of vaccine contaminated by spores; sheep should not be inoculated, therefore, in a dusty shed. Unsterilised bone-meal is an important source of infection (not in the UK).

VetBooks.ir

Signs Three forms of the disease are recognised: the peracute, the acute, and the subacute.

Cattle In most peracute cases, the animal is found dead without having shown any noticeable signs beforehand. Acute: a temperature of 41° C to 41.6° C (106° F or 107° F), a thin, rapid pulse, coldness of the ears, feet, and horns, and 'blood-shot' eyes and nostrils. After a few hours this picture is followed by one of prostration, unconsciousness, and death. In either of the above types there may have been diarrhoea or dysentery.

In the subacute form, the affected animal may linger for as long as 48 hours, showing nothing more than a very high temperature and laboured respirations. Occasionally cattle may be infected through the skin, when a 'carbuncle' follows, similar to that seen in man. Diffuse, painless, doughy swellings are seen in other cases, especially about the neck and the lower part of the chest.

As sudden death of an animal is often wrongly attributed to lightning strike, a farmer should consult a veterinary surgeon (who will carry out a rapid blood test) to make sure that the cause of death is not anthrax – before handling the carcase, cutting into it, moving it, or letting farm dogs, hounds, cats, etc., feed upon it. A blood smear is taken by the veterinary surgeon, stained and examined under the microscope for the presence or absence of the bacterium. If these are absent a carcase can be moved and opened.

Sheep and goats Anthrax in these animals is almost always of the peracute type.

Horses The disease is not always as serious in horses as it is in cattle. Signs depend on the mode of infection. There are two main forms of signs. In one form, due to insect transmission, there is a marked swelling of the throat, neck, and chest. In the second form of equine anthrax, resulting from indigestion, a fit of shivering ushers in the fever. The pulse rate becomes increased, the horse lies and rises again with great frequency; it shows signs of slowly increasing abdominal pain by kicking at its belly, by gazing at its flanks, or by rolling on the ground.

Pigs The disease may follow the feeding of slaughter-house refuse or the flesh of an animal that has died from an unknown disease (which has really been anthrax), or raw bone-meal intended as a fertiliser - all illegal in the UK. There is sometimes swelling of the throat; the intestine may be involved. In this abdominal form the signs may be very vague. Otherwise the pigs are dull, lie a good deal, show a gradually increasing difficulty in respiration, and present in the early stages a swelling of the throat and head which later invades the lower parts of the neck. Recovery is not unknown.

Dogs and cats A localised form, with oedema of the head and neck (similar to that in the pig), is characteristic. Anthrax has also been reported in zoological collections.

Prevention and Treatment In Great Britain, as in most developed countries, anthrax is a NOTIFIABLE DISEASE. Vaccines are not available commercially. In Britain, DEFRA may be contacted for information about emergency supplies of vaccine. Antibiotics, particularly penicillin, if given early enough, may be effective. When cases have occurred check health and, ideally, temperature of in-contact animals daily.

In so far as its prevention is concerned, the important points to remember are (1) disposal of the carcase by efficient and safe means (see DISPOSAL OF CARCASES) and (2) frequent observation of other animals which have been in contact with the dead one; also their isolation if showing a rise in body temperature.

Sodium hypochlorite (or bleaching powder in a hot 10 per cent solution) kills both bacilli and the spores almost instantaneously.

The milk from in-contact animals must be regarded as dangerous until such time as these are considered to be out of danger. The law forbids anyone who is not authorised to cut an anthrax carcase for any purpose whatsoever. Cases of death from this procedure are by no means unknown, and illness following the dressing of a carcase must always be considered suspicious of anthrax until the contrary has been established. The need for reporting illness to the medical authorities by all persons whose work brings them into contact with carcases of animals cannot be too strongly stressed.

Anthrax in human patients Anthrax is now very rare in humans, with only a handful of cases having been notified in recent years. It may take the form of an inflamed pustule accompanied by fever and prostration, if infection is via the skin – e.g. through a cut. In cases of internal infection, by inhaling or swallowing the spores, pneumonia or intestinal ulceration usually cause death within 2 days if not treated promptly. The infection is more often contracted by workers handling infected meat or meat and bone-meal than by farmers. Any person who has handled an anthrax carcase should seek medical advice.

Anthrax Order 1991

This order requires the person in charge of an animal or carcase suspected of being infected with anthrax, which includes any animal that has died

VetBooks.ir

suddenly without obvious cause to notify the local office of Animal Health (AHVLA), which will organise a veterinary investigation. In the event of there being difficulty in contacting Animal Health, the farmer should contact his DEFRA contract Official Veterinarian. If the investigation shows the presence of anthrax, the premises may be declared an infected place. The local authority has the responsibility of disposing of the carcase by incineration or other suitable method. The Veterinary Officer supervises cleansing, disinfection, vaccination, etc. If the owner refuses to carry out these procedures, the Veterinary Officer can have them carried out and recover the cost from the owner. The Anthrax (Amendment) Order 1996 enables the veterinary inspector to require the incineration of things that have been in contact with or used by an infected animal.

Anthroponoses

Diseases transmissible from man to lower animals. Such diseases include: tuberculosis, infestation with the beef tapeworm; influenza in pigs and birds. (Compare ZOONOSES.)

Antibiotic

A chemical compound derived from living organisms or synthesised from biological material capable, in small concentration, of inhibiting the life process of micro-organisms. To be useful in medicine, an antibiotic must (1) have powerful action in the body against 1 or more types of bacteria; (2) have specific action; (3) have low toxicity for tissues; (4) be active in the presence of body fluids; (5) not be destroyed by tissue enzymes such as trypsin; (6) be stable; (7) be not too rapidly excreted; (8) preferably not give rise to resistant strains of organisms. (Professor F. Alexander.)

Antibiotics are much used in veterinary medicine to overcome certain infections, and they have been of notable service, for instance, in the control of certain forms of mastitis in dairy cattle, in the avoidance of septicaemia following badly infected wounds, deep-seated abscesses, peritonitis, etc. Abdominal and other surgery has been rendered safer by the use of antibiotics. The prophylactic use of antibiotics has been an important factor in the intensive production of livestock and poultry. They must not, however, be used indiscriminately, be regarded as a panacea, or be given in too low a dosage and they cannot be used for growth promotion in UK or EU. It is unwise to use antibiotics of the tetracycline group in either pregnant or very young animals owing to the adverse effects upon bone and teeth which may result.

Certain antibiotics are effective GROWTH PROMOTERS. Their widespread use has in part contributed to the development of resistance to antibiotics, and it is vital to realise that antibiotic use must be considered as part of the overall health and welfare plan, and not a substitute for good husbandry. An exception is in the use of intramammary antibiotic infusions when milking cows are dried off; it is the only known way of keeping subclinical infection of the udder under control. These infusions are also a rare example of where the use of two or more antibiotics in the same preparation can be more effective than just one.

Selection of Antibiotic It is often necessary to begin antibiotic therapy before the results of biological examinations are available, and therapy must depend on the clinical features. However, the taking of material for culture and carrying out sensitivity tests are most important procedures. Another factor in veterinary practice is the cost of the drug. However, minimising dose can lead to increasing the possibility of resistance.

Only in a very few instances are mixtures of antibiotics superior to a single drug. In those cases in which more than one antibiotic is required, the full dose of each of the individual antibiotics should be given so as to exceed the MINIMUM INHIBITORY CONCENTRATION. Combined antibiotic therapy does not improve the outlook in chronic urinary infections or, indeed, many chronic infections. Mixtures of antibiotics have been most successful when used in local applications or in infections of the alimentary canal. (See ADDITIVES, and under MILK.) Some of the most widely-used group and individual antibiotics in veterinary medicine are: BENZYLPENICILLIN, procaine penicillin (under PROCAINE HYDROCHLORIDE), AMPICILLIN, AMOXYCILLIN, STREPTOMYCIN, NEOMYCIN, TETRACYCLINES, CHLORAMPHENICOL, GRISEOFULVIN, CHLORAMPHENICOL, ERYTHROMYCIN, GRISEOFULVIN, CEPHALOSPORINS, FLUOROQUINOLONES. (See also CEPHALOSPORIN ANTIBIOTICS, TIAMULIN, SALINOMYCIN; and below.)

For advice on selection of antibiotics for treatment, see *The Veterinary Formulary* (RPSGB/BVA).

A 2012 survey of Irish cattle practitioners in showed that previous experience with a particular antibiotic was a major consideration when prescribing. Non-clinical issues concerning stresses and perceived or actual pressures on the veterinary surgeon had an influence in most cases.

Antibiotic Resistance

The widespread use of antibiotics has become associated with the development of resistance to their effects. Bacteria can become drug-resistant in one of two ways. Chromosomal resistance develops

VetBooks.ir

through mutation and is probably rare. Bacteria which achieve this kind of resistance are unable to transfer it to other bacteria, but pass it on to their own future generations through the ordinary process of cell division.

The second method is transmissible drug resistance (TDR). This is achieved by means of PLASMIDS.

Many bacteria carry, in their cytoplasm, resistance or R factors. These are pieces of DNA which include genes coding for resistance to antibiotics and other genes which facilitate the transit of the R factor to other bacteria. Both groups of genes are carried on plasmids.

A GRAM-NEGATIVE bacterium which possesses an R factor is able to conjugate with other Gram-negative bacteria. This involves intimate contact through a protoplasmic bridge called a sex pilus. When this occurs a duplicate of the R factor is transmitted to the second, recipient, cell, which thereby acquires both the drug resistance and the ability to transmit it to other bacteria.

Inside the gut of an animal being dosed with an antibiotic, these resistant bacteria survive and multiply at the expense of the antibiotic-sensitive bacteria. Cross-infection can then bring about a similar situation in other animals.

The persistence of TDR in the animal gut has been related to the pattern of antibiotic usage. Continuous low-level administration of antibiotics has been shown to increase the incidence of resistant organisms. The emergence of resistant strains of salmonella in calves receiving in-feed antibiotics has been of concern. As long ago as 1972, a MAFF study of 2166 strains of salmonella isolated from farm animals found that 90 per cent were resistant to streptomycin.

There has been concern that the use of antibiotics as growth promoters could encourage development of resistant organisms. Consequently, antibiotics used in this way were to be selected from those not used therapeutically in animals or humans. They were subsequently banned from such use.

On the other hand, specific full-dose treatments for acute conditions are less likely to create persistent resistance problems. For example, administration in dairy herds of an antibiotic via the teat, over short periods of time, or as a preventive during the dry period, seems to have had little effect on drug-resistance in the herd.

Antibiotics, Adverse Reactions to

(See PENICILLIN, SENSITIVITY TO; NEOMYCIN; CHLORAMPHENICOL; TETRACYCLINES; TYLOSIN.)

Antibiotic Supplements

Antibiotic feed supplements are permitted for treatment purposes only. Their use as growth promoters has been banned in the EU since January 2006. (See under ADDITIVES.)

Antibody (Ab)

A substance in the blood serum or other body fluids formed to exert a specific restrictive or destructive action on bacteria, their toxins, viruses, or any foreign protein.

Antibodies are not produced, like hormones, by a single organ, the blood then distributing them throughout the body. Antibody production has been shown to occur in lymph nodes close to the site of introduction of an antigen, in the skin, fat, and voluntary muscle, and locally in infected tissues.

Chemically, antibodies (belonging to a group of proteins called immunoglobulins) are protein molecules of complex structure. In the IMMUNE RESPONSE, antibody and antigen molecules combine together in what is called a complex. These complexes are removed from the body by the RETICULO-ENDOTHELIAL SYSTEM. Agglutination of bacteria and precipitation of soluble protein antigens both occur following combination of antibody and antigen molecules, and are made use of in laboratory tests.

Antibodies are not always protective; some join mast cells and eosinophils after exposure to the specific antigen resulting in the release of histamine, as happens in ALLERGY. (See also REAGINIC ANTIBODIES.)

Anticoagulants

Agents which inhibit clotting of the blood. They are used to prepare blood for transfusion or for various tests. Many substances with anticoagulant properties are commonly used as rodenticides and can result in accidental poisoning of dogs and other animals. They include WARFARIN, dicoumarol and heparin. They are used in the treatment of coronary thrombosis in humans.

Anticoagulins

Substances secreted by leeches and hookworms in order to prevent clotting of the blood, which they suck.

Anticodon

A triplet of nucleotides in transfer RNA; it is complementary to the CODON in messenger DNA which specifies the amino acid

Anticonvulsants

Drugs used in the treatment of epilepsy to control seizures. (See also PHENYTOIN SODIUM.)

Antidiuretic Hormone (ADH)

Also called VASOPRESSIN, ADH is secreted by the posterior lobe of the PITUITARY GLAND. It

VetBooks.ir

stimulates absorption of water by the renal tubules, thus concentrating the urine. A deficiency of ADH leads to DIABETES INSIPIDUS. Avian diuretic hormone is ARGININE VASOTOCIN

Antidotes

Antidotes neutralise the effects of poisons either (a) by changing the poisons into relatively harmless substances through some chemical action, or (b) by setting up an action in the body opposite to that of the poison.

First-aid and other antidotes are given under the various poisons – see POISONING.

Antiemetics

A medicine which prevents vomiting and can be used in motion sickness.

Antienzyme

A substance that inhibits the action of an enzyme. Non-micronised soya contains an anti-pepsin substance.

Antifreeze

Antifreeze is ethylene glycol, and cats and dogs are attracted by its sweet taste. The signs are depression, ataxia and coma, sometimes with vomiting and convulsions. Ethylene glycol is oxidised in the body to oxalic acid, the actual toxic agent, and crystals of calcium oxalate may be found on post-mortem examination in the kidneys and blood vessels of the brain. Treatment attempts to swamp the enzyme systems which bring about this oxidation by offering ethanol as an alternative substrate. This is achieved by the intravenous administration of 20 per cent ethanol and 5 per cent sodium bicarbonate to correct acidosis; vodka (40 per cent alcohol) is a readily available source of alcohol. An alcohol dehydrogenase inhibitor, 4-methylpyrazole, has been reported effective in cases where azotaemia (nitrogen in the blood caused by toxic kidney failure) has not occurred. In early cases use emetics; absorbents do not help.

Antigen

A substance which causes the formation of antibodies. (See IMMUNE RESPONSE; VACCINE; H-Y ANTIGEN.)

Antigenetic Drift, Antigenic Drift

An antigenetic change caused by mutations of genes which may change the infective and antibody characteristics of a virus.

Antiglobulin

An antiserum against the globulin part of the serum, and used in the indirect fluorescent antibody test and COOMBS TEST.

Antihistamines

The action of histamine is dependent on biological receptors which are designated as H1 and H2 depending on the activity of histamine at each site. Antihistamines are drugs which neutralise the effects of histamine in excess in the tissues and are said to act either by (1) antagonising the action of histamine on H1 receptors (e.g. diphenhydramine hydrochloride, mepyramine maleate, chlorpheniramine maleate and promethazine hydrochloride used to treat allergic disorders, laminitis, urticaria, light sensitisation, anaphylaxis) or (2) on H2 receptors (e.g. cimetidine and ranitide) used to treat travel sickness involving dogs and cats). Not all are licensed for use in all species and they should not be used except under professional advice. (See HISTAMINE.)

Antihormones

True antibodies formed consequent upon the injection of hormones.

Antiketogenic

Antiketogenic is the term applied to foods and remedies which prevent or decrease the formation of ketones.

Antimony (Hb)

Antimony (Hb) is a metallic element belonging to the class of heavy metals. Antimony salts are little used now in veterinary medicine than formerly, less toxic substitutes being preferable.

Uses Tartar emetic, the double tartrate of antimony and potassium, was used for intravenous injection against certain trypanosomes and other protozoon parasites. (See ANTIDOTES.)

Antimycotic

Destroys fungi.

Antioxidants

A substance that, in small amounts, can inhibit the oxidation of other compounds. They are used in feeds to prevent rancidity of polyunsaturated fats. In the body they prevent cellular damage such as muscular dystrophy. They are present in several forms including vitamin E. Excessive antioxidant supplementation may actually damage cellular function. (See VITAMINS – Vitamin E.)

Antiphlogistics

(See POULTICES AND FOMENTATIONS.)

Antipyretics

Antipyretics are drugs used to reduce body temperature during fevers (pyrexias).

VetBooks.ir

Antiseptics

Agents which inhibit the growth of micro-organisms, and are suitable for application to wounds or the unbroken skin. Preparations designed to kill organisms are properly called 'disinfectants' or 'germicides'. Many substances may be either antiseptic or disinfectant according to the strength used.

Very strong antiseptic or disinfectant solutions should not be used for wounds because of the destruction of cells they cause. The dead cells may then retard healing, and in some cases are later cast off as a slough.

The following are among substances used, suitably diluted or in formulation as creams or ointments, as animal antiseptics.

Chlorine compounds in several different forms are used for cleansing wounds from the presence of organisms. Among the class may be mentioned eusol, eupad, 'TCP'*, etc. They include sodium hypochlorite and chloramines, both also used as disinfectants.

Quaternary ammonium compounds (see under this heading) are widely used in dairy hygiene. They include cetrimide and benzalkonium chloride.

Dettol*, solution of Chloroxylenol, BP Powerful bactericide of relatively low toxicity. Useful for skin cleansing, obstetrical work, and disinfecting premises. The bactericidal action is reduced in the presence of blood or serum.

Crystal violet in 1 per cent solution has in the past formed a useful antiseptic for infected wounds, burns, fungal skin diseases, and chronic ulcers. Similarly, gentian violet.

Common salt (a teaspoonful to a pint of boiled water) is useful as a wound-cleansing agent and is usually easily obtainable when other antiseptics may be lacking.

Iodoform* is a powerful, poisonous but soothing antiseptic formerly often used for dusting on to wounds as a powder with boric acid.

Iodine* in an alcoholic solution is more penetrating and irritant, especially to delicate skins. For use on the unbroken skin **only**.

Alcohol is a very powerful antiseptic chiefly used for removing grease and septic matter from the hands of the surgeon and the skin of the patient.

Hydrogen peroxide (see under this heading).

* Their injudicious use could lead to toxicity in cats, so for them other antiseptics are preferable.

Antiserum

A serum for use against a specific condition is produced by inoculating a susceptible animal with a sub-lethal dose of the causal agent or antigen and gradually increasing the dosage until very large amounts are administered. The animal develops in its blood serum an antibody which can be made use of to confer a temporary protection in other animals against the bacterium or toxin. Few antiserum preparations are now used, except Tetanus Antitoxin.

The use of antiserum alone confers a temporary immunity, and in most cases this probably does not protect for longer than from 10 days to a maximum of about 21 days. Antisera are used in the treatment of existing disease, and also as a means of protecting animals exposed to infection. (See BLACK-QUARTER; RABIES; TETANUS; JAUNDICE (Leptospiral) for examples of diseases where serum therapy may be useful.) (See also ANAPHYLACTIC SHOCK; IMMUNITY.)

Antisialics

Substances which reduce salivation, e.g. atropine.

Antispasmodics

Antispasmodics are drugs which diminish spasm causing colic or 'cramp'. They mostly act upon the muscular tissues, causing them to relax, or soothing nerves which control the muscles involved. Antispasmodic drugs include ATROPINE, propantheline, cisapride and hyoscine (in Buscopan Compositum)

Antitetanic Serum, Tetanus Antitoxin, TAT

A hyper-immune serum used against TETANUS. Nowadays, the vaccine is preferred or a combination of the antitoxin and vaccine is used.

Antitoxins, Antitoxic Sera

Antitoxins (antitoxic sera) are substances which neutralise the harmful effects of a toxin.

Antivenin

Antivenin is a substance produced by the injection of snake venom into animals in small but increasing doses. In course of time the animal becomes immune to the particular venom injected, and the antivenin prepared from its serum is highly effective in neutralising venom injected by the bite of a snake of the same species. To be of any use it must be administered within about one hour of the snake bite.

Antivenom, Snake Venom Antiserum

Antidote to the venom of adders in the UK; used for the treatment of domestic animals bitten by adders. There are many other antivenoms used to treat bites by specific snakes throughout the world.

Antiviral

A substance used against viruses. (See also INTERFERON.)

VetBooks.ir

Antivitamin
These counteract vitamins. Thiaminase is present in some fish but it is destroyed by cooking. (See AVIDIN.)

Antizymotic
An agent which inhibits fermentation.

Antlers
Antlers are grown by stags (male deer), and male and female reindeer, complete with blood supply to the velvet (the soft hairy outer layer) each year. A prime red deer stag will grow 4 kg in 3 months (May to July in the UK). Its diet must provide 600 g calcium, 300 g phosphorus and 12 g magnesium to achieve this – almost twice as much as a hind in full lactation needs.

Antrycide
A synthetic drug used in the control of trypanosomiasis.

Ants
Ants are of veterinary interest as intermediate hosts of the liver fluke *Dicrocoelium dendriticum*. This fluke, which is smaller than *Fasciola hepatica*, the common fluke, is found in sheep, goats, cattle, deer, hares, rabbits, pigs, dogs, donkeys and, occasionally, man. In the British Isles, the fluke occurs only (it is believed) in the islands off the Scottish mainland and South West England.

The fluke's eggs are swallowed by a land-snail of the genus *Helicella*. From the snail, cercariae periodically escape and slimy clumps of them are eaten by ants (*Formica fusca* in the USA). Grazing animals, swallowing ants with the grass, then become infested.

Ants also act as the intermediate host of a tapeworm of the fowl, guinea-fowl and pigeon, *Raillietina tetragona*.

Pharaoh's ants have been shown to be of considerable medical importance. They are much smaller than the common black ant; the worker, brownish-orange in colour, measures only 2 mm in length. They are a tropical species and in a temperate climate survive where there is central heating or its equivalent.

Their nests have been found behind tiles, in light fittings, fuse-boxes, and even in hospital operating theatres! Small nests are sometimes found between the folds of sheets and towels coming from laundries.

These ants eat meat, and also sweet foods. In their quest for water they visit sinks, drains, lavatories, etc. and can therefore contaminate food. They also, apparently, feed on the discharges from infected wounds.

Pharaoh's ants constitute a public health danger since they can carry disease-producing bacteria. In the isolation unit of a school of veterinary medicine they ruined one experiment by carrying infection from known infected animals to the uninfected 'controls'.

Fire ants (*Soleropsis invicta*) have become established in the southeastern states of the USA. They are very aggressive and masses of them will attack and eat quail fledglings, for example, and unweaned rabbits. People camping out near fire-ant colonies have also been attacked; the ant 'venom' causes blurred vision, loss of consciousness and sometimes convulsions.

Antu
Alphanaphthylthiourea, used to kill rodents. One gram may prove fatal to a 9 to 11 kg (20 to 25 lb) dog. The poison gives rise to oedema of the lungs. (See also THIOUREA.) Antu is banned in the UK.

Anuran
Amphibians having no tails in the adult stage – frogs and toads. Also known as Salientia.

Anuria
Anuria is a condition in which little or no URINE is excreted or voided for some time. (See also KIDNEYS.)

Anus
The opening which terminates the alimentary canal. In health it is kept closed by the sphincter ani, a ring of muscle fibres about 2.5 cm (1 in) thick in the horse, which is kept in a state of constant contraction by certain special nerve fibres situated in the spinal cord. If this ring fails to relax, constipation may result, while in some forms of paralysis the muscle becomes unable to retain the faeces. Imperforate anus is a defect in which an animal is born without any such opening – in effect, the absence of an anus. Absence of an anus is ATRESIA ANI.

Anal Glands, Anal Sacs
There are two of these in the dog, situated below and to each side of the anus. They produce a malodorous fluid which possibly acts as a lubricant to aid defaecation or as a means of territorial marking. Each gland has a duct opening just inside the anus. These ducts may become blocked by a grass seed or other foreign body, so that the secretions cannot escape and the glands swell; but more commonly there is infection. Irritation or pain then results. It may be necessary to manually express the glands to relieve the blockage, or to remove them surgically.

Signs include yelping on sitting down, and tail-chasing; more commonly the dog drags itself along the ground ('scooting, skating,

VetBooks.ir

tobogganing') or licks its hindquarters in a effort to obtain relief.

Perianal fistulae may be due to a number of causes including rupture of the anal sac, inflammation or ulceration. Except in mild cases, the condition may be difficult to treat, surgically or otherwise.

Signs include pain on defaecation and a bad smell. German shepherd dogs are said to be susceptible to the condition.

Perianal furunculosis is sometimes a recurring problem in dogs. Surgical removal of the anal sacs has been recommended to prevent recurrence. (See FURUNCULOSIS.)

Anxiety
In dogs, anxiety may be shown by the animal looking around repeatedly and smacking its lips. This is often seen at veterinary surgeries.

Anxiolytics
Psychotropic drugs used to treat emotional upsets such as anxiety and depression.

Aorta
The principal artery of the body. It leaves the base of the left ventricle and curves upwards and backwards, giving off branches to the head and neck and forelimbs. About the level of the 8th or 9th thoracic vertebra it reaches the lower surface of the spinal column, and from there it runs back into the abdominal cavity between the lungs, piercing the diaphragm. It ends about the 5th lumbar vertebra by dividing into the two internal iliacs and the middle sacral arteries. The internal iliacs supply the 2 hind-limbs and the muscles of the pelvis. At its commencement the aorta is about 1.5 inches (3.75 cm) in diameter in the horse, and from there it gradually tapers as large branches leave it. It is customary to divide the aorta into thoracic aorta and abdominal aorta. (See ARTERIES; ANEURYSM.)

Aortic Rupture
This follows degenerative changes in the aorta, and is a not uncommon cause of death of male turkeys aged between 5 and 22 weeks. It was first reported in the USA and Canada. In Britain most cases occur between July and October, the birds being found dead. The condition has also been reported in ostriches and in mammals including horses.

Aortic Stenosis
A condition in which the flow of blood from the heart into the aorta is obstructed. It may result from a congenital malformation of the heart valves or an obstruction in the aorta itself. It may be an inherited condition in Boxers, Bulldogs, German shepherd dogs and Newfoundlands. It has also been seen in cats.

Signs may include dyspnoea or congestive heart failure. (See STENOSIS.)

APBC
(See ASSOCIATION OF PET BEHAVIOUR COUNSELLORS.)

APDT
(See ASSOCIATION OF PET DOG TRAINERS.)

Apes
These are classed as higher PRIMATES and are the most closely related to man and therefore they are susceptible to many human diseases. Those dealing with these animals should also consult *Black's Medical Dictionary*.

APHA
(See ANIMAL AND PLANT HEALTH AGENCY.)

Aphagia
Inability, or refusal, to eat.

Aphalangia
A congenital absence of a digit or of one or more phalanges.

Aplasia
Defective development or complete absence of a tissue or organ.

Aplastic
Relating to aplasia, the congenital absence of an organ. In aplastic anaemia, there is defective development or a cessation of regeneration of the red cells, etc. (See ANAEMIA.)

Apnoea
Apnoea means not breathing. Aquatic animals such as seals, ducks and penguins display 'diving apnoea' – they hold their breath while under the water.

Apocrine Gland
A gland which sheds some of its cellular content along with its true secretion.

Apodia
A congenital absence of one or more feet.

Apomorphine
A derivative of morphine which has a marked emetic action in the dog, and is used in that animal to induce vomiting when some poisonous or otherwise objectionable material has been taken into the stomach.

VetBooks.ir

Aponeurosis
Aponeurosis is a sheet of tendinous tissue providing an insertion or attachment for muscles, which is sometimes itself attached to a bone, and sometimes is merely a method of attaching one muscle to another.

Apoproteins
Apoproteins are involved in the transport of LIPIDS throughout the body. Apoproteins are produced by cells in the liver or intestine. (See also LIPOPROTEIN.)

Apoptosis
A degenerative process of cells involving coagulative necrosis and shrinkage.

Appaloosa
The Appaloosa Horse Society of America and the British Spotted Horse Society are concerned with the breeding of this horse, which has some Arab blood and is characterised by a silky white coat with black (or chocolate-coloured) spots which can be felt with the finger.

Appendicitis
Inflammation of the appendix; it occurs in rabbits with severe intestinal coccidiosis.

Appendix
A rudimentary part of the small intestine in primates. In the adult rabbit it is 15 cm long and is found at the distal end of the caecum.

Appetite

Pica (depraved appetite) A mineral or vitamin deficiency may account for some cases of animals eating rubbish such as coal, cinders, soil, plaster, stones, faeces, etc. Pica is often associated also with pregnancy, alimentary problems, and is an important sign of rabies in dogs. It may result from worm infections.

In cats pica is a sign of anaemia. They will lick concrete or eat cat litter.

Excessive appetite (Polyphagia) may be a sign of dyspepsia or diabetes, of internal parasites, of tuberculosis, of listeriosis, or of the early stages of cancer.

Diminished appetite Anorexia, or a diminished appetite, is a sign usually present in many problems including infections, especially with fever, and most forms of dyspepsia, in gastritis and enteritis, in many fevers, and in abnormal conditions of the throat and the mouth, when the act of swallowing is difficult or painful. In other cases the appetite is in abeyance for no apparent reason. It can indicate that an animal has overeaten, and a rest from eating may be all that is needed. (See NURSING OF SICK ANIMALS; MINERALS; VITAMINS.)

Apramycin
An aminoglycoside antibiotic with activity against *Bordetella bronchiseptica*, *Campylobacter coli*, *Klebsiella* spp., *Salmonella* spp., *Proteus* spp., *Pseudomonas aeruginosa*, *Shigella sonnei*, *Brachyspira* spp., and *Mycoplasma hyopneumoniae*. It can be given orally or intramuscularly and is used in calves, pigs and poultry.

Aprocontracture
A congenital contraction of the muscles of the hand or feet, fore and hind limbs.

Aproctia
Imperforation or absence of the anus.

Apterygia
Featherless tracts found normally on birds. An absence of feathers under the crest of the head is a normal phenomenon in cockatoos and cockatiels, and many species of bird have normal featherless tracts or apterygia over the neck and under the wings.

Apulmonism
A congenital defect in which part or all of a lung is absent.

Apus
A fetus without feet.

Apyrexia
Means not exhibiting a fever.

Aquaculture
(See FISH-FARMING.)

Aquafeed
Production of fish foods is highly specialised because the feed is distributed in water, with the danger of soluble constituents dissolving.

Aqueduct of Sylvius, Cerebral Aqueduct
The aqueduct of Sylvius (cerebral aqueduct) connects the 3rd and 4th ventricles of the brain, and conveys cerebrospinal fluid.

Aqueous Humour
(See EYE - CONTENTS OF THE EYEBALL.)

Arab Horses
Arab horses originated from the Middle East. They are light horses, normally between 14.1 to 15.1

VetBooks.ir

HANDS (1.41 m to 1.51 m) high. They are normally grey, chestnut or bay; black animals are rare. Piebald and skewbald animals are not permitted. They have pretty, small, dish-shaped heads. They make excellent endurance horses and are also used for racing. The foal can suffer from inherited SEVERE COMBINED IMMUNODEFICIENCY; it develops respiratory problems after the maternal immunity has worn off and will eventually die.

Arachidonic Acid

A fatty acid which can be synthesised by most mammals and birds from linoleic or linolenic acid. This is not the case in felidae, which require arachidonic acid in their diets. It is necessary for prostaglandin formation. (See EICOSANOIDS, OMEGA-3 FATTY ACIDS.)

Arachnida

The class of Arthropoda to which belong the mange mites, ticks and spiders.

Arachnoid Membrane

Arachnoid membrane is one of the membranes covering the brain and spinal cord. (See BRAIN.) Arachnoiditis is inflammation of this membrane.

Araucana Chickens

This breed originated in Chile. They have feather tufts near their ears and no tail. There are of various colours including white, black and black with red breasts. They lay blue shelled eggs.

Arboviruses

This is an abbreviation for arthropod-borne viruses. They are responsible for diseases (such as louping-ill, equine encephalitis and yellow fever) transmitted by ticks, insects, etc. They are known as Togaviruses. (See VIRUSES table.)

ARC

The former Agricultural Research Council, under whose control a number of UK veterinary research institutes functioned. Founded in 1931, it was renamed the Agricultural and Food Research Council (AFRC) in 1983, and was ultimately superseded by the Biotechnology and Biological Sciences Research Council (BBSRC) in 1994.

Arcanobacterium pyogenes

The current name for a common bacterium of most species which causes pus formation and abscesses. It was formerly called *Corynebacterium pyogenes* and then *Actinomyces pyogenes*. (See ACTINOMYCOSIS.)

Areolar Connective Tissue

Areolar connective tissue is loose in character and occurs in the body wherever a cushioning effect, with flexibility, is needed, e.g. between skin and muscle, and surrounding blood vessels.

Arginine

An essential amino acid required for optimal growth, stimulating growth hormone release and acting as a vehicle for nitrogen transport, storage and excretion. It is important in the formation of collagen, maintaining bone, cartilage and connective tissue during growth and in repair. It is involved in a healthy immune system, spermatogenesis and maintaining memory.

Arginine Vasotocin

Avian antidiuretic hormone and the natural reptilian oxytocin (See EGG-BOUND; DYSTOKIA.)

Argulus

A crustacean parasite of freshwater fish which can cause ulceration, poor growth and transmit spring viraemia of carp. These fish lice can be removed by bathing affected fish briefly in saline.

Aristocardia

A cardiac deviation of the heart to the right.

Arizona Infection

In turkeys it was reported for the first time in the UK in 1968. The infection, mainly of birds, is caused by the Arizona group of the enterobacteriaceae – closely related to the salmonellae and the coliform group. Young birds can be infected by contact or through the egg. Nervous signs and eye lesions are characteristic in birds surviving the initial acute illness.

Over 300 antigenically distinct serotypes of Arizona have been identified. One at least appears to be host-adapted to sheep, and has been recovered from scouring sheep, from ewes which died in pregnancy and from aborted fetuses. Food-poisoning in man and diarrhoea in monkeys have been attributed to Arizona infection.

Arrhythmia

Arrhythmia means that the heartbeat is not occurring regularly, or that a beat is being periodically missed. It may be only temporary and of little importance; on the other hand it may be a sign of some form of cardiac disease.

Arsanilic Acid

One of the organic compounds of arsenic which has been used as a growth supplement for pigs and poultry; now no longer used in the EU.

It should not be given within 10 days of slaughter, nor should the recommended dosage rate be exceeded, as residues – especially in the liver – may prove harmful if consumed. The permitted maximum of arsenic in liver is 1 part per

VetBooks.ir

million. In a random survey (1969), 4 of 93 pig livers contained from 1.2 to 3.5 ppm of arsenic, hence the ban.

Blindness, a staggering gait, twisting of the neck, progressive weakness and paralysis are signs of chronic poisoning with arsanilic acid in the pig.

Arsenic (As)

Arsenic (As) is a metal, but the term is commonly used to refer to arsenious acid. It has two forms: the trivalent, which is toxic; and the pentavalent (found in most organic compounds of arsenic), which is not. Arsenic is found in Scheele's green and emerald green – the two arsenites of copper; Orpiment or King's yellow, and Realgar – sulphides of arsenic; Fowler's solution (liquor arsenicalis, BP), which contains arsenic trioxide. It used to be used in older varieties of sheep-dip, rat-poisons, fly-papers, and even wallpapers.

Uses Previously arsenic was used in some compound animal feeds in order to improve growth rate and to prevent histomoniasis (blackhead in turkeys). The disposal of dung containing arsenic residues causes problems: small doses over a long period may give rise to cancer. (See also ARSANILIC ACID.)

Arsenic, Poisoning By

Arsenic is an irritant poison producing in all animals gastroenteritis. The rapidity of its action depends on the amount that is taken, on the solubility of the compound, on the presence or otherwise of food in the digestive system, and on the susceptibility of the animal.

Signs include violent purging, severe colic, straining, a staggering gait, coldness of the extremities of the body, unconsciousness, and convulsions. When the poisoning is the result of the taking of small doses for a considerable period, cumulative signs are observed. These include an unthrifty condition of the body generally, swelling of the joints, indigestion, constant or intermittent diarrhoea, often with a fetid odour, thirst, emaciation, and distressed breathing and heart action on moderate exercise.

Causes

Cattle have died after straying into a field of potatoes sprayed with arsenites to destroy the haulm. In some countries others have died following the application to their backs of an arsenical dressing, and of the use of arsenic-contaminated, old bins for feeding purposes.

Sheep Probably most cases of arsenic poisoning in sheep occurred from the use of arsenical dips before other compounds were introduced. The source of this poisoning is in many cases the herbage of the pastures which becomes contaminated either from the drippings from the wool of the sheep, or from the washing of the dip out of the fleece by a shower of rain on the second or third day after the dipping. Absorption through wounds or laceration of the skin may result in arsenic poisoning, and when dips are made up too strong, absorption into the system may also occur. The obvious precautions, apart from care of the actual dipping, are to ensure that the sheep are kept in the draining pens long enough to ensure that their fleeces are reasonably dry (some 15 to 20 minutes) and subsequently are not allowed to remain for long thickly concentrated in small fields or paddocks. Where double dipping is carried out, the second immersion in an arsenic dip must be at half-strength.

Dogs and cats are particularly susceptible to poisoning by arsenic. The signs are nausea, vomiting, abdominal pain, dark fluid evacuations and death, preceded by convulsions.

Antidotes Sodium thiosulphate is a better antidote than ferric hydroxide, and a solution can be given intravenously. (See also DIPS AND DIPPING.)

Arteries

The arteries carry oxygenated blood away from the heart; that is, blood which has recently been circulating in the lungs, has absorbed oxygen from the inspired air, and has become scarlet in colour. The pulmonary artery is the exception; venous blood of a purple colour which has been circulating in the body and has been returned to the heart, to be sent to the lungs for oxygenation.

The arterial system begins at the left ventricle of the heart with the AORTA. This is the largest artery of the body. It divides and subdivides until the final branches end in the capillaries which ramify throughout all the body tissues except cornea, hair, horn, teeth, scales and feathers. The larger of these branches are called arteries, the smaller ones are arterioles, and these end in the capillaries. The capillaries pervade the tissues like the pores of a sponge, and bathe the cells of the body in arterial blood. The blood is collected by the venous system and carried back to the heart.

Structure Mammalian arteries are highly elastic tubes which are capable of great dilatation with each pulsation of the heart – a dilatation which is of considerable importance in the circulation of the blood. (See CIRCULATION OF BLOOD.) Their walls are composed of three coats: (1) adventitious coat, consisting of ordinary strong fibrous tissue

VetBooks.ir

on the outside; (2) middle coat, composed of muscle fibres and elastic fibres, in separate layers in the great arteries; (3) inner coat or intima, consisting of a layer of yellow elastic tissue on whose innermost surface rests a single continuous layer of smooth, plate-like endothelial cells, within which flows the bloodstream. The walls of the larger arteries have the muscles of their middle coat replaced to a great extent by elastic fibres so that they are capable of much distension. When an artery is cut across, its muscular coat instantly shrinks, drawing the cut end within the fibrous sheath which surrounds all arteries, and bunching it up so that only a comparatively small hole is left for the escape of blood. This, in a normal case, soon becomes filled up with the blood clot which is Nature's method of checking haemorrhage (see BLEEDING).

The proportion of elastic to muscular tissue is much more variable in avian arteries, as between different species and distances from the heart and as the bird ages.

Arteries, Diseases of

These include:

Arteritis, Inflammation of arteries during specific viral diseases such as African swine fever, equine viral arteritis, canine viral hepatitis, etc.

Chronic inflammation, Arteriosclerosis is a process of thickening of the arterial wall and subsequent degenerative changes, resulting in an abnormal rigidity of the tube and hindrance to the circulation.

Degenerative changes include atheroma – thickening and degeneration of the lining of the artery. Degeneration occurs in the arteries of pigs, especially, during the course of several diseases. Examples are haemorrhagic gastritis and Herztod disease.

Thrombosis This includes aortic-iliac THROMBOSIS, and femoral thrombosis in dogs and cats. (See also PARAPLEGIA.)

Embolism (see main entry)

Aneurysm (see main entry)

Equine verminous arteritis (see main entry)

Heartworms (see main entry)

Aortic rupture in turkeys (see main entry)

Arthritis

Inflammation of a joint. A common disease of all farm and pet animals. (See also JOINTS, DISEASES OF.)

Causes include trauma, rheumatism, a mineral deficiency, and FLUOROSIS. Infections which cause arthritis include BRUCELLOSIS, TUBERCULOSIS and SWINE ERYSIPELAS. (See also SYNOVITIS; BURSITIS; JOINT-ILL.)

Degenerative Joint Disease (DJD) occurs in all species but is most often diagnosed in horses and small companion animals. The causes are many; they nutrition, trauma, poisonings, conformation, growth rate problems and ageing. The problem is characterised by degeneration and erosion of the joint articular surface, degeneration of the underlying bone and hypertrophy of the surrounding bone. (See OSTEOARTHRITIS.)

Rheumatoid arthritis A chronic form of inflammatory arthritis, often accompanied by fever and usually with symmetrical involvement of several joints. There may be a genetic predisposition to the condition.

Open-joint injuries may lead to an acute septic arthritis following infection. Prompt treatment often leads to a full recovery.

Septic Arthritis can involve one joint when it is local; it can be result from injury or from an infection entering, when several joints may be involved. Both forms occur in all species and in some there are some specific causes, such as *Streptococcus suis* in pigs.

Arthrodesis

An operation to fix a joint in a given position. By this means a pain-free, stable and strong joint can be achieved e.g. in cases of osteoarthrosis of the carpus to correct osteoarthritis or carpal VALGUS.

Arthrogryposis

(See GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.)

Arthroplasty

A surgical repair of a joint to replace, repair or realign a JOINT. This is done in OSTEOARTHRITIS to relieve pain and restore function.

Arthropods

(adjective, Arthropodal)

These are members of the Phylum *Arthropoda*. They are very widely distributed and include arachnids (MITES, TICKS, SPIDERS), crustaceans (CRABS, SHRIMPS); insects (BEES, FLEAS, FLIES, LICE). They form a major part of the animal ecology (over 740,000 species within 12 Classes) and are parasites, saprophytes and many perform only beneficial functions. They have an

VetBooks.ir

exoskeleton, a hard segmented body and are BILATERALLY symmetrical.

Arthroscopy
The application of endoscopic techniques to the study of joint cavities.

Arthrosis
Degenerative disease of a joint, as opposed to inflammation. (The word can also mean an articulation.)

Artifact
An apparent lesion in a histological or pathological specimen, not existing during life, but made accidentally in preparing the specimen.

Artificial Bones
In racing greyhounds, badly fractured scaphoids have been removed and replaced with plastic prostheses. (A dog called Hare Spy won a race on January 16, 1958, after such an operation.)

Artificial Induction of Parturition
(See PARTURITION, DRUG-INDUCED.)

Artificial Insemination (AI)
The introduction of male germ cells (spermatozoa) into the female without actual service.

The practice is a very old one. In the 14th century Arab horse-breeders were getting mares in foal by using semen-impregnated sponges. In Italy, bitches were artificially inseminated as long ago as 1780, and at the close of the 19th century the practice was applied, to a very limited extent, to mares in Britain.

It was the Russian scientist Ivanoff who saw in AI the possibilities of disease control, and in 1909, a laboratory was established in Russia for the development and improvement of existing techniques. By 1938, well over a million cattle and 15 million sheep had been inseminated in the USSR, where all the basic work was done. Denmark began to take a practical interest in AI in 1936 (and within 11 years had 100 cooperative breeding stations inseminating half a million head of cattle annually); the USA in 1937. The technique quickly spread to other countries.

The UK began to practise AI on a commercial basis in 1942, and by the end of 1950 had close on a hundred centres and sub-centres in operation, serving over 60,000 farms. The introduction of prostaglandins in 1975 enabled synchronisation of oestrus in groups of cattle, greatly facilitating the use of AI. Since 1986, 'do-it-yourself' on-farm AI has been permitted after stockmen have received suitable training and the storage of semen has been adequately monitored. About 93 per cent of dairy cows are produced by artificial insemination and about a third of suckler beef cattle.

Uses The use of AI in commercial cattle breeding is dependent upon the fact that, in normal mating, a bull produces up to 500 times as much semen as is required to enable one cow to conceive. By collecting the semen, diluting it and, if necessary, storing it in a refrigerator, the insemination of many cows from one ejaculate becomes possible.

AI reduces the spread of venereal disease, and hence greatly reduces the incidence of the latter. Farmers in a small way of business are able to dispense with the services of a communal bull – an animal seldom well bred and often infected with some transmissible disease. At the same time, the farmer has the advantage of the use of a healthy, pedigree bull without the considerable expense of buying, feeding, and looking after it. Owners of commercial herds are enabled to grade them up to pedigree standard, with an increase in quality and milk yield or just to genetically improve them. In many of the ranching areas overseas, where stock-raising is carried out on an extensive, rather than an intensive, scale, to achieve satisfactory production of animals for trade and commercial purposes, sires have to be imported at regular intervals from the essentially sire-producing countries – of which Britain is the chief. The method of artificially inseminating a large number of females from an imported sire enables bigger generations of progeny to be raised and consequently more rapid improvement to be achieved.

Methods Various methods are employed to collect semen. Those which give best results involve the use of an artificial vagina in which to collect the semen from an ejaculation. This is used outside the female's body, being so arranged that the penis of the male enters it instead of entering the vagina. The full ejaculation is received without contamination from the female.

After the ejaculate has been collected it is either divided into fractions, each being injected by a special syringe into the cervix or uterus of another female in season, or – in commercial practice – it is diluted 20 times or more with a specially prepared 'sperm diluent', such as egg-yolk citrate buffer, and distributed into 'straws' (plastic tubes). Dilution rates of up to 1 in 100 have been successful, but it appears desirable to inseminate 12 or 13 million sperms into each cow.

The method requires skill to carry out successfully, and necessitates the employment of strict cleanliness throughout. (See CONCEPTION RATES.)

Artificial insemination has also been carried out in pigs (see FARROWING RATES), goats, dogs, turkeys and other birds, bees, etc. Sexed semen is now available in cattle.

VetBooks.ir

Canine AI is now practised in many parts of the world. In the UK the Kennel Club reserves the right to decide whether to accept for registration puppies obtained by means of AI rather than by normal mating. Applications are usually made by the owner of the bitch. Those concerned with a newly imported breed, and who wish to widen the genetic pool, may not be able to find a suitable male for purchase and import. However, if semen from a satisfactory dog can be obtained, and DEFRA agrees to its import under licence, AI may be a good way of increasing the available pool.

Registrations will not be accepted where AI is requested because either the prospective sire or dam is unable to mate owing to disease.

Horse AI is used widely both with chilled semen and deep-frozen semen.

Pig AI is now commonly used in commercial pig herds. Usually it is 'extended life' but not frozen semen. The semen is in a plastic sachet and fitted to a catheter with a plastic plug at the end that fits into the sow's cervix

Turkey AI Farmed turkeys are now bred as male and female lines. Female lines are comparatively slender, with high egg production. Male lines are bred for meat and are much heavier. The resulting disparity between the sizes of the male and female is such that natural mating would result in injury to the female. Most turkey breeding is therefore by artificial insemination. Disposable straws, discarded after use, are used to prevent transmission of infection (notably *Mycoplasma meleagridis* and *E. coli*) but as semen is pooled from several stags, an infected stag can result in many infected hens. The technique of insemination and collection of semen requires skill. In order to ensure the hen have no eggs in the oviduct, insemination should take place at about 16.00 hours.

Sheep and Goat AI It is not usually undertaken; it is mainly used on some pedigree farms.

Birds of Prey AI Artificial insemination has been used successfully in imprinted (trained) birds of prey.

Storage of semen Diluted semen may be stored at AI centres for a few days if kept at a temperature of 5° C (41° F). In practice, a good deal would be wasted because its fertilising power has diminished before it is all required for use. However, bull semen may be stored for long periods when glycerol is added to the sperm diluent. This enables the semen to be stored and transported at –196° C (-321° F), using liquid nitrogen to maintain the low temperature. The advantages of this method are many. There is less wastage of semen, more can be stored, and the semen of any particular bull can be made available on any day. It is possible for several thousand cows to be got in calf by a given bull. The disadvantages of using a given bull or bulls too widely must be borne in mind, but that is a matter of policy and not of technique. Poor storage and/or thawing technique affects semen viability, hence successful fertilisation.

Infected semen Viruses (including that of foot-and-mouth, BVD) and mycoplasmas have, on occasion, been found in stored semen. (See also RABIES; CONTROLLED BREEDING.)

Artificial Rearing of Piglets

(See PIGLETS – ARTIFICIAL REARING.)

Artificial Respiration

This is resorted to in: (1) cessation of respiration while under general anaesthesia; (2) cases of drowning when the animal has been rescued from the water – chiefly applicable to the small animals; (3) poisoning by narcotics or paralysants; (4) cases of asphyxia from fumes, smoke, gases, etc.

Horses and cattle Release from all restraint except a loose halter or head collar, extend the head and neck to allow a straight passage of the air into the lungs, open the mouth, and pull the tongue well out. Should the ground slope, the horse must be placed with its head downhill. While such adjustments are being carried out one or two assistants should compress the elastic posterior ribs by alternately leaning the whole weight of the body on the hands pressed on the ribs, and then releasing the pressure about once every 4 or 5 seconds, in an endeavour to stimulate the normal movements of breathing. As an alternative in a larger animal, a heavy person may sit with some vigour astride the ribs for about the same time, rise for a similar period, and then sit back again. If no response occurs, these measures should be carried out more rapidly.

The inhalation of strong solution of ammonia upon a piece of cotton-wool and held about a foot from the upper nostril often assists in inducing a gasp which is the first sign of the return to respiration, but care is needed not to allow the ammonia to come into contact with the skin or burning will occur. After 2 or 3 minutes' work the animal should be turned on to the opposite side to prevent stasis of the blood. Sometimes the mere act of turning will induce the premonitory gasp. So long as the heart continues to beat, no matter how feebly, the attempts at resuscitation should be pursued. Proprietary calf resuscitators are available to give the 'kiss of life'.

VetBooks.ir

Pigs and sheep The outlines of procedure given for the larger animals are equally applicable. An ordinary domestic funnel can be used for giving pigs the 'kiss of life'.

The method of giving the 'kiss of life' to a piglet is to use a flexible polyethylene funnel, and fit this over the animal's mouth and nostrils. Air is blown into the stem of the funnel, and passes down into the piglet's lungs.

For the method to be effective, the procedure is as follows: (1) hold the piglet by its hind legs with head down in order to drain any fluid from its air passages; (2) turn the piglet with its head upwards and apply the funnel; (3) blow forcefully into the funnel; (4) remove the funnel and allow the piglet to breathe out; (5) repeat the operation. After several repetitions, the piglet should kick or show other signs of life. Lay the animal on its side or stomach and massage its chest and mouth. Piglets apparently stillborn may sometimes be revived by this method.

Piglets have been revived up to half an hour after treatment began. Of course, the heart must be beating and resuscitation started promptly to achieve success.

Dogs and cats A modification of the Schafer system is to lay the dog on its side with the head at a lower level than the rest of the body, place a hand flat over the upper side of the abdomen and the other on the rib-cage, lean heavily on the hands, and in a second or two release the pressure.

The motions of artificial respiration should in all cases be a little faster than those of normal respiration, but a slight pause should always be observed before each rhythmic movement. Use less pressure for cats.

A respiratory stimulant DOXAPRAM may be given by injection. If the anaesthetic machine has the facility, carbon dioxide may be introduced to the recovery mixture at less than 10 per cent of the oxygen flow rate. Insertion of a hypodermic needle in the nasal filtrum (the vertical groove seen on the outside of the nose separating the left and right sides) can stimulate respiration – a well-recognised acupuncture site.

Rabbits and Rodents Artificial respiration in these species must be approached with great care as they are much smaller than the hand that has to affect the procedure. Gentle pressure on the chest wall with the animal in lateral recumbency may assist but endotracheal intubation and direct insufflation of the lungs is a better option.

Reptiles General anaesthesia requires endotracheal intubation and positive pressure ventilation, and as reptiles are so easy to intubate artificial respiration is best applied in this manner.

Birds A similar procedure to reptiles may be adopted but gentle, intermittent digital pressure on the sternum may suffice – movement of the avian sternum is vital for respiration.

Fish Often they can be resuscitated by drawing the whole body 'backwards' (i.e. caudally) in fresh water so that oxygen is passed over the gills.

Ascaridae

A class of worms belonging to the round variety or *Nemathelminthes*, which are found parasitic in the intestines of horses, pigs, dogs, cats, birds and reptiles particularly, although they may affect other animals. They attain a size of 38 cm or 45 cm (15 in or 18 in) in the horse, but are small in other animals. (See ROUNDWORMS.)

Ascaris suum

A roundworm in pigs which is transferred from the sow to offspring. Following ingestion the larvae migrate out of the intestine and go to the liver. As they mature they go to the lungs before being coughed up and then maturing in the intestines. Respiratory signs can occur in the growing pig and can be part of the PORCINE RESPIRATORY DISEASE COMPLEX. In the intestines they can reduce weight gain or on occasions block the intestines. They can be removed with anthelmintics.

Ascites

OEDEMA involving the abdomen; a very common complication of abdominal tuberculosis, of liver, kidney, or heart disease, as well as of some parasitic infestations. In poultry, ascites is sometimes associated with hypoxia ('high altitude disease') although there are other causes including toxins or, in individuals, heart defects or abdominal tumours. It is also seen in ducks with furazolidone poisoning.

Ascorbic Acid

Vitamin C. It is found in many vegetables and fruits especially citrus fruits and naturally synthesised in most animals except primates, fruit bats, guinea pigs and some fish. A vitamin C-responsive condition is seen in animals such as calves following prolonged diarrhoea. Some connective tissue disorders such as EHLERS-DANLOS SYNDROME (see CUTANEOUS ASTHENIA) in rabbits are said to show some response to therapeutic doses.

Ascorbyl Monophosphate

The addition of ascorbyl monophosphate to cat diets has resulted in 20 per cent reduction in plaque formation and a 14 per cent reduction in calculus formation after a 28-day period.

VetBooks.ir

Asepsis

The absence of pathogenic organisms. Aseptic surgery is the ideal, but among animals it may be difficult to attain if carried out under farm conditions – despite care in sterilising instruments and the use of sterilised dressings, rubber gloves, etc. Moreover, it is an exceptionally difficult matter to prevent accidental infection in a surgical wound after the operation, for the animal cannot be put to bed, and it may object to the dressings and do all in its power to remove them. (See ANTISEPTICS; SULFONAMIDES; PENICILLIN.)

Ash Poisoning

Poisoning by *Fraxinus* species has been reported in cattle after eating the green leaves and fruits from a broken branch of a tree. Signs include: drowsiness, oedema involving ribs and flanks, and purple discoloration of perineum.

Aspartate Transferase, Aspartate Aminotransferase (AST)

Also called SERUM GLUTAMIC OXALO-ACETATE AMINOTRANSFERASE (SGOT or GOT). The serum levels tend to rise when tissues are damaged such as LIVER, HEART and MUSCLE.

Aspartic Acid

An amino acid used in the formation of RNA and DNA. It appears to be involved in protecting the liver, promotes normal cell formation and it is useful in endurance situations.

Aspergillosis

A disease of mammals and birds produced by the growth of the fungus *Aspergillus* in the tissues of the body.

Infection probably occurs chiefly through inhalation of the fungal spores, which may be abundant in hay or straw under conditions of dampness. Entry of the spores into the body may also be by way of the mouth; in herbivorous animals from contaminated fodder or bedding; and in cats and dogs from the eating of infected birds or rodents.

Once in the animal's tissues, hyphae grow out from the spores, as happens also in ringworm; and from the branching filaments more spores are produced. Local necrosis and abscess formation are caused.

Numerous organs and tissues can become infected, including the nose and nasal sinuses, the lungs, brain, uterus, and mammary glands.

Cattle and horses *Aspergillus* may cause abortion and lung sensitisation or pneumonia.

Dogs and cats Aspergillosis is a common cause of chronic nasal disease, and should be suspected when there is a discharge from one nostril.

Poultry Respiratory disease or enteritis may occur. In young turkey poults brain involvement has led to an unsteady gait, walking backwards, and turning the head to one side.

Birds Pet parrots and birds of prey kept for breeding or falconry may die from aspergillosis, as can wild birds. Sources of infection include contaminated feed and litter on aviary floors.

Brain infection may occur in all species and give rise to signs described under ENCEPHALITIS. Paresis and ataxia may, rarely, be caused by fungal infections of the spine.

Ketonazole, given by mouth, and irrigation of the sinuses by enilconazole in sodium chloride solution have been used in cases of canine nasal aspergillosis. Oral antimycotic agents such as itraconazole and topical antimycotics such as enilconazole (by nebulisation) are often used in parrots but with variable results.

Asphodel

(See BOG ASPHODEL.)

Asphyxia

Suffocation may occur during the administration of anaesthetics by inhalation, during the outbreak of fires in animal houses, where the fumes and the smoke present are responsible for oedema, and in cases of poisoning. (See also 'KITCHEN DEATHS'.)

Signs The direct cause of death from asphyxia is an insufficiency of oxygen supplied to the tissues by the blood. The first signs are a rapid and full pulse, and a quickening of the respirations. The breathing soon changes to a series of gasps, and the blood pressure rises, causing the visible membranes to become intensely injected and later blue in colour. Convulsions supervene. The convulsions are followed by quietness, when the heartbeat may be almost imperceptible and respiratory movements practically cease. The actual time of death is unnoticed as a rule, since death takes place very quietly.

During the stage of convulsions, when the amount of carbon dioxide circulating in the blood is increased, the smaller arteries vigorously contract and cause an increase in the blood pressure. This high blood pressure produces an engorgement of the right side of the heart, which cannot totally expel its contents with each beat, and becomes more and more dilated until such time as the pressure in the ventricles overcomes the strength of the muscle fibres of the heart and the organ ceases to beat. During this stage immediate relief follows bleeding from a large vein.

Treatment (See ARTIFICIAL RESPIRATION.) If the breathing is shallow and the membranes livid, administration of OXYGEN is indicated.

VetBooks.ir

Prevention Ensure adequate ventilation in rooms where there is a gas or solid-fuel heating system. (Many dogs and cats have been found dead in the kitchen in the morning as a result of CARBON MONOXIDE poisoning.)

Aspiration

(See PARACENTESIS.)

Aspirin, Acetylsalicylic Acid

It is the oldest known non-steroidal anti-inflammatory drug (NSAID). An analgesic; also used in prevention of thrombosis. It is available in tablet and powder form.

Must be used with extreme caution and under professional supervision in cats; the dose not exceeding 10 mg/kg on alternate days.

In both cats and dogs, overdosing with aspirin may cause inflammation of the stomach, haemorrhage, some pain and vomiting. The antidote is sodium bicarbonate which can be given in water by stomach tube; or, for first-aid purposes, by the cat-owner, in milk or water. (See SALICYLIC ACID AND SALICYLATES - SALICYLATE POISONING.)

Aspirin has been used to lessen the effects of PORCINE REPRODUCTIVE RESPIRATORY SYNDROME (PRRS/blue-eared pig disease).

In horses it can be used in large doses of 100mg/kg to lower the requirement of phenylbutazone for treating chronic laminitis.

Asplenia

Absence of the spleen, or its failure to function.

Association of Pet Behaviour Counsellors (APBS)

Address: PO Box 46, Worcester, WR8 9YS. Telephone: 01386 75115; email: info@apbc.org.uk; website: www.apbc.org.uk.

Association of Pet Dog Trainers (APDT)

Address: APDT, PO Box 17, Kempsford, GL7 4WZ. Telephone: 01285 810811; email: info@apdt.co.uk; website: www.apdt.co.uk.

AST

(See ASPARTATE TRANSFERASE.)

Asthenia

Asthenia is another name for debility. Asthenic is applied to the exhausted state that precedes death during some fevers.

Asthma

Asthma is a term somewhat loosely applied to a number of conditions in which the main sign is breathlessness. Strictly speaking, the term should be reserved for those conditions where a true spasmodic expulsion of breath occurs without the effort of a cough. The so called 'asthma' of birds is due in nearly every case to ASPERGILLOSIS. Asthma in horses may be difficult to differentiate from 'BROKEN WIND' also called RECURRENT AIRWAY OBSTRUCTION (RAO), and in all animals from simple BRONCHITIS.

Causes These are obscure, but it is generally held that true spasmodic asthma is of nervous origin, and due to a sudden distressful contraction of the muscle fibres which lie around the smaller bronchioles. In some cases asthma may be an allergic phenomenon. In other cases a chronic inflammation of the lining mucous membrane of the small tubes is the cause.

The spores of fungi are potent allergens, and can account for many cases of asthma, especially recurrent summer asthma, in man. There are, however, a number of patients with seasonal (summer or autumn) asthma who are not sensitive to spores of any of the above nor to pollen. (See ALLERGY.)

Dogs Many cases that are really chronic bronchitis are spoken of as 'bronchial asthma' owing to their similarity to asthma in man, with which many owners of animals are familiar. In true asthma, the attacks of dyspnoea (i.e. distressed respiration) occur at irregular intervals, and there are periods between them when the dog is to all appearances quite normal. The attacks occur suddenly, are very distressing to witness, last for 10 minutes to half an hour, and then suddenly cease. The dog gasps for breath, makes violent inspiratory efforts without much success, exhibits a frightened, disturbed expression and stands till the attack passes off.

The condition appears to be hereditary in some breeds, especially the Maltese terrier. Cardiac dysfunction also gives rise to 'asthma' due to pulmonary oedema. (See also ATOPIC DISEASE.)

Treatment Bronchodilators, such as aminophylline, clenbuterol or ephedrine, and antihistamines or heart stimulants may be of service. The treatment used will depend on the cause of the problem; e.g., diuretics are useful in cases of pulmonary oedema due to heart failure. Regulation of exercise and diet is necessary. (See also CHRONIC OBSTRUCTIVE PULMONARY DISEASE; BRONCHITIS.)

Astomia

The congenital absence of the mouth.

Astragalus, Talus

Astragalus (Talus) is the name of one of the bones of the tarsus (hock), with which the tibia forms the main joint. The articulation between these bones is

VetBooks.ir

sometimes referred to as the 'true hock joint', the others being more or less secondary and less freely movable joints.

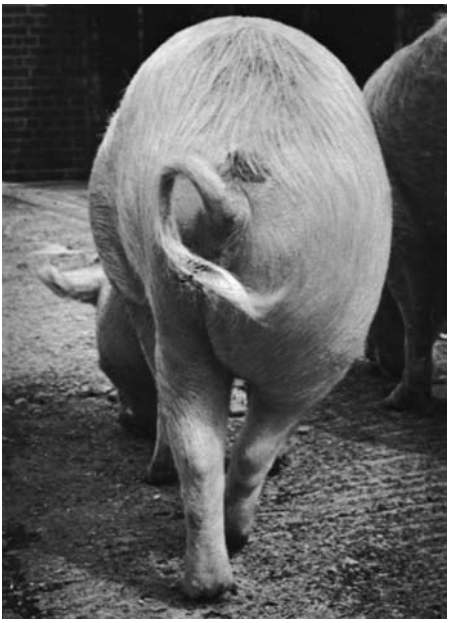
Astringents
Substances which contract tissues and stop discharges; they include sulphate of zinc, alum, tannic acid, witch-hazel.

Astrocytes
Supporting cells found in the central nervous system, and each consisting of a cell body and numerous branching processes. Astrocytes are thought to be concerned with the nutrition of neighbouring nerve cells. They may also be involved in the tissue damage which occurs in cases of stroke.

Astrovirus
Astrovirus was first detected in the faeces of children in 1975, and has since been isolated from lambs, calves, turkeys, deer, etc. It is not regarded as a serious pathogen in veterinary medicine, but studies in gnotobiotic lambs indicate that the virus multiplies in the epithelial cells of the villi of the small intestine, producing some degree of atrophy of the villi, with diarrhoea.

Asymmetric Hindquarter Syndrome (AHQS)
Outbreaks of a lop-sided condition of the hindquarters in the pig, known as asymmetric hindquarter syndrome, have been described by J. T. Done and others. This condition has been seen in Germany, Belgium, and Britain.

AHQS, which would appear to have a hereditary basis, could be of economic importance since it affects carcase conformation, and could lead to carcase condemnation.



The abnormality does not usually become obvious before pigs reach about 30 kg (66 lb) liveweight, when one thigh may be seen to be much smaller than the other though of the same length. Even in severe cases it was observed that the gait was normal.

The incidence of AHQS within litters of affected families varies from 0 to 80 per cent, and the breeds involved include Large White, Hampshire and Lacombe.

Asymptomatic
This means the absence of clinical signs, as is seen in the 'CARRIER' animal or the carrier state.

Asynechia
The lack of continuity in an organ or tissue.

Asystole
A failure of the heart to contract, generally due to the walls having become so weak that they are unable to contract and expel the blood, with the result that the organ becomes distended – a feature found after death.

Asymmetric Hindquarter Syndrome (AHQS).

Atavism
A 'throw-back' in the genetic sense. It is a factor that has been dormant or not expressed for several generations and then reappears in an individual or indivduals.

Ataxia
Ataxia means the loss of the power of governing movements, although the necessary power for these movements is still present. A staggering gait results. Ataxia is a sign which may be observed in many diverse conditions, for example, rabies, weakness or exhaustion, encephalitis, meningitis, poisoning and a brain tumour. It may be seen in all animals.

Cattle A progressive form of ataxia of probably inherited origin has been found in French-bred Charolais heifers, with signs first appearing in the first year: slight intermittent ataxia progresses to recumbency over 1 to 2 years. Urine is passed in a continuous but uneven squirting flow. When excited, affected heifers may show nodding of their heads.

Cats Ataxia is seen in feline infectious peritonitis poisoning by ethylene glycol (anti-freeze), alpha-chloralose, and streptomycin, for example, and before eclampsia (lactation tetany). Congenital

VetBooks.ir

cerebellar ataxia may be seen in kittens, usually when born to mothers infected with parvovirus (see FELINE INFECTIOUS ENTERITIS). There is uncoordinated movement of the head, especially when feeding, and they stand with their legs apart to aid balance. The condition does not worsen and, unless very serious, kittens usually adapt well.

Atelectasis
Failure of the fetal lungs to expand at birth, either partial or complete.

Atelencephalia
The imperfect development of the brain, same as ATELENCEPHALIA.

Atelocardia
An incomplete development of the heart.

Atelocheiria
An incomplete development of the hand.

Ateloencephalia
The imperfect development of the brain, same as ATELENCEPHALIA.

Atelopodia
A development defect of the foot (hindlimb).

Atelostomia
The incomplete development of the mouth.

Atheroma
A degenerative change in the inner and middle coats of the arteries in which a deposit of lipid material is formed. (See ARTERIES, DISEASES OF.) In the horse it is also an epidermal inclusion cyst of the false nostril.

Atherosclerosis
A condition in which deposits of cholesterol and other material in the inner lining (intima) of arteries restricts the blood flow. It is seen quite commonly in captive birds of prey and caged parrots with inadequate diets.

Athymism
The absence of the thymus gland and its secretions.

Atipamezole
This is an α-2 adrenergic receptor agonist used to reverse the sedative, analgesic, cardiovascular and respiratory effects of medetomidine in dogs and cats.

Atlas
Atlas is the name given to the 1st of the cervical vertebrae, which forms a double pivot joint with the occipital bone of the base of the skull on the one hand, and forms a single gliding pivot joint with the epistropheus or axis – the 2nd cervical vertebra – on the other hand. The freedom of movement of the head is due almost solely to these 2 joints.

Atlodidymus
A malformed fetus with one body and two heads; a synonym for dicephalus.

Atony
Atony means want of tone or vigour in muscles or other organs. (See also TONICS.)

Atopic Dermatitis
An often seasonal condition which involves pruritus, frequently of the feet, face and the ventral abdomen with self-trauma. There may be secondary pyoderma, otitis externa and excessive sweating (hyperhidrosis). It is particularly seen in dog breeds including ENGLISH SETTERS; WEST HIGHLAND WHITE TERRIERS; WIRE-HAIRED FOX TERRIERS; YORKSHIRE TERRIERS.

Atopic Disease
A hypersensitivity to pollens and other inhaled protein particles. (See ALLERGY.) There is intense itching affecting the feet, abdomen, and face as well as sneezing, conjunctivitis, rhinitis and asthma; there may be some discoloration of the coat. In allergy tests on 208 dogs, about 40 per cent were found to be hypersensitive to human dandruff.

The condition was originally thought to be due to allergic dermatitis due to inhalation of allergens. It is now recognised to be very complex and due to immune dysfunction and allergic reactions that can be either food induced or non-food induced. In dogs, it starts under three years old, mainly in animals living indoors. There is PRURITUS before there are any skin lesions affecting the front feet and inside of the ear flap, but not the ear margins or the upper body, and it responds to GLUCOCORTICOID treatment. It is often inherited and is seen in breeds such as DALMATIANS.

Atopic disease also occurs in cats and cattle (See BOVINE ATOPIC RHINITIS).

Atopy
A syndrome mainly seen in dogs where there is a Type 1 hypersensitivity (an allergy) often due to an inherited predisposition. IgE (immunoglobulin E) is involved.

ATP
(See ADENOSINE - ADENOSINE TRIPHOSPHATE.)

Atresia
Atresia means the absence of a natural opening, or its obliteration by membrane. Atresia of the

VetBooks.ir

rectum is found in newly-born pigs, lambs, calves, and foals. Atresia is sometimes met with in heifers with one or both uterine horns absent, when it constitutes what is known as 'WHITE HEIFER DISEASE'. Atresia of the cloaca has been recorded in African Grey parrots (*Psittacus erithacus erithacus*).

Atresia ani, Anal atresia

It is a congenital condition resulting in the absence of faeces and the anus closed off resulting in the abdomen swelling. There is usually a dimple where the anus should be and the anal sphincters are often developed. Surgical correction is often possible and undertaken in dogs and some other species.

Atretogastria

The absence of the normal opening(s) (cardiac and/or pyloric orifices) of the stomach.

Atreturethria

An imperforation of the urethra.

Atria

(singular, Atrium)

In birds these are found in the lungs, and are small air vesicles which radiate out from the PARABRONCHI and are where exchange of gases occurs.

Atrial

Relating to the atrium or AURICLE of the heart.

Atrial Septal Defect

A congenial condition in which there is a septal defect between the two atria (a 'hole in the heart'). This is because of a failure of the normal closure mechanisms of the ostium primum and ostium secondum. It is seen in all animals, but is rare. In dogs, some breeds are more susceptible, including BOXERS.

Atrichia

Absence of hair.

Atrioventricular Tissue

It is responsible for transmitting the impulse from the atria (auricles) of the heart to the ventricles. Also known as Purkinje tissue.

Atrium

(See AURICLE.)

Atrophic Myositis

(See under MUSCLES, DISEASES OF.)

Atrophic Rhinitis

A disease of pigs affecting the nasal passages. (See under RHINITIS, ATROPHIC, INCLUSION BODY RHINITIS.)

Atrophy

Atrophy is a wasting of the tissues. Following paralysis of a motor nerve, when the muscles supplied by it are no longer able to contract, atrophy of the area takes place. This is seen in paralysis of the radial nerve. (Compare HYPERTROPHY.)

Disuse Atrophy occurs when muscles are not used for a long period, for example when a limb is not used for locomotion because of a painful lesion or injury located somewhere in the limb.

Atropine

An alkaloid contained in the leaves and root of the deadly nightshade (*Atropa belladonna*). Preparations of belladonna owe their anticholinergic actions to the presence of atropine, which blocks transmission at sensory nerve-endings and thus relieves pain and spasm in parts to which it is applied. It checks secretion in all the glands of the body when given internally; and whether given by the mouth or rubbed on the skin it causes a dilatation of the pupil of the eye and paralysis of accommodation. In large doses it induces a general stimulation of the nervous system, but this action is rapidly followed by depression, and the primary effect is not noticed in the administration of ordinary doses. The action on the heart is one of stimulation, since the inhibition fibres are paralysed, while the accelerator nerves are not interfered with, except when large doses are given and paralysis of all motor fibres occurs.

Uses Atropine is used as a premedicant to anaesthesia as it reduces respiratory tract secretions. It is also used to dilate the pupil in order to facilitate eye examinations, and to reduce salivation in mouth and dental operations. As an antidote to morphine poisoning and also to some of the organophosphorus compounds used as farm sprays, it is given as the sulphate of atropine by hypodermic injection.

Atropine Poisoning

Atropine poisoning may occur as the result of the unintentional administration of too large amounts of the alkaloid ATROPINE or of the drug BELLADONNA in one form or another, or it may be induced by feeding on the plant growing wild.

The signs of poisoning shown are restlessness, delirium, dryness of the mouth, a rapid and weak pulse, quick, short respirations, an increase in temperature, and dilatation of the pupil. In addition there is sometimes seen a loss of power in the hind-limbs.

Antidotes To those animals that vomit, an emetic should be given at once if the poison has been taken by the mouth. Horses and cattle should

VetBooks.ir

have their stomachs emptied by the passage of the stomach-tube, in so far as that is possible. Stimulants should be given, and pilocarpine, by injection, is the antidote.

Attapulgite

A clay which is used in the treatment of non-specific diarrhoea. Toxins adhere to the substance and then pass out in the faeces. (See also BONE CHARCOAL).

Attenuated

A term used to describe a reduction in the virulence of a micro-organism, particularly applied to those incorporated in VACCINES.

Auditory Nerve, Acoustic Nerve

The auditory nerve (acoustic nerve) is the 8th of the cranial nerves, and is concerned with the special sense of hearing. It arises from the base of the hind-brain just behind and at the side of the pons. It is distributed to the middle and internal ears, and in addition to its acoustic function it is also concerned with the balance of the body. (See EAR.)

Augnathus

A fetus with a double lower jaw.

Aujeszky's Disease

A viral disease, primarily of pigs. It is also known as pseudorabies and infectious bulbar paralysis. It can occur in other species; the infection usually being contracted from contact with pigs or consumption of pig carcases. The disease has a very short incubation period, and is characterised by intense itching. It was first described in Hungary by Aujeszky in 1902, and has been eradicated from the UK, Denmark, Sweden and parts of other countries in the EU. It has also been found in several parts of the USA, South America, Australia, the continent of Europe, etc. In the UK, the disease is NOTIFIABLE and an eradication campaign began in 1983. Monitoring continues by sampling cull animals at slaughterhouses. The infection may be windborne. Vaccines are available, but their use is prohibited in the UK except Northern Ireland. However, gene-deleted vaccines can be used in eradication programmes as it is possible to differentiate serologically a pig which has been vaccinated from one which has been exposed to infection.

Signs

Pigs Signs include abortion, sneezing, anorexia and dullness besides some evidence of pruritus, vomiting, diarrhoea, convulsions, drooling of saliva and paralysis of the throat. Mummification of the fetuses may occur in pregnant sows affected with Aujeszky's disease. Such sows may show loss of appetite and constipation, or stiffness and muscular incoordination without itching at all. For the screening of pig serum samples, the ELISA test has been found the most sensitive, speediest and cheapest of four methods for detecting antibodies to Aujeszky's disease virus. (Central Veterinary Laboratory.)

Prevention: Intranasal vaccination with attenuated virus is more effective than parenteral vaccination with inactivated virus, as maternally derived antibodies interfere with the latter.

Dogs and cats Restlessness, loss of appetite, vomiting, salivation, signs of intense irritation (leading to biting or scratching) about the face or some other part, and occasionally moaning, groaning, or high-pitched screams are among the signs observed. Many cases are seen as deaths overnight in previously healthy animals following eating infected meat.

In one outbreak, 11 out of a pack of 51 harrier hounds died of the disease (apparently as a result of being fed raw carcase meat from a large pig unit). Infected rats may be another vector.

Cattle The first sign to be observed is usually a persistent licking, rubbing or scratching of part of the hindquarters (or sometimes of the face) in an attempt to relieve the intense itching. The affected part soon becomes denuded of hair, and may be bitten and rubbed until it bleeds. This has produced the name of 'Mad itch'. Bellowing, salivation and stamping with the hind-feet may be observed. Within 24 hours the animal is usually recumbent and unable to rise on account of paralysis. Death, preceded by convulsions, usually occurs within 36 to 48 hours of the onset of signs.

Goats Deaths have occurred in goats kept with infected pigs. Signs include restlessness, sweating, distressed bleating and convulsions; some animals may be found dead without signs being noticed.

Poultry One-day-old chicks have died after being inoculated with a Marek's disease vaccine. Aujeszky's disease vaccine virus adapted to chicken cells was likely to have been the cause.

Horses The virus was isolated from the brain of a horse showing the following signs: excessive sweating, muscle tremors and 'periods of mania'.

Public health Aujeszky's disease virus can infect people, but it seems that only laboratory workers are likely to find this a health hazard.

VetBooks.ir

Aural
Relating to the ear.

Aural Cartilages
(See AURICULAR CARTILAGES.)

Auricle, Atrium
The auricles, right and left, are the chambers at the base of the heart which receive the blood from the body generally, and from the lungs respectively. Opening into the right auricle are the cranial and caudal vena cavae, which carry the venous blood that has been circulating in the head and neck and the abdomen and thorax. This blood is pumped into the right ventricle through the tricuspid valve. Opening into the left auricle are the pulmonary veins which bring the arterial blood that has been purified in the lungs; when this auricle contracts the blood is driven into the left ventricle through the mitral valve. (See HEART; CIRCULATION OF BLOOD.)

Auricular Cartilages
Auricular cartilages are the supporting structures of the ears. There are three chief cartilages in most animals, viz. the conchal, which gathers the sound waves and transmits them downwards into the cavity of the ear and gives the ear its characteristic shape; the annular, a cartilaginous ring below the former which is continuous internally with the bony acoustic canal; the scutiform, a small quadrilateral plate which lies in front of the others and serves for the attachment of muscles which move the ear.

Accidents and diseases of the cartilages of the ear are not common in animals, with the exception of dog/cat fights. Ulceration of the cartilages, chiefly the annular, occurs as a complication of ear inflammation in the dog. Laceration of the conchal cartilage is seen as the result of the application of a twitch to the ear in the horse.

Auscultation
Auscultation is a method of diagnosis by which the condition of some of the internal organs is determined by listening to the sounds they produce. Auscultation is practised by means of the stethoscope.

Australian Cattle Dog
It is found in small numbers in the UK. Progressive retinal atrophy may be found in this breed, but with an unknown mechanism of inheritance.

Australian Shepherd Dogs, Aussies
Working dogs which possibly originated from the AUSTRALIAN CATTLE DOG but which were developed in the Western USA. The breed is mainly found in the USA and there are very few in Australia. The dog has medium length black, red, blue merle and red merle, is usually tailless and is a medium-sized breed (male 23 kg to 29 kg, female 18 kg to 20 kg). It has several potential defects including COLLIE EYE ANOMALY, CATARACT, and PROGRESSIVE RETINAL ATROPHY (due to a recessive trait).

Australian Silky Terrier
A breed of dog resembling large (3 kg to 4 kg) YORKSHIRE TERRIERS, with a silky coat coloured blue or grey with tan. They can show PROGRESSIVE RETINAL ATROPHY.

Australian Stumpy Tail Dogs
Derived from cattle dogs originally from England crossed with dingos. Found in relatively small numbers in the UK. They have a dense, straight-haired coat speckled red or speckled blue in colour. They are smaller than the AUSTRALIAN CATTLE DOG and have a stumpy tail. They males are 46 cm to 50 cm (18 in to 20 in) at the shoulder and weigh 15 kg to 20 kg (33 lb to 44 lb). They can suffer from PROGRESSIVE RETINAL ATROPHY, due to a recessive trait.

Australian Terriers
A small terrier (6 kg to 7 kg) with short legs, erect ears, docked tail and a harsh medium-length coat. They can show VON WILLEBRAND'S DISEASE.

Australorp Chickens
This breed comes from Australia. It is black with a green sheen to its feathers. The male is about 4 kg (9 lb) and the female 3 kg (6.5 lb). They produce about 250 light brown eggs per year.

Autochthonous
In veterinary use, the term describes the seeding of the digestive tract with normal flora and fauna in all species and is especially important in herbivores. It refers particularly to the rumen in ruminants and the caecum in rabbits and horses. Usually these micro-organisms are obtained from the parents or others of the same species in a herd, and come mainly from environmental exposure.

Autogenous
Autogenous means self-generated, and is the term applied especially to bacterial and viral vaccines manufactured from the organisms found in discharges from the body and used for the treatment of the particular individual from which the bacteria were derived.

Auto-Immune Disease
Auto-immune disease is due to a failure of the bodily defence mechanisms in which antibodies

VetBooks.ir

become active against some of the host's own cells. The cause, as far as is understood, is an over-production of interferon-α. This results in an immune-stimulating protein being produced and precursor dendritic cells then grow into mature cells while still in circulation. In this situation they digest host DNA and produce chemicals against the host's DNA. Normally such dendritic cells are removed by the thymus gland and the peripheral tolerance mechanism, but this fails in the presence of excess interferon-α. One of the original descriptions of such disease was Hashimoto's thyroiditis in humans. In animals, an example is spontaneous auto-immune thyroiditis which occurs in dogs, poultry, monkeys and rats, and resembles Hashimoto's thyroiditis of man. Other examples are auto-immune haemolytic disease, in which the blood's red cells are affected; and glomerulonephritis in small animals.

Immune-mediate diseases are of two kinds: (1) primary, an auto-immune reaction only against self; and (2) secondary, a similar reaction occurring when viruses, tumours, parasites or drugs are involved.

Drugs are being developed to suppress interferon-α production if it appears that an auto-immune disease is developing. A *Type 1 reaction* is one where the antibodies are directed against the body itself, whereas a *Type 2 reaction* is directed against the antibody complex formed by the body and is seen in some cases where herpes viruses are involved.

Primary diseases are either organ-specific, e.g. auto-immune haemolytic anaemia (see under ANAEMIA, or systemic, e.g. LUPUS ERYTHEMATOSUS. (See also THROMBOCYTOPENIA; POLYARTHRITIS; PEMPHIGUS; BOVINE and CANINE AUTOIMMUNE HAEMOLYTIC ANAEMIA; DIABETES MELLITUS.)

Auto-Infection

Infection of one part of the body, hitherto healthy, from another part that already is suffering from the disease. Thus, sheep suffering from 'orf' on their feet may bite the painful areas and convey the organisms to their mouth, where the disease becomes established.

Autointoxication

It is a condition where toxins build up in the body of an animal and cause illness.

Autologous

Derived from the same animal.

Autolysis

Self-digestion of an organism by its own enzymes. (See also NECROSIS.)

Autonomic Nervous System

The autonomic nervous system is that part of the nervous system which governs the automatic or non-voluntary processes. It governs such functions as the beating of the heart, movements of the intestines, secretions from various glands, etc. It is usually regarded as composed of 2 distinct but complementary portions: the parasympathetic and the sympathetic systems.

The parasympathetic system is composed of a central portion comprising certain fibres present in the following cranial nerves: oculomotor, facial and glossopharyngeal; and the whole of the outgoing (efferent) nerves in the important vagus nerve. There is also a sacral set of autonomic nerve fibres present in the ventral roots of some of the sacral nerves.

The sympathetic system is composed of nerve fibres present in the ventral roots of the spinal nerves lying between the cervical and lumbar regions.

The two systems are mutually antagonistic in that stimulation of each produces opposite effects. These effects are shown in the form of the now classic table (see below).

Under normal circumstances there is a harmony preserved between the working of the two systems, which are flexible enough to provide for the ordinary exigencies of life. The sympathetic system is stimulated during the 'fight or flight' reaction, which comes into effect during emergency situations.

Organ	Stimulation by chemical or other means of	
	Parasympathetic	Sympathetic
Pupil	Contracts	Dilates
Heart	Slows	Accelerates
Salivary glands	Thin watery secretion	Thick glairy secretion
Stomach and intestines	Causes movement	Inhibits movement
Pyloric, anal, and ileocaecal	No action	Causes constriction
Bladder	Contracts	Relaxes
Bronchial muscles	Causes contraction	Causes relaxation
Gastro-intestinal and bronchial glands	Produces secretion	No action
Sweat glands	No action	Causes secretion

The effect of stimulation of the parasympathetic and sympathetic nervous systems.

Autonomic Polyganglionopathy

(See FELINE DYSAUTONOMIA.)

VetBooks.ir

Autopsy

Autopsy (from the Greek, seeing with one's own eyes) is the examination of the internal structures of the body performed after death. From a post-mortem examination much valuable information can be learned, especially when there has been doubt about the disease condition during life. It has been said that it is 'unfair to the living animals, as well as a handicap to the progress of veterinary science, for owners to prohibit an autopsy because of sentiment'.

An autopsy is obligatory where some NOTIFIABLE DISEASES, e.g. rabies, are involved, so that laboratory tests may be carried out to confirm or establish diagnosis. In the case of rabies, gloves and goggles must be worn, and every precaution taken, by the person carrying out the autopsy. Examination of avian carcases, especially parrots, is performed in a Microbiological Safety Cabinet which extracts air (and infective organisms such as *Chlamydophila psittaci*) over the carcase and away from the technician). With other communicable diseases (see ZOONOSES) similar precautions are necessary.

Valuable information can be obtained in slaughter-houses as to the extent of a disease, such as liver-fluke infestation in cattle and sheep, over a region or indeed throughout a whole country; and if suitably recorded and collated, the information can indicate the economic importance of diseases in farm animals and so lead to disease-control measures being taken as part of a regional or national campaign.

See under WOOL BALLS IN LAMBS for an example of a layman's misinterpretation of post-mortem findings.

Autosexing

Some breeds of poultry can have different feathering colours, allowing the sexes to be differentiated even at birth. Most of these have been produced by crossing two breeds until they breed pure. Examples of this are the Welbar originally produced by crossing the WELSUMMER and BARRED PLYMOUTH ROCK male and the Legbar (a cross of the LEGHORN with the BARRED PLYMOUTH ROCK). In domestic turkeys there are some strains where the, male is like a bronze turkey and the females are auburn or copper in colour and this can be seen at hatching.

Autosite

A fairly normal member of asymmetric conjoined twins, the other twin being dependent on the autosite for its nutrition.

Autosomes

Autosomes are the chromosomes present in the nuclei of cells other than the sex-chromosomes. They are of the same type in both sexes in each species of animal, whereas the sex-chromosomes of the female are different from those of the male. (See CYTOGENETICS.)

Autotomy

The loss of the tail of lizards as a defence mechanism – the shed piece wiggles and distracts the predators allowing the reptile to escape. It is seen in lizards that do not require their tails for locomotion – therefore it is not seen in chameleons, monitors or marine iguanas. The shed extremity regrows, albeit without the same skin pattern. (See IGUANAS.)

Autovaccine

A vaccine prepared from an organism isolated from an animal and injected back into the same animal. The most common auto- (or autologous) vaccine is that prepared for treatment of warts (angleberries) in cattle. See AUTOLOGOUS.

Autumn Aeromonad Disease

The disease is caused by *Aeromonas liquefaciens* in fish at a time of stress, for example, adult brown trout are vulnerable during the spawning season. Skin lesions may be invaded by *Saprolegnia* fungus and the abdominal skin may show severe inflammation. The internal organs are very haemorrhagic. In severe cases the kidney is liquefied. Immature fish or non-spawning adults may carry the infection.

Autumn Fly, Musca Autumnalis

This is a non-biting fly which is a serious pest of grazing farm livestock in the UK and elsewhere. They cause cattle to huddle together and to cease feeding. Large numbers may collect on the upper part of the body, feeding on secretions from nose, mouth, eyes and on discharges from any wounds. (See FLIES – Fly control measures.)

Auxins

Plant hormones. These include oestrogens in pasture plants.

Avascular Necrosois of the Femoral Head

(See LEGG-CALVÉ-PERTHES DISEASE.)

Avermectins

A group of chemical compounds first derived from a fungus discovered in Japan in 1975, effective in very low dosage with a broad spectrum of activity against nematode parasites and also against external parasites. (See IVERMECTIN, DORAMECTIN, MOXIDECTIN.) The discovery of the fungus in a soil sample was part of Merck Sharp & Dohme's international screening programme.

VetBooks.ir

Technically, the avermectins are a series of macrocyclic lactone derivatives produced by fermentation of the actinomycete *Streptomyces avermitilis*. Different formulations are available for administration as injections, drenches, boluses and pour-on forms. The group includes products for cattle, sheep, pigs, and in some countries for goats. Avermectins are safely used in many animals, but are known to be toxic in CHELONIA and in some breeds of dogs, notably BORDER COLLIES and their crosses.

Avian

An adjective to describe related to or derived from birds.

Avian Bornavirus (ABV)

A virus that has been identified as the causal agent of proventricular dilation disease (PDD) in psittacine birds. It results in high mortality and has been reported worldwide since the late 1970s. There is at post mortem dilation of the proventriculus with nervous lesions, including encephalitis, myelitis and neuritis. Besides psittacines the infection has been found in wild Canada geese (*Branta canadensis*) and Trumpeter swans (*Cygnus buccinator*).

Avian Contagious Epithelioma

(See under FOWL POX.)

Avian Gastric Yeast

Macrorhabdus ornithogaster previously known as *Megabacterium*, a pathogenic organism of the intestinal tract of cage birds. (See MEGABACTERIOSIS.)

Avian Hepatitis

Hens producing α-3 enriched eggs showed a higher mortality when infected with avian hepatitis virus E than normal hens.

Avian Infectious Encephalomyelitis

A disease of chicks and turkey poults; also known as epidemic tremor.

Cause A picornavirus. (Infection via the egg, as well as bird to bird.)

Signs If infection is egg-borne, signs are seen in the first 10 days after hatching; if infected after hatching, at 2 to 5 weeks old. There is leg weakness, followed by partial or complete paralysis of the legs. The chicks struggle to balance with the help of their wings. Trembling of the head and neck occurs in some cases.

Diagnosis An ELISA test.

Mortality A 40 per cent rate is not unusual.

Prevention Vaccination has proved very successful.

Avian Infectious Laryngotracheitis

Avian infectious laryngotracheitis of poultry is caused by a herpesvirus, prevalent in NW England. Loss of appetite, sneezing and coughing, a discharge from the eyes, difficulty in breathing are the main signs. Birds of all ages are susceptible. Mortality averages about 15 per cent. No treatment is of value. Control is best achieved by depopulation and fumigation. A vaccine has been used.

Avian Influenza

Avian influenza (it used to be called fowl plague, but the term is no longer used) attacks domesticated fowl chiefly, but turkeys, geese, ducks and most of the common wild birds are sometimes affected. It is not known to affect the pigeon. The disease is found in Asia, Africa, the Americas and to a lesser extent in parts of the continent of Europe, and is always liable to be introduced to countries hitherto free from it through the migrations of wild birds. An outbreak occurred among turkeys in Norfolk in 1963; this was the first recorded outbreak in Britain since 1929. An outbreak occurred in the Republic of Ireland in 1983; a slaughter policy followed. Infection may have come from Pennsylvania, where a similar policy was adopted.

Already in this century, there have been outbreaks of a severe form of the disease in the Netherlands, Belgium and Germany (2003) and milder outbreaks in the Americas in 2004. However, in 2004 and 2005, there was a severe series of outbreaks caused by H5N1 strain in South East Asia, Japan, China and Korea, with spread to, and mortality in, the human populations. Unusually, this virus can also infect felidae. The EU stopped all imports from the area. As a result, the OFFICE INTERNATIONAL DES EPIZOOTIES proposed a new definition of avian influenza: 'infection by an influenza A virus that has intravenous pathogenicity index in 6-week old chickens greater than 1.2 or any influenza virus of H5 and H7 subtype.' 'Poultry' covers all birds kept in captivity for the production of meat or eggs, for restocking game or for breeding.

Cause *Myxovirus influenzae*.

Signs In some cases the number attacked is small, while on the same premises the next year 80 per cent or 90 per cent of the total inhabitants of the runs may die. The affected birds often die quite suddenly. In other instances the sick birds isolate

VetBooks.ir

themselves from the rest of the flock, preferring some dark out-of-the-way corner where they will be undisturbed. They are dull, disinclined to move, the tail and wings droop, the eyes are kept closed; the bird may squat on its breast with its head tucked under a wing or in amongst the shoulder feathers; food is refused, but thirst is often shown; the respirations are fast and laboured but not impeded by mucus; the temperature is very high at the commencement (43° C to 44° C [110°F to 112° F]), but falls shortly before death to below normal. (The normal temperature of birds is 41° C [106.5° F].) The comb and wattles become purple or blue and oedema of the head and neck is common. The illness seldom lasts more than 24 to 36 hours, and often not more than six.

Control Vaccines are available but their use is incompatible with an eradication policy. They are used in parts of the USA and in Italy.

Avianised Vaccines

Vaccines that are prepared by passage of the antigen through egg tissue.

Avian Listeriosis

An infectious disease of poultry, occurring as an epidemic among young stock (often as an accompaniment of other diseases) or sporadically among adults.

Cause *Listeria monocytogenes*, a Gram-positive motile rod-shaped organism.

Signs In the epidemic type, wasting occurs over a period of days or even weeks. For 48 hours before death birds refuse all food.

The sporadic type is characterised by sudden death from myocarditis without much loss of condition.

Diagnosis Depends upon bacteriological methods. (See also LISTERIOSIS.)

Avian Lymphoid Leukosis

Avian lymphoid leukosis virus (LLV) infection is widespread among chickens in the UK, and causes mortality from tumours.

This disease, which has to be differentiated from Marek's disease, affects birds of 4 months upwards and is egg-transmitted, shows variable signs but, typically, the liver is enlarged.

It may be identified by the presence of neutralising antibodies in the serum or by virus detection by ELISA.

Control High standards of hygiene and flock management; no vaccines are available.

Avian Malaria

(See *Plasmodium gallinaceum*.)

Avian Monocytosis

(See 'PULLET DISEASE'.)

Avian Nephritis

A viral infection first detected in the UK in 1988. In chick embryos it causes stunting, haemorrhage and oedema as well as nephritis.

Avian Pox

(See AVIPOX.)

Avian Sex Determination

Avian sex determination by laparoscopy has been widely used since 1976, but is losing popularity in favour of sexing by examination of DNA in avian blood including that found in emerging feathers.

Avian Tuberculosis

The increase in the number of farmed poultry kept in free-range systems or with access to outdoors has led to an increase in the incidence of this disease. It is usually seen in birds over 2 years old but can occur in young birds. Ostriches are usually kept outdoors and are particularly at risk if near woodland, as wood pigeons (*Columba palamuis*) and feral pigeons are often heavily infected – as are wild birds such as starlings.

Cause *Mycobacterium avium.*

Signs Dullness, loss of appetite, lethargy and a tendency to squat in a sleeping position with the head tucked under one wing.

Body temperature may reach 44° C (112° F).

The comb and wattles may become almost purple, and swollen because of oedema. In young birds, there is muscle wastage and the comb may become pale in colour. The disease progresses slowly. It used to be referred to by pigeon fanciers as 'going light'.

Infection occurs following ingestion of food and water contaminated by the droppings of infected birds. Infection has been found in eagles at post-mortem examination, presumably from consumption of infected prey.

Cage birds can also be affected. Chronic wasting disease can be seen in the intestinal form and cutaneous mycobacteriosis has been reported in parrots. The public health significance of mycobacteriosis in companion animals must be addressed with great care.

Cattle Avian tuberculosis rarely causes progressive disease, but the presence of avian TB bacteria will affect the interpretation of the tuberculin test. This infection must be differentiated from

VetBooks.ir

Mycobacterium bovis infection by using avian tuberculin as well as mammalian in the test. (See TUBERCULIN TEST.)

Sheep Avian tuberculosis can cause miliary tuberculosis in sheep.

Pigs A non-progressive infection is often found in lymph nodes at slaughter. The source of infection in housed pigs can be the use of peat as litter. *M. avium* survives in peat for a considerable period.

Post-Mortem Emaciation is usually well marked, and whitish-yellow nodules are present in the liver and spleen; also the intestines. The lungs are rarely affected in avian tuberculosis. In birds that have died suddenly, death is often found to be due to rupture of the liver which, when affected with tuberculosis, is often enlarged and friable.

With valuable pedigree birds the intradermal tuberculin test may be employed, but before applying this test all birds should be examined and all thin birds destroyed, since those in the advanced stages of the disease may fail to react. Birds which pass the test should be put in clean houses on fresh ground.

(See also DISPOSAL OF CARCASES.)

Aviculture
The husbandry, keeping, breeding and rearing of birds, especially in cages and aviaries.

Avidin
A protein in raw egg white that neutralises the B-vitamin biotin.

Avilamycin
An antibiotic feed additive formerly used as a growth promoter in pigs and poultry. Its use in the EU was prohibited in 2006.

Avipox
The name given to the VIRUS that infects birds. Almost all species are susceptible (except cockatiels – *Nympicus hollandicus*). Lesions follow damage to the skin (often by ECTOPARASITES); classically, they form papules and pustules. In some species the lesions become fibrous, proliferative and become almost neoplastic in appearance. Sometimes lesions spontaneously regress but in canaries (*Serinus* species) they can fatally involve the respiratory system. Treatment involves topical antiseptics and antibiotics to control secondary infection and improved husbandry, especially nutrition, to encourage immunity development. The problem is being increasingly seen in British wild birds and appears to be spread at the bird table. Avipox is used in the manufacture of some vaccines.

Avitaminosis
Avitaminosis is a term used to describe conditions produced by a deficiency or lack of a vitamin in the food. Thus 'avitaminosis A' means a deficiency of vitamin A. (See VITAMINS.)

Avocado Leaves
Persea americana fed to goats and sheep, during a drought in South Africa, caused death within a few days from heart disease.

Awns
An American review in dogs and cats over a one-year period showed that grass awns comprised 61 per cent of all foreign body cases. The most common site is the ear canal (51 per cent), and rupture of the tympanum has been an occasional sequel. Other sites are the interdigital skin in dogs - which again is quite common - and the conjunctiva, nose and lumbar region. Perforation of a bronchus leads to necrosis of a lung lobe. In cats, chronic cystitis has been caused by awns in the bladder.

Axial
Derived from an axis. Often used with bones. See Opposite ABAXIAL.

Axilla
Axilla is the anatomical name for the region between the humerus and the chest wall, which corresponds to the armpit in the human being.

Axis
The second cervical vertebra or epistropheus upon which the atlas or first vertebra is placed. It includes an odontoid peg which allows the axis to rotate on the axis. See ATLAS.

Axolotl
Axolotl (*Ambystoma mexicanum*) is the 'tadpole' stage of a mole salamander (*Ambystomatidae*) that remains and breeds at this stage, unless the environment alters in some way so that it develops into the Mexican mole salamander. Axolotyls are occasionally kept as pets but, more recently, they have been kept for the production of fertile eggs for the use in screening compounds for teratogenicity.

Axon
(See NERVES.)

Axonopathy
A disease of axons.

VetBooks.ir

Ayrshire Cattle

A breed of dairy cow originating from Scotland. It has a red-brown and white coat. It milks well but produces less volume than the FRIESIAN or the HOLSTEIN. It is smaller than either of these two breeds and relatively fine-boned. Its male calves are of limited value for producing beef. It is susceptible to vulval squamous cell carcinoma in Kenya.

Azamethiphos

An organo-phosphorus compound used for the control of mature and pre-adult and adult stages of sea lice (*Lepeophtheirus salmonis* and *Caligus* spp.) in farmed salmon. Treatment involves raising the salmon cage until it is at a depth of about 2 m (6 ½ ft) at the centre and then enclose the cage in a tarpaulin so that it is totally leakproof. Oxygen is added to the system followed immediately by the drug. The tarpaulin is removed after 30 to 60 minutes. Persons operating the system have to do so under the terms set out in the Control of Substances Hazardous to Health Regulations 1999.

Azaperone

A neuroleptic drug used in pigs for reducing aggression and preventing fighting. It is used as a sedative when pigs are being transported (not for slaughter, as it has a 10-day withdrawal period) and may be given as premedication before administering an anaesthetic or to reduce excitement when assistance at farrowing is required. Its effect may be less reliable in Vietnamese pot-bellied pigs.

It is also used for sedation in ostriches.

Azotaemia

The presence of urea and other nitrogenous products in greater concentration than normal in the blood, particularly in paralytic myoglobinuria in horses.

Azoturia

The presence of urea and other nitrogenous products in greater concentration than normal in the urine.

(See EQUINE RHABDOMYOLYSIS.)

VetBooks.ir

B

Babesia

Babesia is another name for piroplasm, one of the protozoan parasites belonging to the order Haemosporidia. These are generally relatively large parasites within the red blood cells and are pear-shaped, round or oval. Multiplication is by division into two or by budding. Infected cells frequently have two pyriform parasites joined at their pointed ends. Sexual multiplication takes place in the tick.

Babesiosis, Piroplasmosis

Nearly all the domestic mammals suffer from infection with some species of *Babesia*; sometimes more than one species may be present. The general signs are the appearance of fever in eight to 10 days after infection, accompanied by haemoglobinuria, icterus; unless treated, 25 to 100 per cent of the cases are fatal. Red blood cells may be reduced in number by two-thirds. Convalescence is slow and animals may remain 'salted' for three to eight years.

Transmission Development occurs in certain ticks which transmit the agent to their offspring. The various species are similar, but are specific to their various hosts. The ticks should probably be regarded as the true or definite hosts, while the mammal is the intermediate host.

Cats *Babesia felis* is a (rare) cause of lethargy, inappetence and anaemia, and occasionally jaundice and death.

Cattle (See RED-WATER FEVER.) Red-water in the UK and Ireland as well as the tropics is a most important disease.

Dogs They are affected by *B. canis*. It is also a ZOONOSIS. It results in anaemia and also reproductive and infertility problems with ENDOMETRITIS and ABORTION in bitches and EPIDIDYMITIS and ORCHITIS in dogs. It is not in the UK and animals going to New Zealand and Australia have to be blood tested.

Sheep Ovine babesiosis may be due to at least 3 species of *Babesia*. There is a relatively large form, *Babesia motasi*, which is comparable to *B. bigemina* of cattle, and which produces a disease, often severe, with high temperatures, much blood-cell destruction, icterus and haemoglobinuria. This is the 'carceag' of Eastern and Southern Europe. The second parasite, of intermediate size and corresponding to *B. bovis* of cattle, is *Babesia ovis*. It produces a much milder disease with fever, jaundice and anaemia, but recoveries generally occur. The small species is *Theileria ovis*, which appears to be similar to *T. mutans* of cattle and is relatively harmless to its host.

B. motasi, *B. ovis*, and *T. ovis* are all transmitted by *Rhipicephalus bursa*.

Animals recovered from *T. ovis* infection apparently develop a permanent immunity to it. The disease occurs in Europe, Africa, Asia, and North America.

Signs In acute cases the temperature may rise to 41.5° C (107° F), rumination ceases, there is paralysis of the hindquarters, the urine is brown, and death occurs in about a week. In benign cases there may only be a slight fever for a few days with anaemia.

A theileriosis, caused by *T. hirci*, has been described from sheep in Africa and Europe. It causes emaciation and small haemorrhages in the conjunctiva.

Bacillary Haemoglobinuria

A disease of cattle caused by *Clostridium haemolyticum (Cl. oedematiens)* type D.

Bacillary White Diarrhoea

(See PULLORUM DISEASE OF CHICKS.)

Bacillus

This genus of Gram-positive rod-shaped organism contains many species, some of which are not regarded as pathogenic, and some that are. They are found in soil, water, and on plants. Spores formed by bacilli are resistant to heat and disinfectants, and this fact is important in connection with *B. anthracis*, the cause of ANTHRAX. Another pathogenic bacillus is *B. cereus*, a cause of food poisoning and also of bovine mastitis. (See BACTERIA.)

Bacitracin

An antibacterial formerly used as a feed additive; its use for this purpose has been banned in the EU.

Back-cross

Back-cross is the progeny resulting from mating a heterozygote offspring with either of its parental homozygotes. Characters in the back-crosses generally show a 1:1 ratio. Thus, if a pure black bull is mated with pure red cows (all homozygous), black calves (heterozygotes) are produced. If the heifer calves are 'back-crossed' to their black father, their progeny will give one pure black to every one impure black. If a black heterozygous son of the original mating is mated to his red mother, the progeny will be one red to one black.

Back-crossing can be employed as a means of test-mating, or test-crossing to determine whether a stock of animals is homozygous, when it will never throw individuals of different type, or whether it is heterozygous, when it will give the two allelomorphic types. (See GENETICS, HEREDITY AND BREEDING.)

Back-Fence

(See STRIP-GRAZING.)

Back Muscle Necrosis (BMN)

A disease of pigs first described in Belgium in 1960, and recognised 8 years later in Western Germany (where it is colloquially known as 'banana disease'). It has been recorded in the UK, with 20 cases occurring in a single herd.

Signs A sudden and sporadic condition affecting pigs weighing over 50 kg. In the acute stage, the animal shows signs of pain, has difficulty in moving, becomes feverish, loses appetite and appears lethargic, and shows a characteristic swelling on one or both sides of the back. When only one side is affected, spinal curvature occurs with the convexity of the curve towards the swollen side.

The colloquial name 'banana disease' apparently arose from arching (as compared with lateral curvature) of the back, which is often seen in affected animals.

Some pigs die from acidosis and heart failure; some recover, apparently completely; while others are left with atrophy of the affected muscles resulting in a depression in the skin parallel to the spine. Some examples of BMN are discovered only in the slaughterhouse.

Post-Mortem examination reveals necrosis and bleeding, especially in the longissimus dorsi muscle, as well as the widely recognised condition known as PSE or pale soft exudative muscle.

Causes The disease is thought to be associated with stress; it is probable that heredity also comes into the picture.

Backyard Chickens, Backyard Hens, Backyard Poultry

These are a very common companion animal that is found in urban and country areas including schools and also they produce eggs. They are also used for showing. In a 2010 Greater London survey showed most had good living conditions and were able to express their natural behaviours, although three quarters of owners did not comply with the DEFRA regulations for catering waste. (See also ANIMAL BY-PRODUCTS REGULATIONS 2003; POULTRY AND POULTRY KEEPING.)

Bacteraemia

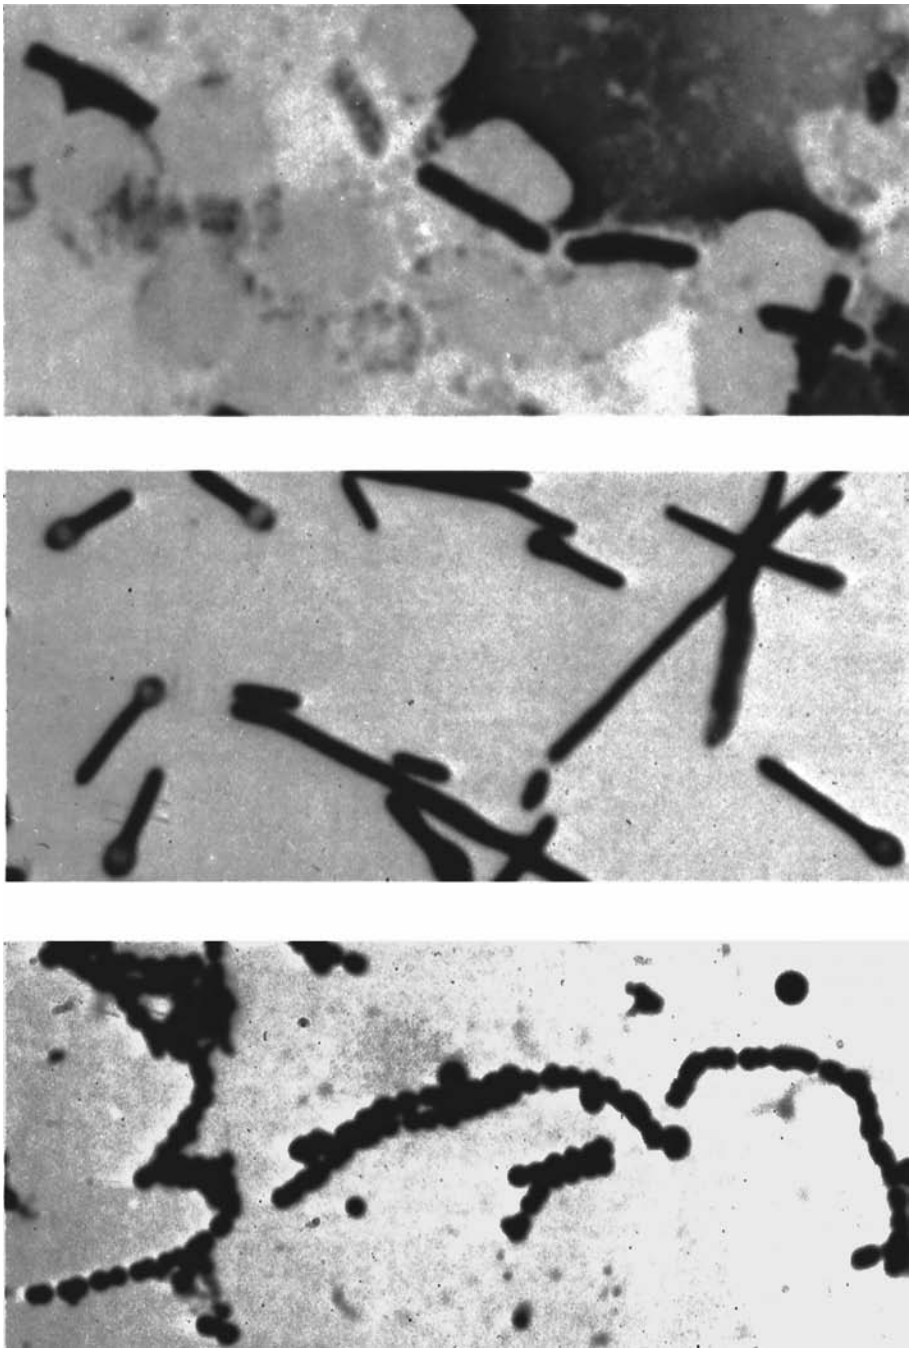
The temporary presence of non-muliplying bacteria in the blood.

Bacteria

Microscopic single-cell plants with important functions in nutrition and in disease processes. According to peculiarities in shape and in group formation, certain names are applied: thus a single spherical bacterium is known as 'coccus'; organisms in pairs and of the same shape (i.e. spherical) are called 'diplococci'; when in the form of a chain they are known as 'streptococci'; when they are bunched together like a bunch of grapes the name 'staphylococcus' is applied. Bacteria in the form of long slender rods are known as 'bacilli'; wavy or curved forms have other names. (See illustration on next page.)

Reproduction The mode of multiplication of most bacteria is exceedingly simple, consisting of splitting into a single bacterium into two. Since the new forms may similarly divide within half an hour, multiplication is rapid. (See illustration on page 69; see also PLASMIDS.)

Spore-Formation Some bacteria have the power to protect themselves from unfavourable conditions by changing their form to that of a 'spore'. These are very resistant to adverse environmental conditions. It is most commonly seen in species of *Bacillus* and *Clostridium*.



Size Bacteria vary in size from less than one MICRON (one-thousandth of a millimetre) diameter, in the case of streptococci and staphylococci, up to a length of 8 microns, in the case of the anthrax bacillus.

Mobility Not all bacteria possess the power of movement, but if a drop of fluid containing certain forms of organism which are called 'motile' is examined microscopically, it will be observed that they move actively in a definite direction. This is accomplished, in the motile organisms, by means of delicate whip-like processes called FLAGELLAE which thrash backwards and forwards in the fluid and propel the body onwards.

Methods of diagnosis

1. Microscopical In order to satisfactorily examine bacteria microscopically, a drop of the fluid containing the organisms is spread out in a thin film on a glass slide. The organisms are killed by heating the slide, and the details of their characteristics made obvious by suitable staining with appropriate dyes. (See under GRAM-NEGATIVE; also ACID-FAST ORGANISMS.)

VetBooks.ir

Bacteria. Photomicrographs of 1. *Bacillus anthracis* (× 4200); 2. *Clostridium tetani* (× 3250) (showing the characteristic drum-stick appearance); 3. *Streptococcus pyogenes* (× 3000).

Some bacteria of veterinary importance

Name	Associated or specific diseased conditions caused
Actinobacillus lignieresii	Actinobacillosis, wooden tongue.
Aequuli	Fatal septicaemia in foals and pigs.
A. pleuropneumoniae	Pleuropneumonia in pigs.
Arcanbacterium pyogenes	Abscesses in liver, kidneys, lungs or skin in sheep, cattle and pigs especially; present as a secondary organism in many suppurative conditions; causes summer mastitis in cattle. Was called *Corynebacterium pyogenes* and then *Actinomyces pyogenes*.
Actinomyces bovis	Actinomycosis, lumpy jaw.
Aeromonas shigelloides	Chronic diarrhoea in cats.
Bacillus anthracis	Anthrax in all susceptible animals.
Bacillus cereus	Bovine mastitis; food poisoning.
Bacillus licheniformis	Abortion in cattle, ewes.
Baccilus piliformis	Tyzzer's disease.
Bacteroides species	Foot infections in horses.
Bartonella henselae	Cat-scratch fever in man and angiomatosis.
Bartonella vinsonii	Dogs.
Bibersteinia trehalosi	Sudden death, septicaemia in sheep. Formerly *Pasteurella trehalosi*.
Brachyspira hyodysenteria	Swine dysentery. Formerly *Serpulina hyodysenteriae* and before then *Treponema hyodysenteriae*.
B. pilosicoli	Colitis in pigs.
Bordetella bronchiseptica	Complicates distemper in the dog. Kennel cough. Atrophic rhinitis.
Brucella abortus	Brucellosis abortion, undulant fever in man (in part).
Brucella melitensis	Brucellosis in goats; Malta fever and undulant fever in man (in part).
Campylobacter fetus	Infertility, abortion.
C. jejuni	Abortion.
Chlamydophila abortus	Enzootic abortion in sheep.
Chlamydophila psittaci	Psittacosis in parrots, ornithosis in other birds and mammals including man.
Clostridium botulinum (*five types – A to E*)	Botulism in man and animals.
Cl. chauvoei	'Black-quarter' (and also pericarditis and meningitis in cattle) in cattle and partly in sheep.
Cl. difficile	Chronic diarrhoea in dogs and piglets.
Cl. haemolyticum novyi	'Bacillary haemoglobinuria disease' in cattle, sheep; septicaemia in horses and pigs (wound infection). (Formerly *Clostridium novyi* Type D.)
Cl. septicum	Gas gangrene in man; black-quarter; braxy in sheep.
Cl. novyi	Type B Black disease in cattle, sheep.
Cl. perfringens A	Enterotoxaemia in sheep, goats. (Formerly *Cl. welchii* A.)
Cl. perfringens B	Lamb dysentery, haemorrhagic enteritis in sheep, goats. (Formerly *Cl. welchii* B.)
Cl. perfringens C Subtype 1	Struck in sheep. (Formerly *Cl. welchii* A=C.)
Subtype 2	Necrotic enteritis in USA.
Cl. perfringens D	Pulpy kidney, enterotoxaemia in sheep, goats. (Formerly *Cl. welchii* D.)
Cl. sordellii	Abomasitis and enterotoxaemia in cattle, sheep.
Cl. tetani	Tetanus in man and animals.
Corynebacterium pseudotuberculosis	Caseous lymphadenitis in sheep; goats and occasionally cattle, some cases of ulcerative lymphangitis and acne in horses.
C. equi	A cause of pneumonia in the horse and of tuberculosis-like lesions in the pig.
Dermatophilus congolensis	Chronic dermatitis. Lumpy wool, strawberry foot-rot in sheep.
Group EF-4 bacteria	Pneumonia in dogs and cats, and isolated from human dog-bite wound.
Dichelobacter nodosus	Foot-rot in sheep. Necrosis of skin or mucous membrane in rabbits after their resistance has been lowered by some other pathogen. Formerly *Fusiformis nodosus* then *Bacteroides nodosus*.
Erysipelothrix rhusiopathiae	Swine erysipelas.
Eschicheria coli (subtypes are many)	Always present in alimentary canal as commonest organism; becomes pathogenic at times, partly causing enteritis, dysentery (lambs), scour (calves and pigs), cystitis, abortion, mastitis, joint-ill, etc.
Fusobacterium necrophorum	Associated with foot-rot in sheep, foul-in-the-foot in cattle; calf diphtheria; quittor, poll evil, and fistulous withers in horses; necrosis of the skin in dogs, pigs and rabbits; navel-ill in calves and lambs; various other conditions in bowel and skin. (Formerly *Fusiformis necrophorus*.)
Histophilus somni	'Sleeper syndrome', pneumonia, septicaemia in cattle. (Formerly *Haemophilus somnus*.)
H. parainfluenzae *H. parasuis*	Chronic respiratory disease in pigs.
Klebsiella pneumonia	Metritis in mares; pneumonia in dogs, mastitis in pigs, cattle etc.
Lawsonia intracellularis	Proliferative enteropathy, proliferative haemorrhagic enteropathy, necrotic enteropathy, regional ileitis in pigs.
Leptospira icterohaemorrhagiae	Leptospiral jaundice, or enzootic jaundice of dogs; Weil's disease in man.

VetBooks.ir

Some bacteria of veterinary importance (continued from previous page)

Name	Associated or specific diseased conditions caused
Lept. canicola	Canicola fever in man and nephritis in dogs.
Lept. hardjo-bovis and *Lept. hardjo-prajitno*	Abortion, infertility in cattle, bovine mastitis and milk drop syndrome.
Listeria monocytogenes	Listeriosis.
Mannheimia haemolytica	Pneumonia and pasteurellosis in ruminants. (Formerly *Pasteurella haemolytica*.)
Moraxella bovis	New Forest eye in cattle, keratoconjunctivitis.
Mycobacterium bovis	Bovine tuberculosis.
Myc. avium subspecies *paratuberculosis* (MAP)	Johne's disease of cattle and other ruminants. (Formerly *Myc. Johnei*.)
Myc. Tuberculosis	Tuberculosis in man and animals.
Pasteurella multocida	Fowl cholera. Haemorrhagic septicaemia in cattle.
P. tularensis	Tularaemia in rodents.
Pseudomonas aeruginosa	Mastitis in cattle, contaminant on bacteriological culture.
P. mallei	Glanders in equines and man.
P. pseudomallei	Melioidosis in rats and man; occasionally in dogs and cats.
P. pyocyanea	Suppuration in wounds, otitis in the dog.
Salmonella abortus equi	Contagious abortion of mares naturally, but capable of causing abortion in pregnant ewes, cows, and sows experimentally.
S. abortus ovis	Contagious abortion of ewes occurring naturally.
S. dublin	Causes enteritis, sometimes abortion.
S. gallinarum	Klein's disease or fowl typhoid.
S. pullorum	Pullorum disease.
S. cholerae suis	Salmonellosis septicaemia in pigs.
S. typhimurium	Salmonellosis.
Staphylococcus albus	Suppurative conditions in animals.
Staph. aureus	Suppurative conditions in animals and man, especially wound infections where other pus-producing organisms are also present. Present in various types of abscess, and in pyaemic and septicaemic conditions. Cause of mastitis in cows.
Staph. hyicus	A primary or secondary skin pathogen causing lesions in horses, cattle, and pigs. It may also cause bone and joint lesions.
Staph. pyogenes	Often associated with the other staphylococci in above conditions; causes mastitis in cows.
Streptococcus agalactiae	Mastitis in cattle.
Strep. dysgalactiae	Mastitis in cattle, arthritis in sheep.
Strep. equi	Strangles in horses; partly responsible for joint ill in foals and sterility in mares.
Str. pyogenes	Many suppurative conditions, wound infections, abscesses, etc.; joint-ill in foals. (In the above conditions various other streptococci are also frequently present.)
Str. suis	Infects not only pigs but also horses and cats.
Str. uberis	Mastitis in cattle.
Str. zooepidemicus	Wounds in horses; mastitis in cattle and goats.
Taylorella equigenitalis	Contagious equine metritis. (Formerly *Haemophilus equigenitalium*.)
Vibrio	(see under CAMPYLOBACTER)
Yersinia enterocolitica	(see under YERSINIOSIS)
Y. pestis	Plague in man and rats. In an often subclinical form this may also occur in cats and dogs.
Y. pseudotuberculosis	(see under YERSINIOSIS)

For other, non-bacterial infective agents, see VIRUSES; RICKETTSIA; MYCOPLASMA; CHLAMYDOPHILA.

2. Cultural characteristics By copying the conditions under which a particular bacterium grows naturally, it can be induced to grow artificially, and for this purpose various nutrient substances known as media are used. (See CULTURE MEDIUM.)

After a period of incubation on the medium on previously sterilised Petri dishes or in tubes or flasks, the bacteria form masses or colonies, visible to the naked eye.

The appearance of the colony may be sufficient in some instances for identification of the organism.

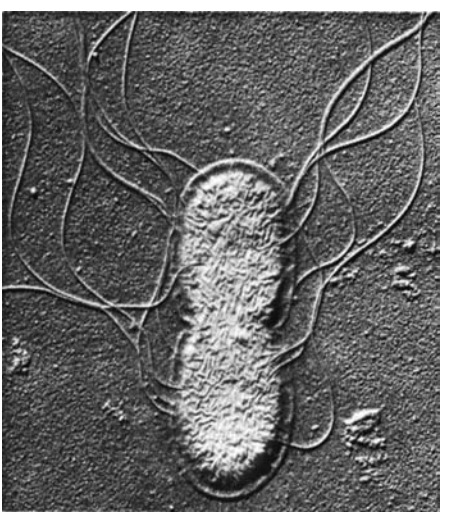
3. (See LABORATORY TESTS.)

4. Animal inoculation This may be necessary for positive identification of the organism present in the culture. One or more laboratory animals are inoculated and, after time allowed for lesions to develop or signs to appear, the animal is killed and a post-mortem examination made. The organisms recovered from the lesions may be re-examined or re-cultured. This procedure is now rarely used in the United Kingdom and requires Home Office licensing.

Bacterial Adhesiveness

Some pathogenic bacteria adhere to the mucous membrane lining the intestine, and this character-

istic may be an important criterion of virulence. Bacteria which possess this property include *E. coli*, *Salmonella typhimurium*, *Mycoplasma pneumoniae*, and *Moraxella bovis*.



Many strains of *E. coli* have a filamentous protein antigen called K88. This enables K88-positive *E. coli* to adhere to piglets' intestinal mucosa and to multiply there. K99 is the main adhesive antigen in cattle.

Bacterial Gill Disease

A disease of fish caused by poor water quality and infected with filamentous bacteria including *Flavobacterium* spp. The bacteria-infected gills become swollen and coated with mucus; asphyxia follows. Treatment may include restoration of good quality aquatic environment, and the use of potassium permanganate, benzyl permanganate, benzylkonium chloride, diquat or chloramine T copper sulphate, and zinc-free malachite green may be used if fungal infection is also present. Dosage must be carefully calculated to avoid toxic side effects.

Bacterial Kidney Disease

Bacterial kidney disease may affect farmed fish. Signs include pinpoint haemorrhages at the base of pectoral fins and on their sides; occasionally 'popeye' may be seen. In pacific salmon, cavernous spaces may be found in the muscles. Prolonged treatment with sulfonamides in the feed may control the disease, which may be due to infection by a coccobacillus carried by wild fish.

Bacterium about to divide. *Salmonella dublin* in the process of division into 2. Note also the flagellae.

Bactericide

An agent that destroys bacteria such as some disinfectants and antimicrobial agents. These compounds are thus described as bactericidal. Compare with BACTERIOSTATIC.

Bacteriophages

Bacteriophages are viruses which multiply in and destroy bacteria. Some bacteriophages have a 'tail' resembling a hypodermic syringe with which they attach themselves to bacteria and through which they 'inject' nucleic acid. 'Phages' have been photographed with the aid of the electron microscope. The growth of bacteriophages in bacteria results in the lysis of the latter, and the release of further bacteriophages. Phage-typing is a technique used for the identification of certain bacteria. Individual bacteriophages are mostly lethal only to a single bacterial species.

Bacteriostatic

An agent which inhibits the growth of microorganisms, as opposed to killing them. The term is often used to describe antimicrobial activity. Compare with BACTERICIDE.

Bacteroides

Species of this anaerobic bacterium, including *B. melaninogenicus*, are frequently isolated from equine foot lesions and wounds. *B. nodosus* (now called *Dichelobacter*) is one of the organisms found in foot-rot in sheep.

Bacteruria

Presence of bacteria in the urine. Bovine tuberculosis-infected badgers often excrete the organism in their urine.

Bactoscan

A method of determining bacterial numbers and is routinely used to test milk in the UK and other countries for human consumption. It indicates contaminants, the hygiene level of milk production and mastitis. The Bactoscan machine automatically separates out bacteria by centrifugation, they are then stained and counted. (See MILK TESTING.)

Baculoviruses

A group of viruses affecting insects. They are very host-specific and have been used in the control of specific insect pests while leaving beneficial species unharmed. Interest has also been shown in the possibility of using them as carriers of antigens in genetically engineered vaccines.

Badgers

Several species of badger inhabit different parts of the world. The so-called true badger, *Meles meles*, can grow up to 80 cm long, excluding tail. It is an

VetBooks.ir

omniverous animal with greyish coat and black-and-white stripes on the face. Badgers live in extensive underground burrows called setts.

Tuberculosis in badgers caused by *Mycobacterium bovis* was first described in Switzerland in 1957, and in England in 1971. Transmission of the infection to cattle led to their reinfection in the south-west of England initially but then spread to the Midlands and Wales. Badgers are now regarded as a significant reservoir of *M. bovis* infection. However, a policy of culling badgers in TB-affected areas has been controversial. Legal culling ceased in 1996 but has since been reintroduced to a limited extent.

The 2003 Krebs report on bovine tuberculosis in cattle and badgers recommended that badger culling should end in most of the UK. It would be replaced by a trial in areas repeatedly affected by TB. The so-called 'Krebs trial' compared the effectiveness of culling all badgers in limited areas with the results of culling only those badgers assumed to be linked with bovine TB in other areas, and with no culling in a third area. In areas where all badgers were culled this resulted in other badgers recolonising the areas (perturbation).

An injectable vaccine has been licensed for badgers, and work progresses on oral vaccination. There is some work on developing a vaccine to protect cattle against TB.

Badgers Act 1991

This makes it an offence to damage, destroy or obstruct a sett, disturb a badger in a sett, or put a dog into a sett.

Badgers (Further Protection) Act 1991

This legalises euthanasia of a dog, and disqualification of its owner from keeping a dog, after the offending dog has killed, injured or taken a badger, or the dog's owner has ill-treated or dug a badger out of its sett.

Bagot Goats

An ancient native breed recorded since the 1380s; the name is derived from the Bagot family of Blithfield Hall, Staffordshire, England. They are medium-sized with horns and long hair which is (ideally) black from the nose to behind the shoulder and then white.

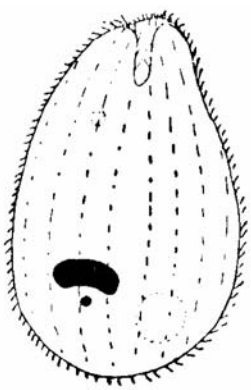
Bakery Waste

Bakery waste has been fed to pigs. It is much safer to use than swill and it is legal to feed provided that it contains no animal protein. Biotin deficiency may result if it is fed to excess.

Balance, Nutritional

The balance between what is taken in from the diet and what is excreted. For example, if an animal excretes more nitrogen than it receives from the protein in its feed, it is in negative nitrogen balance and losing protein. Similarly, reference is made to water balance, sodium balance and electrolyte balance.

Balanitis



(See PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Balanoposthitis

Inflammation of the prepuce and penis. It occurs as infectious penoposthitis in cattle infected with bovine herpes 1 virus. Enzootic penoposthitis occurs in sheep and is often known as 'PIZZLE ROT'.

Balantidium

A ciliated, protozoon parasite of pigs' intestines. As a rule, it causes no harm; but if the pig becomes debilitated from other causes, it can act as a secondary invader causing dysentery. The parasite is pear-shaped and about 80 microns long by 60 microns broad. The nucleus is sausage-shaped.

Balantidium coli.

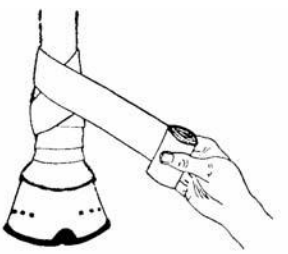
'Baldy Calf' Syndrome

An inherited lethal disease, causing alopecia, skin cracking and ulceration with progressive loss of weight or failure to grow. It is found in the descendants of a Canadian Holstein in Australia. Inherited epidermal dysplasia has been suggested as a more appropriate name. A single autosomal recessive gene is thought to be involved.

Baling Wire

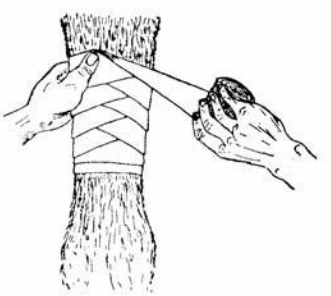
Discarded pieces of this may be swallowed by cattle and give rise to traumatic pericarditis. In Britain, it has largely been replaced by plastic baler twine. (See under HEART DISEASES.)

Ballottement



A technique of clinical examination in which the movement of any body or organ, suspended in a fluid, is detected.

BALT
An acronym for BRONCHIAL ASSOCIATED LYMPHOID TISSUE, the lymph tissue present in the lungs.



'Banana Disease' of Pigs
(See BACK MUSCLE NECROSIS.)

Banana Meal
Used as a livestock feed ingredient in the tropics when home production exceeds export requirements. Birds have a limited capacity to digest it and a 7.5 per cent upper limit of broiler diets is set.

Bandages and Bandaging
The application of bandages to veterinary patients is much more difficult than in human practice, because not only must the bandage remain in position during the movement of the patient, but it must also be comfortable, or it will be removed by the teeth or feet; and it must be so adjusted that it will not become contaminated by either urine or faeces.

'Figure-of-eight' bandage (roller) for fetlock, also known as a 'spica'.

Ascending spiral-reversed bandage for fore-arm.

Wounds often heal more readily if left uncovered, but bandaging may be necessary to give protection against flies and the infective agents which these carry. Much will depend upon the site of the wound, its nature, and the environment of the animal.

Bandages may be needed for support, and to reduce tension on the skin. The Robert-Jones bandage (a padded, stiffened, supporting bandage) and splints are commonly used in orthopaedics. (See also illustration.)

Bantam Chickens
A small variety of chicken also called MINIATURE CHICKENS; most larger chicken breeds now have a bantam type, or small counterpart. The name derives from Bantam, which was once a major seaport in Indonesia and where sailors restocked with provisions after long sea voyages. They found the small live birds useful as fresh food on their voyages. When bantams are of a particular breed they will have the breed's characteristics, but usually weigh a quarter to a fifth of the standard breed. They make good pets and should be tended and fed in the same way as other chickens. They can be good egg layers and are good mothers. They are often used for hatching eggs of other chickens. Old English bantam roosters were used for fighting in Europe. The life expectancy is about one to three years. The true bantams (no larger breed counterpart) include SEBRIGHT, DUTCH and PEKIN breeds.

Bantam Poultry
The term is used for other small types of poultry besides chickens.

Barbering
A condition of rabbits, mice, rats and gerbils kept in groups, where a dominant individual chews the hair or fur of a subservient individual. The appearance of the barbered pelage is as if were shaved with a clipper – a stubble is formed. Treatment is to remove the dominant animal or the affected one.

Barbiturates
Barbiturates are derivatives of barbituric acid (malonyl-urea). They include a wide range of very valuable sedative, hypnotic or anaesthetic agents. Several are used in veterinary practice, including pentobarbitone, phenobarbitone and thiopentone. An overdose is often used to euthanase dogs and cats; and farm animals where the brain is required for examination, as in suspected BSE cases.

In case of inadvertent barbiturate poisoning, use a stomach tube and keep the animal warm. Treatment includes CNS stimulants, e.g. bemegride, doxapram, caffeine or strong coffee.

(See also under EUTHANASIA; HORSE-MEAT.)

Barium (Ba)
While not an essential mineral in vertebrates, there is some evidence that barium it is required by certain molluscs, including those that are farmed (oysters, mussels, etc.). Barium salts are given as meals or enemas to render the alimentary tract opaque to X-rays.

Barium-Meal Techniques in Dogs and Cats
(See under X-RAYS.)

VetBooks.ir

Barium Poisoning

Barium chloride has been used in rat poison; the bait may be eaten by domestic pets.

The signs are excessive salivation, sweating (except in the dog), muscular convulsions, violent straining, palpitation of the heart and, finally, general paralysis.

Treatment Induce vomiting or use a stomach pump to remove the poison. Epsom salts dissolved in water act as an antidote by converting the chloride into the insoluble sulphate of barium.

Barium Sulphate

Barium sulphate, being opaque to X-rays, is given by the mouth prior to a radiographic examination of the gastrointestinal tract for diagnostic purposes. (See X-RAYS.)

Barium Sulphide

Barium sulphide has sometimes been used as a depilatory for the site of surgical operations.

Bark

A change in the tone of a dog's bark occurs in many cases of rabies.

Bark Eating

Bark eating by cattle should be regarded as a sign of a mineral deficiency, e.g. manganese and phosphorus. The remedy is use of an appropriate mineral supplement.

Barker Foal

A maladjustment syndrome in which a violent breathing action results often in a noise like a dog barking.

Barley, *Hordeum vulgare*

A major type of cereal grain used in almost all types of farm livestock and also in many pet feeds. It has a relatively high energy level (not as high as RYE or WHEAT) and low protein content (but higher than other cereals except wheat used for livestock).

Barley Poisoning

As with wheat (and to a much lesser extent, oats) an excess of barley can kill cattle and sheep not gradually accustomed to it. The main signs are severe acidosis and death. Treatment is sodium bicarbonate, by injection; gastric lavage; or rumenotomy.

It is important that barley should not be fed in a fine, powdery form. To do so is to invite severe digestive upsets, which may lead to death. Especially if ventilation is poor, dusty food also contributes to coughing and may increase the risk of pneumonia.

'Barn Itch'

The American name for sarcoptic mange in cattle.

Barnvelder Chickens

A medium-heavy breed of chickens originating from Holland. The colours include double laced with a single vertical comb and yellow legs. Other colours include white, black, brown, partridge, blue and blue laced varieties. They produce dark brown eggs. The males weigh about 3.5 kg (7.5 lb) and the hens 2.5 kg (5.5 lb).

Baroreceptors

Nerve endings that detect changes in pressure.

Barred Plymouth Rock Chickens

A breed used for meat and eggs and often called 'Rockies'. They are used in AUTOSEXING to produce different colours for the sexes, such as the Welbar, by crossing the WELSUMMER and the Legbar with the LEGHORN. Hens are crossed with RHODE ISLAND RED males to produce BLACK ROCK CHICKENS.

Barrier Cream

A protective dressing for the hands and arms of veterinarians engaged in obstetrical work or rectal examinations.

Barrow

A castrated male pig.

Bars of Foot

At each of the heels of the horse's foot the wall turns inwards and forwards instead of ending abruptly. These 'reflected' portions are called the bars of the foot. They serve to strengthen the heels; they provide a gradual rather than an abrupt finish to the important wall; and they take a share in the formation of the bearing surface, on which rests the shoe.

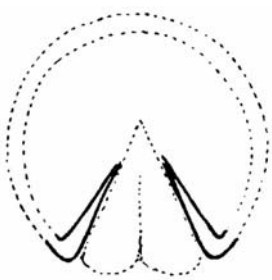


Diagram of the position of the bars of the horse's foot. The dotted line shows the outline of the wall and frog.

The bars are sometimes cut away by farriers or others, who hold the erroneous idea that by so doing they allow the heels of the foot to expand; what actually happens in such instances is that the union between the component parts of the foot is destroyed, and the resistance to contraction which

they afford is lost. They should therefore be allowed to grow and maintain their natural prominence. (See also illustration.)

Bartonella organisms

They are associated with animal disease. *Bartonella henselae* can result in 'cat scratch disease/fever' and bacillary angiomatosis in humans. The organism has been found in cats but not dogs. *Bartonella vinsonii* is found in dogs.

Treatment Neoarsphenamine has been used. It is important to perform effective ectoparasite control.

Bartonellosis

Infection with *Bartonella* organisms, which occasionally occurs in dogs and cattle but is of importance in laboratory rats. Signs are mainly those of anaemia.

Basenji

A small brown and white dog, originating in Africa, which is unable to bark. Inheritable congenital defects include haemolytic anaemia, inguinal hernia and persistent pupillary membrane (See PUPILLARY MEMBRANE, PERSISTENT). They may also inherit the condition intestinal lymphangiectasia, which causes loss of protein from the gut. They also show PYRUVATE KINASE DEFICIENCY and FANCONI SYNDROME. Basenji bitches normally have only one reproductive cycle a year.

Basic Slag

Basic slag is a by-product of the smelting industry often used as a fertiliser. It has caused poisoning in lambs, which should not be allowed access to treated fields until the slag has been well washed into the soil. Adult sheep have also been poisoned in this way, scouring badly, and so have cattle. In these animals the signs include: dullness, reluctance to move, inappetence, grinding of the teeth, and profuse watery black faeces.

Basidiobolus ranarum

A normal commensal fungus of the alimentary tract of frogs and toads which can cause disease in frogs. It can enter through wounds and is seen as hyperaemia and sloughing of the skin on the underside and may cause abnormal behaviour. For example, water-dwelling species may opt to go on land and vice versa. It is usually fatal and may be zoonotic.

Basophil

A type of white blood cell. (See under BLOOD.)

Basophilic

Blue-staining.

Basset Hound, Bassett Hound

A long-bodied, long-eared, short-legged breed. Ectropion, inguinal hernia and glaucoma may be inherited conditions. Back problems caused by cervical spondylosis may occur, and failure of the anconeal process (elbow) to develop properly may be seen. Glaucoma is inherited by an unknown mechanism and THROMBOPATHIA by an autosomal dominant trait. GONIODYSGENESIS is also seen.

Baths

Bathing of animals may be undertaken for the sake of cleanliness, for the cure of a parasitic skin disease, or for the reduction of the temperature.

Cattle and sheep (See DIPS AND DIPPING.)

Dogs For ordinary purposes the dog is bathed in warm water, in which it is thoroughly soaked. It is then lathered with a suitable shampoo (many proprietary brands are available) or hard soap, rinsed off and dried. A wide range of specially formulated shampoos is available for specific skin conditions.

Dish-washing detergent liquid should not be used for shampooing puppies or even adult dogs.

Cats Because cats are fastidious creatures which wash themselves nearly all over (they cannot reach the back of their necks or between their shoulder blades), the question of bathing them does not arise except in cases of a severe infestation with external parasites; very old cats which have ceased to wash themselves; entire tom cats which as a result of stress or illness have also ceased to look after themselves; as a first-aid treatment for heat stroke/stress; and in some cases where a cat has fallen into a noxious liquid.

Shampoos/flea-killers, etc. sold for use on dogs are not all safe for cats. Owners should read the small print on packets and look for 'safe for cats' where a preparation has not been prescribed by a veterinary surgeon.

Baths are used to help the treatment of certain muscle and joint problems.

Chinchillas Sand baths are essential for chinchillas to keep their coats in good condition. Chinchilla sand should be similar to volcanic ash in the wild, with nine parts of Fuller's earth to one part of sand. (Poultry perform dust bathing given the opportunity.)

Bathycardia

An abnormally low positioning of the heart in the thorax.

Bathygasty

An abnormally low position for the stomach.

VetBooks.ir

Bating
Bating is the action performed by a bird of prey when it goes to fly suddenly from a perch to which it is tethered causing the leash to jerk it back towards the perch. This can result in injuries, especially a fracture of the tibiotarsal bone. Injuries can be minimised by the use of a very short leash.

Batrachochytrium dendrobatidis
A fungus responsible for a fatal dermatitis in FROGS and SALAMANDERS. The fungus may be due to hybridisation and it invades the skin and spores are released into ponds. Any pond with infected frogs will be infected and the infection only reaches other ponds by infected amphibians. Some frog species appear resistant including the South African Clawed Toad (*Xenopus laevis*) and the American Bullfrog (*Rana catesbeiana*) and may have spread to countries where these frogs have been traded.

Bats
(See also RABIES; VAMPIRE BATS; HISTOPLASMOSIS.) Bats are mammals, and usually produce one offspring in late spring or early summer. Fifteen species have been identified in Britain, where they are classified as protected creatures under the Wildlife and Countryside Act 1981. Bats can live for up to 30 years. They can die of EUROPEAN BAT LYSSA VIRUS (EBLV) which is like the rabies virus. In Canada, millions of bats have died from WHITE-NOSED SYNDROME, a fungal infection. All bats should be handled with care, using stout gloves to prevent being bitten.

Battery System
A method of intensive egg production involving keeping hens in cages with a sloping floor, with 1, 2, or up to 5 birds per cage. Feeding and watering may be on the 'cafeteria' system, with food containers moving on an endless belt, electrically driven. The eggs are usually collected from racks at the front of the cages.

There have long been objections on welfare grounds to current battery systems and in January 2012 they were banned from the EU. Benefits achieved in good examples of battery cage systems (e.g. a smaller risk from parasites, good access to food and water) may be outweighed by their deficiencies (e.g. prevention of nesting behaviour, perching, dust-bathing; bone weakness caused by lack of freedom to move about).

From 1 January 2003 the permitted cage size was increased to allow a minimum of 550 cm^2 per hen and since that date no new cages could be installed. 'ENRICHED CAGES', or alternative non-cage systems, were specified for new or replacement systems by 1 January 2002. The 'enriched cages' have 750 cm^2 space per hen and provide a nest, litter to allow pecking and scratching, and perches. In the EU, battery cages were phased out by the end of 2011 with use of enrichment cages allowing more space per bird.

'Cage layer fatigue', a form of leg paralysis, is sometimes encountered in battery birds. Birds let out of their cages on to a solid floor usually recover. (See also INTENSIVE LIVESTOCK PRODUCTION; EGG YIELD.)

A battery rearing system has, in a somewhat different form, been applied to pig rearing.

Bay
A colour in horses which is tan or red-brown.

Bayeux Pigs
A French breed produced by crossing a white lop-eared Normandy pig with the black BERKSHIRE, it was used to help produce the PIÉTRAIN breed. It was believed to have become extinct in the 1960s. There are still pigs around that look like the Bayeux, but these are probably not purebred.

Baylisascariosis, Baylisascariasis
Infection with one or more species of parasitic helminths. The hosts are usually mammals (mainly mustelids). It infects the alimentary tract, but in hosts not naturally involved in the parasite's life cycle, including man, the parasite may migrate into body tissues including the brain and eye. Baylisascariosis is an emerging zoonosis in North America.

BBSRC
BBSRC is the abbreviation for the Biotechnology and Biological Sciences Research Council which succeeded the Agricultural and Food Research Council in 1994. The main Institute of Animal Health laboratory is now centered at the Pibright Laboratory. (See AFRC.) The BBSRC Headquarters address is Polaris House, North Star Avenue, Swindon, Wiltshire SN2 1UH. Telephone: 01793 413200; website: www.bbrsc.ac.uk.

B Cells
One of the two types of lymphocytes. They are important in the provision of immunity, and they respond to antigens by dividing and becoming plasma cells that can produce antibodies that will bind with the antigen. Their source is the bone marrow in mammals and the BURSA OF FABRICIUS in birds. It is believed that the function of B cells is assisted by a substance provided by T CELLS. With HAPTENS it is apparently the B cells which recognise the protein carrier, and the T cells which recognise the hapten. (See also LYMPHOCYTE; IMMUNE RESPONSE.)

BCG Vaccine

BCG vaccine may be used for dogs and cats in Britain in households where a member of the household has tuberculosis. The vaccine does not cover every strain of *Mycobacterium tuberculosis,* however. Currently it cannot be used in cattle as it interferes with the tuberculin test, but trials show that it can assist in preventing infection. The vaccine has been licensed for immunising badgers. It has been used in the treatment of equine sarcoid.

BCVA

(See BRITISH CATTLE VETERINARY ASSOCIATION.)

Beagles

A breed of dog traditionally kept in packs. Behavioural problems may develop in solitary animals kept as pets. Inheritable conditions include primary and secondary CLEFT PALATES, CONGENITAL HAEMOLYTIC ANAEMIA, GLAUCOMA and EPILEPSY (sex-linked). A number of conditions which appear to be inherited in this breed but with an unknown mechanism of inheritance include EPIPHYSEAL DYSPLASIA, INTERVERTEBRAL DISC PROTRUSION and RETINAL DYSPLASIA. Conditions inherited as recessive traits include RENAL DYSGENESIS and RENAL AGENESIS. HAEMOPHILIA due to Factor VII (possibly autosomal dominant trait) and VIII deficiencies (sex-linked recessive trait) are reported. SPINA BIFIDA is inherited as a dominant trait and PULMONARY STENOSES are due to polygenic factors. There is also familial PYRUVATE KINASE DEFICIENCY in the breed.

Beak

(See DE-BEAKING; SHOVEL BEAK.)

Beak Trimming

A blunting of the end of the beak. In some cases it can be achieved by inserting an abrasive material (claw-shortening abrasive) in the bottom of the feed trough, which reduces any excess beak growth as the birds feed.

There are moves to phase out the practice, on welfare grounds. (See also DE-BEAKING.)

Bearded Collie Dogs

A breed of dog with a coat needing considerable attention. It is a long-lived breed at 13.7 years. Hip dysplasia has a multifactorial inheritance while HYPOADRENOCORTICISM (Addison's disease) has an unknown inheritance mechanism.

Becquerel

The standard unit for measuring radiation. The quantity of radionucleotide that undergoes decay per second. (See RADIATION, EXPOSURE TO.)

Bedding and Bedding Materials

Whenever animals are housed in buildings, it is both necessary and economical to provide them with some form of bedding material. The reasons are as follows:

1. All animals are able to rest more adequately in the recumbent position, and the temptation to lie is materially increased by the provision of some soft bedding upon which they may more comfortably repose than on the uncovered floor. Indeed there are some which, in the event of the bedding being inadequate, or when it becomes scraped away, will not lie down at all.
2. The provision of a sufficiency of some non-conductor of heat (which is one of the essentials of good bedding) minimises the risk of chills.
3. The protection afforded to prominent bony surfaces – such as the point of the hip, the points of the elbow and hock, the stifles and knees, etc. – is important, and if neglected leads to bruises and injuries of these parts.
4. From the point of view of cleanliness, both of the shed or loose-box and of the animal's skin, the advantages of a plentiful supply of bedding are obvious.
5. In the case of sick animals, the supply and management of the bedding can aid recovery. (See also SLATTED FLOORS.)

Horses

Wheat straw Wheat straw undoubtedly makes the best litter for either stall or loose-box. Its main disadvantage is its inflammability.

Wheat straw should be supplied loose or in hand-tied bundles for preference. Trussed or baled straw has been pressed and has lost some of its resilience or elasticity in the process. The individual straws should be long and unbroken, and the natural resistive varnish-like coating should be still preserved in a sample. The colour should be yellowish or a golden white; it should be clean-looking and free from dustiness. Straw should be free from thistles and other weeds.

Wheat straw has a particular advantage in that horses will not eat it unless kept very short of hay.

Oat straw This straw is also very good for bedding purposes, but it possesses one or two disadvantages when compared with wheat straw. The straw is considerably softer, more easily broken and compressible than wheat and, being sweet to the taste, horses eat it.

Barley straw is inferior to either of the preceding for these reasons: it is only about half the length; it is very soft and easily compressed and therefore does not last as long as oat or wheat;

VetBooks.ir

more of it is required to bed the same-sized stall; and it possesses numbers of awns. The awns of barley are sharp and brittle. They irritate the softer parts of the skin, cause scratches, and sometimes penetrate the soft tissues of the udder, lips, nose, or the region about the tail.

Rye straw Rye straw has the same advantages as wheat straw, but it is a little harder and rougher.

Peat-moss Peat-moss is quite a useful litter for horses. It is recommended for town stables and for use on board ship, or other forms of transport. A good sample should not be powdery, but should consist of a matrix of fibres in which are entangled small lumps of pressed dry moss. It is very absorbent – taking up six or eight times its own weight of water. When it is used, the drains should be of the open or 'surface' variety or covered drains should be covered with old sacks, etc.

It should never be used in a loose-box in which there is an animal suffering from any respiratory disease, on account of its dusty nature.

Sand makes a fairly good bed when the sample does not contain any stones, shells, or other large particles. It is clean-looking, has a certain amount of scouring action on the coat, is cool in the summer, and comparatively easily managed. Sand should be obtained from a sand pit or the bed of a running stream; it should not be obtained from the seashore, because the latter is impregnated with salt, and likely to be licked by horses when they discover the salty taste of which they are very fond. If this habit is acquired the particles of sand that are eaten collect in the colon or caecum of the horse and may set up a condition known as 'sand colic', which is often difficult to alleviate. It is useful when a horse has COPD, as are wood shavings and sawdust.

Ferns and bracken make a soft bed and are easily managed, but they always look dirty and untidy, do not last as long as straws, and are rather absorbent when stamped down. With horses that eat their bedding there is a risk of bracken poisoning.

Cattle Wheat straw is the most satisfactory. Oat straw is used in parts where little or no wheat is grown. Barley straw is open to objection as a litter for cows on account of its awns, which may irritate the soft skin of the perineal region and of the udder. Sawdust has been found very convenient in cow cubicles, also shavings. Sand has been used on slippery floors below straw bedding, when it affords a good foothold for the cows and prevents accidents. Sand can cause blockage of slurry systems. (See also DEEP LITTER FOR CATTLE.) Special rubber mats have been found practicable and economic for use in cow cubicles. Shredded paper has been used for cattle (and also horses).

A disadvantage of sawdust is that its use has led to coliform mastitis (sometimes fatal) in cattle. This is caused by hardwoods, softwoods contain natural cresols. Sand may then be preferable.

In milk-fed calves, the ingestion of peat, sawdust or wood shavings may induce hypomagnesaemia.

Pigs Many materials are used for the pig, but probably none possesses advantages over wheat straw, unless in the case of farrowing or suckling sows. These should be littered with some very short bedding which will not become entangled round the feet of the little pigs, and will not irritate the udder of the mother. For this purpose chaff, shavings and even hay may be used according to circumstances.

Straw can make up for deficiencies in management and buildings as nothing else can. It serves the pig as a comfortable bed, as a blanket to burrow under, a plaything to avert boredom, and a source of roughage in meal-fed pigs which can help obviate digestive upsets and at least some of the scouring which reduces farmers' profits. Straw can mitigate the effects of poor floor insulation, of draughts, and of cold; and in buildings without straw, ventilation (to quote David Sainsbury) 'becomes a much more critical factor'.

As a newborn piglet spends so much of its time lying in direct contact with the floor of its pen, much body-heat can be lost through conduction. Depending on the type of floor, this effect can be large enough to affect the piglet's growth rate and be a potential threat to its survival. Providing straw can be equivalent to raising the ambient temperature from 10° C to 18° C (50° F to 64° F). Wooden and rubber floors are not as effective as straw in reducing conductive heat loss.

Dogs and cats Dogs (and pigs) have died as a result of the use for bedding of shavings of the red African hardwood (*Mansonia altissima*), which affects nose, mouth, and the feet, as well as the heart.

Fatal poisoning of cats has followed the use of sawdust, from timber treated with pentachlorophenol, used as bedding.

Hamsters Synthetic bedding materials should be avoided as they can cause injury.

Poultry (See LITTER, OLD.)

Rabbits Peat-moss is recommended as it neutralises ammonia formed from urine; rabbits are particularly susceptible to ammonia in the atmosphere.

B

Bedlington Terrier

A small, soft-coated terrier with distinctive arched-back appearance. Together with some West Highland white terriers, they are prone to inherited copper toxicosis. The breed is relatively intolerant of high copper levels in the diet and may develop cirrhosis of the liver as a result. Zinc acetate has been used for treatment. Other inheritable conditions include brittle bones (OSTEOGENESIS IMPERFECTA) and RETINAL DYSPLASIA.

Bedsonia

(See CHLAMYDOPHILA.)

Beef Breeds and Crosses

The native British beef breeds are the Aberdeen Angus, Shorthorn Hereford, Devon, South Devon, Sussex, Galloway, Highland, Luing and South Devon. Continental breeds including the BELGIAN BLUE, BLONDE D'AQUITAINE, BROWN SWISS, CHAROLAIS, CHIANINA, GELBVIEHS, LIMOUSIN, PIEDMONTESE and SIMMENTAL have been imported for use in the United Kingdom. The continental breeds are more muscular, have higher mature weights and better performance than native breeds.

Most beef breed bulls are generally used as terminal sires on cows not required for breeding dairy herd replacements, and some beef cross heifers are used for suckler herd replacements. The cross-bred calves exhibit hybrid vigour and fetch a premium in the market over pure-bred dairy calves.

(See also CATTLE, BREEDS OF.)

Beef Cattle Husbandry in Britain

Around 58 per cent of home-produced beef is derived from the dairy herd, partly from dairy-bred calves reared for beef and partly from culled dairy cows. A further 34 per cent comes from the beef suckler herd.

Store systems Cattle are usually on one farm for less than a year, typically a winter (yard finished) or summer period (grass finished), but sometimes as short a period as 3 months. Only part of the production cycle takes place on a single farm, the possibility for using a wide range of technical inputs is limited. The profitability is dominated by the relationship between buying and selling prices, and these systems are characterised by large year-to-year fluctuations in margins. As a generalisation, the longer the cattle are on the farm, the higher the margin. The animals are finished for beef elsewhere.

Beef Shorthorn Cattle

Evolved in the 18th century from Teeswater and Durham cattle, Shorthorns were originally dual-purpose (milk and meat) but the Beef Shorthorn herdbook started in 1958. The society allowed the introduction of MAINE-ANJOU CATTLE blood to improve muscling. (See DAIRY SHORTHORN CATTLE; SHORTHORN CATTLE.)

Bees

Honey bees (*Apis* spp.) represent one of the oldest forms of animal husbandry. There is only one species of honey bee in the UK and there is an annual loss 10 per cent - 30 per cent of colonies. Bumble bees have 23 UK species (*Bombus* spp.); they collect pollen and not nectar and have a more limited range than honey bees; solitary bees have over 200 UK species. Bees fertilise 87 crop species that form 35 per cent of world food production.

Modern beehives are designed so that the honey-filled combs can be removed and replaced without disturbing the main chamber, a practice that also minimises swarming. The Italian Yellow-Banded bee is a better 'housekeeper' than the honey bee and is sometimes used in hives, when hygiene is important. The introduction is made by placing combs of Italian bee larvae in the honey bee hive so that the Italian bees do the cleaning up. The colour of the honey bee and the introduced Italian bees is derived from how they are fed; both will therefore look the same although the new arrivals will keep their housekeeper characteristics. Improved pollination of fruit farms can occur by having small patches of native plants on farmed land to attract bees.

Bees are subject to several diseases of which VARROASIS is the most prevalent. The bee louse is seen as bees defaecate in the hive, although usually they excrete while on the wing. Colony collapse syndrome occurs in the USA and its cause is uncertain. Its presence in the UK is arguable. A University of Stirling study has shown that Neonicotinoid pesticides, used to protect major crops, can be harmful to bees. Thus, imidacloprid slowed spring population growth and reduced queen numbers. Thiamethoxam appeared to affect navigation ability of bees after foraging. A temporary two-year ban on use of NEONICOTINOIDS was introduced in the EU during 2013.

Other diseases include brood diseases (chalk brood, chilled brood, European foul brood, Sac brood [also known as addled brood or stone brood]), viral diseases, and protozoal diseases (amoebiosis, nosemosis [*Nosema cerana*, *N. apis*]). American foulbrood (caused by *Paenibacillus* bacterium) is a NOTIFIABLE DISEASE; infected hives must be destroyed and movement restrictions placed on bees and equipment from the apiary concerned. It was detected in an apiary in Perthshire, Scotland, and also found elsewhere. The infected hive was destroyed and movement

VetBooks.ir

restrictions placed on bees and equipment from the apiary concerned. European foul brood caused by *Melissococcus plutonius* can be rapidly detected by a gold nanoparticle test, although an atypical strain has been recorded.

The National Bee Unit, run by DEFRA, provides advice on bee health issues (National Bee Unit, The Food and Environment Research Agency, Sand Hutton, York YO41 1LZ. Telephone: 01904 462510; email: nbu@fera.gsi.gov.uk).

General advice can be obtained from the British Beekeeping Association (BBKA), National Beekeeping Centre, Stoneleigh Park, Kenilworth, Warks CV8 2LG. Telephone: 02476 690 682; email: bbka@britishbeekeepers.com.

(See also under BITES, STINGS AND POISONED WOUNDS.)

Beetles

In poultry houses these insects in poultry houses have been shown to be reservoirs of avian reovirus, Newcastle Disease virus, Infectious Bursal Disease (Gumboro Disease) and *Salmonella* spp.

Beet Tops

(See POISONING – Fodder poisoning.)

Beevbilde Cattle

Breeding is based on 54 per cent polled Lincoln Red Blood, 40 per cent polled Beef Shorthorn, and 6 per cent Aberdeen Angus.

Behaviour Problems

Antisocial, or inappropriate, behaviour in dogs and cats is an increasingly common problem. There are a number of possible causes, including genetic traits in particular breeds, hormonally triggered behaviour and intentional or unintentional mistreatment. The fact that many animals are left alone for long periods while their owners are at work can encourage misbehaviour. The animal becomes distressed during the periods of absence and may resort to urinating or defecating; or in the case of dogs, chewing furniture. Then over-excitement, with uncontrolled barking and jumping, results on the owner's return. Aggressive behaviour to people or other animals is another common problem. Conversely, a pet may become obsessively attached to a single person, resenting any show of affection to that individual by another. While veterinary surgeons and 'pet counsellors' can offer advice on correcting unacceptable behaviour, it is greatly to be preferred that the problem is avoided in the first place.

When choosing a dog or cat, it is always advisable to see the puppy or kitten in its home environment. A pup from a litter born to a well-behaved bitch in a caring home is much more likely to develop into a good companion than a dog reared on a puppy farm with little opportunity to socialise with people. And one removed too early from its litter mates may later show aggression towards, or fear of, other dogs or cats. It also helps to avoid problems if a pet is selected that the owner can cope with easily. Big dogs need lots of space and lots of exercise; long haired breeds take a lot of grooming.

Punishment for 'bad' behaviour is rarely beneficial. Removing the cause, if possible, can help; rewarding for 'good' (correct) behaviour as part of a retraining process is more effective. Retraining requires patience and perseverance. The process may be assisted by the short-term use of medication. Megestrol (Ovarid) may be useful where the behavioural problem is hormonally triggered (spraying, aggression); or tranquillising drugs may be prescribed.

Belgian Blue Cattle

A beef breed noted for exceptional double hindquarter muscling. The British name is a misnomer, and it is now called BRITISH BLUE. DYSTOKIA may be a problem, in pure breeds and ones with Blue blood in them, partly due to a relatively narrow pelvis. Problems are much less in dairy type cattle, e.g. Holsteins. Maiden heifers should **not** become pregnant to a Belgian Blue bull or cows that have previously had dystokia after mating with Blue bulls.

Belgian Shepherd Dog

It is a breed in which cataract can be inherited as a dominant trait. Hip dysplasia is multifactorial while in the Tervueren form of the breed, epilepsy may be inherited by an unknown mechanism.

Belladonna

Belladonna is another name for the deadly nightshade flower (*Atropa belladonna*). (See ATROPINE.)

Belted Galloway Cattle

A beef breed, often called 'Belties', it is a variety of Galloway with a distinctive wide white strip around the abdomen in both black and dun animals. They are often slightly smaller and more dairy-like than the main beef breed type. (See GALLOWAY CATTLE.)

Beltex Sheep

A portmanteau name of Belgium and Texel; it is an offshoot of the Texel, with double muscling, used as a terminal sire for meat production. The breed entered Britain in 1989. They are polled and have no wool on the head or feet. The rams weigh about 90 kg (198 lb) and the ewes 70 kg (154 lb). Some ewes require CAESAREAN SECTION.

Bemigride

A central nervous system stimulant; may be used to counter barbiturate poisoning.

Belladonna (*Atropa belladonna*), also known as deadly nightshade, has thick, fleshy roots, dark green leaves, and purplish flowers. The berries change in colour from green to red, and then to black. The plant grows to a height of about 1.6 m (5 ft). All parts of the plant are poisonous.

Benadryl

Benadryl is the proprietary name of beta-dimethylamino-ethylbenz-hydryl ether hydrochloride, which is of use as an antihistamine in treating certain allergic conditions. (See ANTIHISTAMINES.

Benazepril

A medicine for congestive heart failure in dogs and chronic renal insufficiency in cats. It is rapidly absorbed from the intestinal tract and forms benazeprilat which is a potent inhibitor of angiotensin converting enzyme reducing the conversion of angiotensin I to angiotensin II. The result is a reduction in vasoconstriction of arteries and veins, retention of sodium and water by the kidneys and remodelling of cardiac hypertrophy and degenerative renal changes.

Bengal

A breed of cat developed from crossing the domestic cat (*Felis catus*) with the Asian wild cat (*F. ornata*). It is not considered as a hybrid between a wild animal and a domestic animal under the Dangerous Wild Animals Act 1976. The breed is prone to hip dysplasia and distal neuropathy. An anatomical anomaly described as 'flat chest syndrome' can also occur leading to breathing difficulties.

Benthos

This is the area round the sea bed. Several benthic species of fish are farmed including the common sole, Dover sole and turbot. The last species lay 1,500,000 eggs at a time and so it requires only a few female fish to start a farm.

Benzalkonium Chloride

One of the quaternary ammonia compounds; it is used as an antiseptic and detergent. (See under QUATERNARY AMMONIUM COMPOUNDS.)

Benzene Hexachloride (BHC)

The gamma isomer of this (lindane) is a highly effective and persistent ectoparasiticide, which was formerly the main ingredient of several proprietary preparations, designed for use as dusting powder, spray, dip, etc. Its use in animals is now banned in many countries, including the UK, although the compound still keeps appearing in the environment and occasionally in animals. It is highly toxic for fish.

BHC is the common abbreviation for the gamma isomer. (See BHC POISONING.)

Benzimadazoles

A family of pharmaceutical products used as anthelmintics used in the treatment of roundworms and, in some cases, fluke infestations in mammals, birds and reptiles. Examples include ALBENDAZOLE, FLUBENDAZOLE, MEBENDAZOLE, OXFENDAZOLE, and THIABENDAZOLE.

Benzocaine

Benzocaine is a white powder, with local anaesthetic properties, used as a sedative for inflamed and painful surfaces and for general anaesthesia in fish.

Benzocaine-poisoning This has occurred in cats following use of either a benzocaine spray or ointment, and results in methaemoglobin appearing in the blood.

Signs In one case a cat showed signs of poisoning following an application of the cream to itchy areas. Cyanosis, open-mouthed breathing and vomiting occurred. Collapse followed within 15 minutes.

Improvement was noticed within 10 minutes of giving methylene blue intravenously; and within 2 hours breathing had become normal again. The cat recovered.

Benzoic Acid

Benzoic acid is an antiseptic substance formerly used for inflammatory conditions of the urinary system. It is excreted as hippuric acid, and renders the urine acid. It is used in the treatment of ringworm, and as a food preservative.

VetBooks.ir

Benzoic Acid Poisoning Cases of this have been reported in the cat, where benzoic acid was used as a food preservative, giving rise to extreme aggressiveness, salivation, convulsions and death. A curious sign sometimes observed is jumping backwards and striking out with the fore-limbs 'as though catching imaginary mice'.

Benzoyl Peroxide

It is used in shampoos for dogs to control bacterial skin disease and seborrhoea.

Benzyl Benzoate

Benzyl benzoate is a drug formerly used for treating mange in dogs and sweet itch in horses. A 25 per cent preparation may be applied to mite, etc., bites in pigeons.

Benzyl benzoate is usually employed as an emulsion. It should not be used over the whole body surface at once.

Benzylpenicillin

Bactericidal antibiotic, active against Gram-positive bacteria, and given by parenteral or intramammary infusion. It is inactivated by PENICILLINASE.

Bephenium Embonate

A drug which is used in sheep to kill Nematodirus worms.

Berkshire Pigs

They are said to be 'Britain's oldest pig breed', being black pigs with white on the legs, faces and tips of the tail. They are early maturing and have a dished face, short legs and are of medium length. In Britain they are now a rare breed, and probably helped to develop the PIÉTRAIN breed.

Bernese Mountain Dog

A large, long-haired breed, mainly black with white with brown markings. Three inherited conditions have been recorded: primary and secondary CLEFT PALATES, HYPOMYELINOGENESIS and OSTEOCHONDROSIS but the mechanism is unknown and VON WILLEBRAND'S DISEASE. Also known as the Swiss mountain dog.

Berrichon Du Cher

A French breed of heavy milking sheep. The breed contains some merino blood.

Beryllium (Be)

This is believed to be an essential trace element, but its role has not been determined. Fumes from industrial plants can contain beryllium and inhalation can result in pneumonia.

Besnoitiosis

A protozoan disease usually affecting the skin and mucous membranes; other effects may include sterility. Not normally found in temperate countries but may appear following climate change.

Beta-Adrenergic Agonists, Beta Adrenoreceptor Agonists, β-agonists

These are pharmaceutical agents that bind on beta receptors on striated muscles (skeletal, heart) and smooth muscles (especially relaxing bronchial and uterine smooth muscle) as well as improving energy production. They mimic the actions of ADRENALIN and NORADRENALIN. There are two types: ß1 agonists such as adrenalin and ß2 agonists including salbutamol and CLENBUTEROL HYDROCHLORIDE. They are the opposite of beta-blockers. (See also RACTOPAMINE.)

Beta-Blocker

(See AGONIST.)

Betahydroxybutyrate (BHB; BHBA; BOHB)

A ketone body which can be measured in blood to determine the energy status. The higher the level, the poorer the energy intake. It is particularly of use in ruminants. It can be measured in milk with a cow-side test.

Betaine

The name commonly used for trimethylglycine; it is present in many feed ingredients especially sugar beet pulp. Growing animals use much energy in maintaining osmotic balance in their alimentary tracts. Betaine can spare some of the energy, resulting in improved growth. Its presence may be the reason why sugar beet pulp is regarded as 'nature's blotting paper' when treating diarrhoea.

β-Lactamase, Beta-Lacramase

Enzymes produced by bacteria which cause resistance to certain antibiotics (e.g. penicillins, cephalosporins) by breaking down the β-lactam ring.

Betamethasone

A corticosteroid.

BEVA

(See BRITISH EQUINE VETERINARY ASSOCIATION.)

Beveren

One of the oldest and largest breeds of rabbit. Coat colour is blue, white, black, brown and lilac. The animals are docile, energetic and inquisitive so that they make good pets.

BHB
(See BETAHYDROXYBUTYRATE.)

BHC
(See BENZENE HEXACHLORIDE.)

BHC Poisoning
This may arise, especially in kittens and puppies, from a single dose (e.g. licking of BHC-containing dusting powder). Signs include: twitching, muscular incoordination, anxiety, convulsions.

A farmer's wife became ill (she had a convulsion) after helping to dip calves, but recovered after treatment. Two of the calves died.

BHC is highly poisonous for fish; it must be used with great care on cats (not used in UK), for which other insecticides such as selenium preparations are to be preferred.

The use of BHC sheep dips is no longer permitted in the UK.

BHS
Beta haemolytic streptococcus, a Gram-positive circular bacterium, naturally occurring in chain formation and causing red blood cells to lyse in the laboratory incubator. (See LYSIS.)

Bibersteinia trehalosi
The current name for an organism previously known as *Pasteurella haemolytica* biotype T and then *Pasteurella trehalosi*. It is a Gram-negative pleomorphic rod particularly causing septicaemia in sheep. It has also been found in cattle where it forms part of the bovine respiratory disease syndrome. (See PASTEURELLOSIS IN SHEEP; BOVINE RESPIRATORY DISEASE COMPLEX; ENZOOTIC PNEUMONIA OF CALVES; ENZOOTIC PNEUMONIA OF PIGS; ENZOOTIC PNEUMONIA OF SHEEP.)

Bicarbonate
A salt containing HCO_3; the amount in blood determines the acid/base balance. Sodium bicarbonate is used as an antacid in ruminal acidosis. A saturated solution is a useful DEMULCENT applied to the skin.

Bichon Frise
A breed of small white dog from Belgium, not unlike a miniature poodle, which has become popular in Britain in recent years. Cataract can be inherited by an unknown mechanism.

Bifid Tongue
A cleft tongue.

Bighead
Term used to describe osteodystrophia fibrosa in horses and goats caused by a calcium/phosphorus imbalance in the diet. (See BRAN DISEASE). In Australia it is attributed in horses to the ingestion of buffel, pangola, setaria, kikuyu, green panic, guinea and signal grass, which contain high levels of oxalate that chelates the calcium in the intestines and prevents adequate absorption, thereby eventually leading to osteofibrosis.

'Big Head'
A condition associated with *Clostridium novyi* (type A) and other clostridial species infection in rams which have slightly injured their heads as a result of fighting. It occurs in UK, Australia and South Africa. (See also HYDROCEPHALUS.)

Bilateral
Occurring on two sides, having two sides. (See also UNILATERAL.)

Bile
Bile is a thick, bitter, golden-brown or greenish-yellow fluid secreted by the liver and stored in the gall-bladder, except in horses which do not have the organ. It has digestive functions, assisting the emulsification of the fat contents of the food. It has in addition some laxative action, stimulating peristalsis, and it aids absorption of fats and fat-soluble vitamins. (See CHOLECYSTOKININ.)

JAUNDICE or ICTERUS is a sign rather than a disease; it may be caused when the flow of the bile is obstructed and does not reach the intestines, but remains circulating in the blood or from haemolysis. As a result, the pigments are deposited in the tissues and discolour them, while the visible mucous membranes are yellowish.

Vomiting of bile usually occurs when the normal passage through the intestines is obstructed, and during the course of certain digestive disorders. (See also GALLSTONES.)

Bile Acids
Steroid acids produced from the liver. The amount circulating in the blood can be measured in conjunction with other tests in an attempt to assess liver function.

Bilharziosis
Bilharziosis is a disease caused by bilharziae or schistosomes; these are parasites of about 0.25 cm to 1 cm in length which are sometimes found in the bloodstream of cattle and sheep in Europe, and of horses, camels, cattle, sheep, and donkeys in India, Japan and the northern seaboard countries of Africa. (See SCHISTOSOMIASIS.) Dogs may also suffer from these flukes.

Biliary Fever
(See CANINE BABESIOSIS; EQUINE BILIARY FEVER.)

VetBooks.ir

Bilirubin
A bile pigment circulating in blood; it is a breakdown product of the blood pigment haem.

Biliverdin
A bile pigment that circulates in the blood of herbivores.

Bill
See BEAK, usually large.

Binovular Twins
Binovular Twins result from the fertilisation of 2 ova, as distinct from 'monovular twins' which arise from a single ovum.

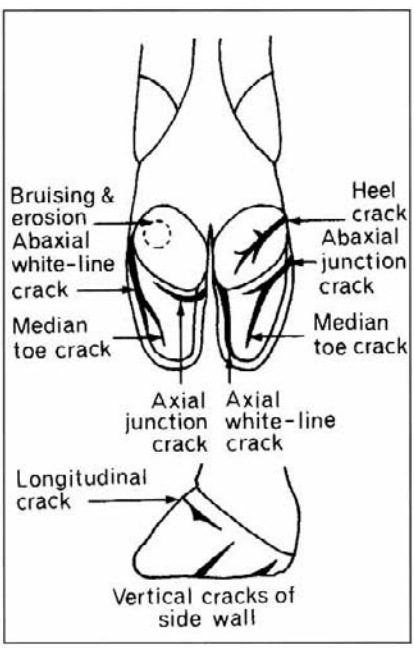
Biochemistry
The study of chemical reactions within the body.

Biocide
A biocide destroys living organisms; sodium hypochlorite (bleach) is an example.

Biofilm
A layer of organic material adhering to the inner surfaces of pipes and equipment. It is an excellent material for bacterial growth and must be removed regularly to prevent this. Attention should also be paid in kennels where water is supplied by nipple drinkers. Flushing with 1.5 to 3.0 bars of pressure can dislodge it.

Bioluminescence
The emission of light by an organism, such as is seen in fireflies and some fish. It results from a chemical reaction which produces light with virtually no heat.

Biomass
All the living organisms in a given area. In veterinary practice, the term is used to express stocking density as kilograms of live animals per square metre of floor space.



Biophysics
The study of physical actions within the body.

Biopsy
Biopsy is a diagnostic method in which a small portion of living tissue is removed from an animal and examined by special means in the laboratory so that a diagnosis may be made.

Biosecurity
A term used to describe the precautions necessary on farms (and certain other establishments where animals are kept) to prevent disease entering and infecting the animals resident on the premises. It is achieved by controlling and minimising all movements of animals, animal products, people, transport, etc., onto the farm, and discouraging vermin and bird entry. Animals brought on the farm should be (as far as possible) of known origin and of a similar health status to those already present. They should have received vaccinations or other preventive treatments for any diseases present on the previous farm as well as those on the one to which they are moving. They should be quarantined before being exposed to some of the resident animals: ideally, old cull animals before the latter leave the farm, to ensure that the new entrants have experienced the pathogens present on the farm and also to check that the culls do not contract anything from the new entrants.

Biotechnology
The application of biological knowledge, of micro-organisms, systems or processes to a wide range of activities, such as cheese-making, animal production, waste recycling, pollution control, and human and veterinary medicine. For the manipulation of genes, see GENETIC ENGINEERING.

Biotechnology and Biological Sciences Research Council
The body established in 1994 which incorporates the work of the Agriculture and Food Research Council, and the Biotechnology Directorate and Biological Sciences Committee of the former Science and Engineering Research Council.

The position of foot lesions in pigs suffering from a biotin deficiency. (With acknowledgements to Dr Peter Brooks.)

Biotin
A water soluble vitamin of the B group; also known as vitamin H.

A deficiency of biotin is linked to foot problems, mainly associated with the hoof. The hoof horn in horses and cattle is believed to be strengthened by a biotin-rich diet; foot lesions in pigs (see illustration on previous page) may similarly benefit, as may 'soft' or diseased claws of dogs.

Biotype
A group or strain of a micro-organism or species that has distinguishable physiological characteristics.

Biphosphonates
These are used where there is a loss of bone density to prevent the breaking down of bone.

Bird-Fancier's Lung
Patients may be regarded as having bird-fancier's lung if they satisfy all the following criteria: recent history of avian exposure; serum avian precipitins; diffuse shadowing on chest radiograph; a significant reduction (less than 70 per cent predicted value) of carbon-monoxide transfer factor (single breath); and improvement or no deterioration when exposure to birds and their excreta is ceased.

In some cases there have been changes in the intestine (villous atrophy).

In the acute form, most often seen in pigeon-fanciers after cleaning the loft, influenza-like signs, a shortness of breath and a cough occur after four to six hours. The disease in elderly patients has to be differentiated from bronchitis and emphysema.

Bird Import Controls
Bird import controls were imposed in Great Britain in 1996, and a licence is required for all imports of captive birds and hatching eggs. All birds except those from Belgium are subject to a quarantine of 35 days. Birds imported into the EU are subject to quarantine. (See also PIGEONS.)

Bird Louse
Bird louse is a parasitic insect belonging to the order Mallophaga, which attacks most domesticated and many wild birds. The lice eat feathers and the cells shed from the surface of the skin, but they do not suck blood. Dusting with parasiticide powder is an efficient remedy. A small cage bird affected with lice may be placed in a paper bag and dusted with insecticidal powder such as pybuthrin/piperonyl butoxide. (See LICE.)

Bird Malaria
A tropical disease of fowls and turkeys caused by *Plasmodium gallinaceum*, *P. durae* and other species, transmitted by mosquitoes.

It may run a rapidly fatal course, or a chronic one with anaemia and greenish diarrhoea.

Birds
(See under AVIAN; also CAGE AND AVIARY BIRDS, DISEASES OF; GAME BIRDS, MORTALITY; TURKEYS; POULTRY AND POULTRY KEEPING; ORNITHOSIS; BOTULISM; FALCONS, DISEASES OF; PETS, CHILDREN'S AND EXOTIC; RABIES; OSTRICH; RHEA.)

Birds, Blood Sampling
The toenail-clip method enables blood to be collected into a micro-haematocrit tube or pipette. The bird can be held with its back against the palm of the hand, head between thumb and forefinger, making sure the sternum is not impeded. The resultant sample may be contaminated with droppings and so the jugular vein is preferred. With a little practice, it is accessible even in small birds.

Larger cage birds have easily accessible jugular veins, the right side being larger than the left. In pigeons and doves (Columbiformes), the presence of a venous anastomosis makes attempts to puncture the jugular vein dangerous in these species. In raptors, fowl and pigeons, the brachial vein is favoured; the tarsal vein is preferred for blood sampling in water fowl.

Birds, Humane Destruction of
For poultry and other birds, a lidless wooden box or chamber (of a size to take a polypropylene poultry crate) and a cylinder of carbon dioxide with regulating valve are useful. The box has a 1.3-cm (½ in) copper pipe drilled with 0.35-cm (9/64-in) holes at 10-cm (4-in) centres fitted at levels 5 cm (2 in) and 66 cm (2 ft 2 in) from the bottom and connected by plastic tubing to the regulator valve of the cylinder.

Birdsville Disease
Birdsville disease occurs in parts of Australia, is due to a poisonous plant *Indigofera enneaphylla*, and has to be differentiated from Kimberley horse disease.

Signs Sleepiness and abnormal gait with front legs lifted high. Chronic cases drag the hind limbs.

Birhinia
Congenital deformity consisting of a double nose.

Birman
A foreign breed of short-hair cat. Degenerative distal polyneuropathy has been identified in this breed as an autosomal recessive trait.

Birnavirus
A member of the family Birnaviridae, it is a non-enveloped virus containing two segments of

VetBooks.ir

double-stranded RNA. It causes INFECTIOUS BURSAL DISEASE and TRANSMISSIBLE VIRAL PROVENTRICULITIS in chickens and INFECTIOUS PANCREATIC NECROSIS in salmon and trout.

Birth

(See PARTURITION.)

Bisexual

An animal having both male and female sex organs. Many male freshwater fish in British river and lake waters are bisexual, a condition attributed to oestrogens in the water. The oestrogens are thought to have originated from oestrogens in the urine of women taking contraceptive pills.

Bismuth (Bi)

Bismuth (Bi) is one of the heavy metals.

Uses The carbonate, subnitrate, and the salicylate may be used in irritable and painful conditions of the stomach and intestines; also to relieve diarrhoea and vomiting.

The oxychloride and the subnitrate are used like barium, in bismuth meals prior to taking X-ray photographs of the abdominal organs for purposes of diagnosis.

Bison

Large ruminant ungulates which are in the Bovidae Family. Two species survive, the American bison (*Bison bison*) and the European bison or WISENT (*Bison bonasus*). The American bison is also called the American BUFFALO. Both species are under threat with small numbers in the wild and there are captive breeding programmes in operation. They are used for meat.

Bistoury

A surgical knife used to open up stenosed (closed up) teats, fistulae, sinuses; and abscesses.

Bites, Stings and Poisoned Wounds

The bites of animals, whether domesticated or otherwise, should always be looked upon as infected WOUNDS. In countries where RABIES is present, the spread of this disease is generally by means of a bite.

TETANUS is always a hazard from bites.

Bees, wasps and hornets cause great irritation by the stings with which the females are provided. Death has been reported in pigs eating windfall apples in which wasps were feeding. The wasps stung the mucous membrane of the throat, causing great swelling and death from suffocation some hours later.

Antihistamine preparations may be used in treatment if numerous stings make this necessary.

Cat-bites and Scratches can be dangerous and a threat to human health. They can introduce Suppuration, *Pasteurella multocida*, *Streptococcus* spp., *Fusobacterium* spp. and *Bartonella* spp., the last is the possible cause of CAT-SCRATCH FEVER. Tetanus is less likely to be contracted from cats and dogs than from horses. (See WOUNDS; RABIES.)

Dog-bites are usually inflicted upon other dogs, defenceless sheep or goats, and sometimes pigs; cattle may be bitten by the herd's dog and serious wounds result. The bite is generally a puncture wound or large tear, depending upon the part that is bitten. Where an animal is bitten in numerous places, even though no individual bite is large, there is always a considerable degree of danger. Antibiotics should be given by injection. The wounds should be dressed with some suitable antiseptic, the hair or wool being first clipped from the area; and left open. (See WOUNDS; RABIES.)

In the USA, about a million dog-bites a year require medical treatment of people; and in the UK the figure has been estimated as about 99,000. Dog-bite wounds are often infected by *Pseudomonas* species, *Staphylococcus aureus*, *Streptococcus viridans*, *Pasteurella multocida*, and Group EF-4 bacteria.

Horse-bites Actinobacillosis has been transmitted to a bitten person.

Monkey-bites can transmit encephalitis caused by *Herpes simiae*; human infectious hepatitis; also TB. (*Lancet*, **2**, 553.)

Rodent-bites The main organism transmitted by rodents is *Leptospira icterohaemorrhagiae*, which causes Weil's disease in man. Hantaan virus is also transmitted by rodents and causes Korean haemorrhagic disease (which has many synonyms) in man.

Snake-bites (See SNAKES.)

Spider-bites (See SPIDERS.)

Bittersweet Poisoning

The common 'bittersweet' – *Solanum dulcamara* – is a frequent denizen of hedgerows and waste lands, and, although not likely to be eaten to a great extent by domesticated animals, cases of poisoning due to its ingestion have been recorded. All parts of the plant – stem, leaves and berries – contain the toxic principle, which is an alkaloid similar to *Solanine* found in the potato.

Signs In cattle and sheep there is giddiness, quickening of the respiration, staggering gait, dilated pupil, greenish diarrhoea and raised temperature.

Bittersweet (*Solanum dulcamara*) has purple flowers with bright yellow anthers. The berries are first green, then yellow, finally turning to a brilliant red. This is a climbing plant and may reach a height of 2 m (6 ft) or so. Bittersweet is also known as woody nightshade.

Black Disease

Black disease is the name given to infectious necrotic hepatitis of sheep and occasionally of cattle in Australia, New Zealand, Scotland, Wales and NW England. It is typically caused by a combined attack of immature liver flukes and bacteria, e.g. *Clostridium novyi* Type B, which is one of the so-called 'gas gangrene' group, and is capable of forming resistant spores.

On post-mortem examination the most striking feature is the rapidity with which affected sheep decomposed. In carcases of sheep recently dead or killed in the later stages, the skin is a dark bluish-black colour, and the underlying tissues are congested and oedematous. In the liver, where the most constant lesions are found, there are one or more necrotic areas about 2.5 cm (1 in) in diameter.

In cattle, black disease caused by *Clostridium novyi* Type B (*Cl. oedematiens* type B) may not be associated with liver fluke.

Prevention An antiserum and a vaccine are available.

Blackface Sheep

A name used to describe SCOTTISH BLACKFACE SHEEP. It was the most numerous sheep in 2003 representing about 1.7 million ewes and about 11 per cent of the pure-bred flock. Blackface are particularly found in Scotland and the North of England; the ewes are often crossed with rams of BORDER LEICESTER, BLUE-FACED LEICESTER or other breeds.

Black Faeces

Black faeces are passed when either iron or bismuth salts are given to dogs and pigs. The most serious cause of black motions is haemorrhage into the early part of the digestive system. A dark-coloured diarrhoea may be seen in the dog suffering from deficiency of the B vitamin.

Black Hair Follicular Dysplasia

A genetic disorder of the follicles of black-pigmented hair in black dog breeds. In the black areas the hair is sparse and the skin scaly. It is seen in LARGE MUNSTERLANDERS.

Blackhead

This disease mainly occurs in turkeys (see BLACKHEAD OF TURKEYS), but it can also infect chickens and game birds such as partridges and pheasants. It can result in high mortality (see GAME BIRDS, MORTALITY).

Blackhead of Turkeys, Histomoniasis; Histomoniosis

Blackhead of turkeys (histomoniasis) is a very common and fatal disease of young turkeys (from three weeks to four months old), which is caused by a small protozoon parasite, *Histomonas meleagridis*, and which may spend part of its life in the roundworm (*Heterakis gallinae*, as an intermediate host) where it can live in suspended animation. The histomonas is found in adult worms and eggs; ingestion of the latter is the chief means of spread. Direct transmission from bird to bird is also possible.

Though turkeys are chiefly affected, the disease is also common in guinea fowl and may be seen in partridges, pheasants, grouse, quail and pea-fowl; it is rare in poultry. Where the worm has been present on the premises, it is difficult to remove the parasite.

Signs Loss of appetite and of condition. The droppings may be semi-liquid and bright yellow. Death, in five to eight days, may occur in 70 per cent to 90 per cent of turkeys, in which the disease is very acute and prevalent in summer and autumn.

Treatment Dinitridazole or nifursol, administered in the feed, may be used for prevention and treatment (these are now banned in the UK).

VetBooks.ir

Black-Leg
(See BLACK-QUARTER.)

Black-Quarter
Black-quarter, also called black-leg, quarter-ill, etc., is an acute specific infectious disease of cattle, sometimes of sheep, and likewise of horses and camelids, characterised by the presence of rapidly increasing swellings containing gas, and occurring in the region of the shoulder, neck, thigh and quarter, and sometimes in the diaphragm. Young cattle between the ages of three months and two years are most susceptible.

The disease has been seen in the reindeer, camel, and the buffalo.

Causes *Clostridium chauvoei*, which lives in the soil until such time as it gains entry into the animal body either along with the food or else by abrasions of the skin (see TATTOOING).

On exposure to the air, the organisms form spores which are resistant to extreme cold or heat.

Signs The finding of a dead animal may be the first indication of the disease; though sometimes lameness is observed, and part of the udder swollen and very painful. If seen in the early stages, the swelling is hot and pits on pressure, but, increasing rapidly, it becomes puffed up with gas (emphysematous), and if pressed it crackles as if filled with screwed-up tissue-paper. Death usually occurs within 24 hours. Sheep show somewhat similar signs, but they may be attacked at almost any age. There are often blood-stained discharges from both the nostrils and the rectum.

Prevention Marshy ground that has been responsible for the loss of numerous animals in the past has often been rendered safe by the draining of the land and heavy liming.

Vaccine A vaccine is very effective.

Curative There is generally no opportunity to treat cases, since death occurs after only a few hours' illness; otherwise penicillin and antiserum may be tried.

Black Rock Chickens
This is a first cross hybrid of RHODE ISLAND RED (male line) and BARRED PLYMOUTH ROCK (female line) produced by Harco/Arbor Acres. A very successful hybrid for free range, laying 280+ brown eggs per year. They are black in colour.

'Black Tongue'
The counterpart of human pellagra. It is shown in the dog fed a diet deficient in nicotinic acid. (See also SHEEPDOGS and 'BROWN MOUTH'.) Signs include discoloration of the tongue, a foul odour from the mouth, ulceration, loss of appetite and sometimes blood-stained saliva and faeces. Death will occur in the absence of treatment.

Black Turkey
These were the original variety of turkey in Great Britain; they are now known as the NORFOLK BLACK.

Black Vomit
Black vomit is due to the presence of blood in the stomach. Either the appearance of the vomit may be that of black masses of clotted blood, or it may resemble coffee-grounds.

Black-Water Fever
A form of babesiosis (see under BABESIA); also known as TEXAS FEVER; it causes a severe form of human malaria.

BLAD
(See BOVINE LEUKOCYTE ADHESION DEFICIENCY.)

Bladder, Diseases of
(See under URINARY BLADDER, DISEASES OF; also GALL-BLADDER.)

Bladder Cancer
This may cause difficulty in passing urine, sometimes with blood in the urine. Signs in dogs included HAEMATURIA, DYSURIA, TENESMUS, INCONTINENCE, and POLYURIA. Many of the tumours are carcinomas (see CANCER) and on CYSTOTOMY often PAPILLOMAS are found during removal of urinary calculi.

A squamous cell carcinoma occurs in the bladder of older suckler cows following ingestion of bracken (which contains activating factors) over many years. The main sign is blood in the urine with frequent MICTURITION. There is no cure, but improving the nutritional status of the cattle helps prevent it.

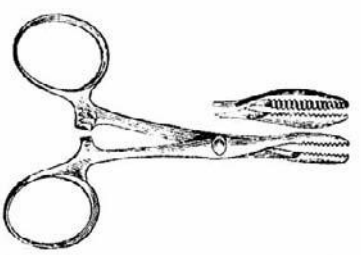
'Blaines'
A local name often used to describe URTICARIA in cattle.

Blastocyst
Blastocyst is the name given to a very early stage in the development of the fetus.

Blastomycosis of Dogs
Infection with *Blastomyces dermatitidis*.

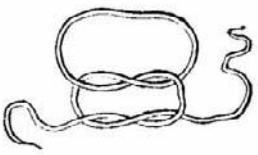
The disease is fairly common in both man and dogs in North America. Diagnosis depends upon a laboratory demonstration of the fungus, which typically causes chronic debility often with a fatal outcome.

Infection is usually through inhalation. Bone lesions, resulting in lameness, often occur; sometimes the brain, nose, eyes, and prostate gland show lesions.



'Bleeder Horses'

Those which show blood at their nostrils after hard exercise. (See also RACEHORSES – Pulmonary haemorrhage.)



Bleeding, Haemorrhage

Bleeding (haemorrhage) may be classified according to the vessel or vessels from which it escapes: e.g. (a) arterial, in which the blood is of a bright scarlet colour and issues in jets or spurts corresponding in rate and rhythm to the heart-beats; (b) venous, when it comes from veins, is of a dark colour, and wells up from the depth of a wound in a steady stream; and (c) capillary, when it gradually oozes from a slight injury to the network of capillaries of an area. (See also under CANINE HAEMOPHILIA; HAEMORRHAGIC DIATHESIS; INTERNAL HAEMORRHAGE.)

Natural arrest When an artery with a small calibre is cut, the muscular fibres in its middle coat shrink, and the cut end is slightly retracted within the stiffer fibrous covering. This results in a diminution in the size of the cut end and in a lessened capacity for output of blood. In the space between the end of the muscular coat and at the end of the fibrous coat a tiny clot commences to form, which, later, is continued into the lumen of the vessel. This is added to by further coagulation of blood, until the whole of the open end of the vessel and of the cavity of the wound is sealed by a clot. A fall in blood-pressure, due to shock and loss of blood, contributes to the natural arrest of bleeding. (See CLOTTING OF BLOOD.)

Artery forceps, with jaws shown enlarged.

Surgeon's knot, or reef knot, used for ligaturing cut vessels.

Bleeding, external: first aid for When a vein is cut, crimson blood will flow. From a cut artery, scarlet blood will spurt, issuing in jets corresponding with the heartbeats.

When a large vessel is cut, pressure should be applied above the wound if the bleeding is from an artery, below it if bleeding is from a vein; but the first-aider should take precautions (see RESTRAINT.)

Pressure with the fingers is a helpful preliminary while someone else is finding material to use as a pressure pad. For large animals a clean pillowslip, small towel, or piece of sheet will serve; for small animals a clean handkerchief may suffice. The pad is then placed over the wound, and held there; pressure being applied and maintained for a quarter of an hour.

Tourniquet Only if these measures fail to stop serious haemorrhage should a tourniquet be used. A tourniquet can be improvised from a rolled handkerchief, its two ends knotted, slipped around the limb, and tightened with a pencil. Tightening must be just sufficient to stop the bleeding, no more. For large animals a piece of rubber tubing or a soft rope may be used. **A tourniquet must never be left on for more than 20 minutes, or permanent damage to the limb will result**. When releasing the tourniquet, do so gradually. A tourniquet should not be used on cats, in which a pressure pad will suffice to control bleeding.

Professional help should be obtained as soon as possible.

Sometimes the actual point or points of bleeding cannot be located, especially when the wound is deep or ragged, and the blood issues in a more or less continuous stream showing no tendency to clot. In such cases it is necessary to resort to packing the wound with GELATIN SPONGE.

Professional help will also be needed to counter SHOCK. (See also BLOOD TRANSFUSIONS; DEXTRAN.)

Bleeding from special parts

1. The Horns The horns of cattle are sometimes broken by falls or blows, and severe bleeding follows. If the horn is broken completely off, the haemorrhage is to the outside from the stump, but it often happens that while the bony horn-core is fractured the horn itself holds the broken end in position, and the escaping blood finds its way down into the frontal sinus and out by the nostril. Haemorrhage from a stump may be controlled by

VetBooks.ir

the application of a pad and a bandage. Thermocautery, using a disbudding iron, may assist.

2. Legs and Feet The tourniquet described above may be applied, to the lower side of the injury if the bleeding is venous, and above if it is arterial. When the upper parts of the limbs are injured and the haemorrhage is considerable, one of the methods of pressure is adopted until professional veterinary aid can be obtained.

3. Stomach The vomiting of blood by dogs, cats and pigs in considerable amounts is a very serious sign of severe injury or disease in the stomach.

A dog may be offered ice cubes to lick. The animal should be kept as still as possible, and veterinary assistance obtained. Alcohol is not advisable, as it causes a dilatation of the vessels of the stomach wall and tends to promote the bleeding.

4. Uterus and Vagina After parturition in all animals there is a certain risk of haemorrhage, especially in those which have a diffuse placenta, such as the mare and ass, and when the fetal membranes have been forcibly removed. If it is copious, it may prove fatal. Prompt veterinary attention is necessary. (See also under WOUNDS; INTERNAL HAEMORRHAGE.)

5. Navel in piglets. See under VITAMINS - VITAMIN DEFICIENCIES for prevention.

Bleeding, internal (See INTERNAL HAEMORRHAGE.)

Bleeding Calf Syndrome

(See BOVINE NEONATAL PANCYTOPENIA.)

Blepharitis

Inflammation of the eyelids. It is usually associated with conjunctivitis.

Blepharospasm

Blepharospasm is a spasm of the eyelids.

Blindness

(See under EYE, DISEASES AND INJURIES OF; also VISION.)

Blister

A collection of fluid causing a swollen sac, separating the stratum corneum from the stratum germinativum measuring less than 5 cm in diameter.

Blister Disease

A condition in snakes housed in conditions of excess humidity. It is particularly common in water and garter snakes. The blisters are sterile but prone to secondary infection. They may be lanced and treated with antiseptic and correcting the underlying cause.

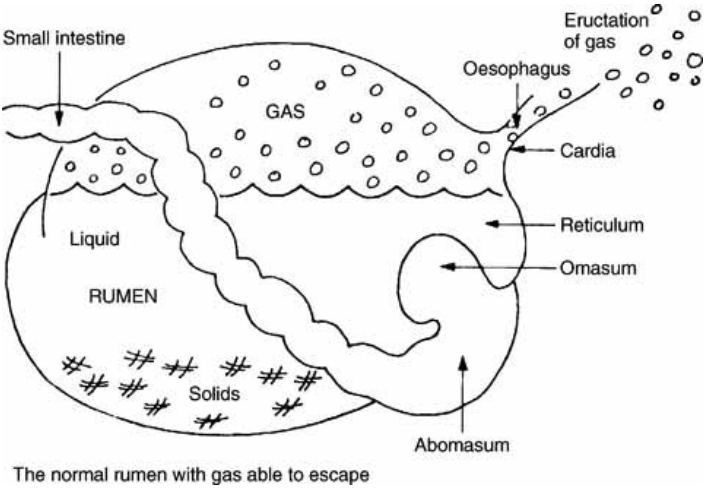
Bloat

Also known as ruminal tympany (gas in rumen), it occurs in cattle, sheep and goats. With the increased use of lucerne and clovers, bloat has become of more common occurrence among cattle and is now a matter of serious economic importance. It may be of two types: free gas bloat or frothy bloat.

Free gas bloat The rumen becomes distended with gas, and pressure is exerted upon the diaphragm.

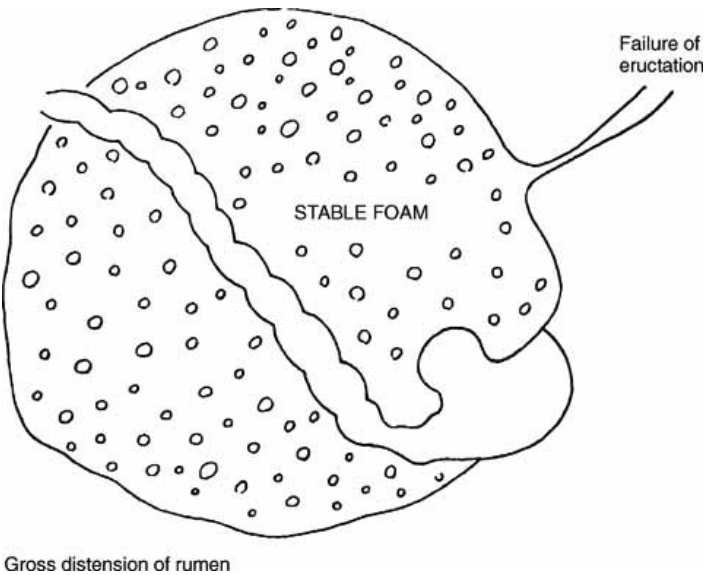
The medium-sized cow's rumen has a capacity of some 160 litres (35 gallons), and fermentation within it gives rise to bubbles of gas. This comprises carbon dioxide (CO_2) and methane (CH_4) in surprisingly large quantities; cattle producing as much as 800 litres of CO_2 in 24 hours, and as much as 500 litres of CH_4. Some of this gas, perhaps a quarter, escapes via the bloodstream to the lungs and is breathed out, but that still leaves a great deal which can be expelled only by belching. If something makes that impossible, then gas pressure builds up and is exerted on the diaphragm, heart and lungs, so that the cow is soon in considerable distress.

The cow's ability to belch may be affected by physical obstruction of the oesophagus; paralysis of the muscular wall of the rumen; and foaming of the rumen contents.



The first diagram shows a healthy state of affairs in the rumen, with the cardia – a muscular valve at the junction of oesophagus and rumen – temporarily open so that gas can escape up the oesophagus. But when this tube is obstructed by a piece of potato, turnip or a tumour or an abscess, the gas cannot get away (or not in sufficient quantity), and 'gassy bloat' results. Paralysis of the muscular wall of the rumen has a similar effect, since expulsion of gas is aided by contraction of these muscles.

The most common cause of gassy bloat is ruminal acidosis following a barley diet, or in cases of obstruction or dysfunction of the oesophageal or cardiac sphincter.



In such cases an antacid drench may be effective, but passing a stomach tube, where this is practicable, can provide immediate relief by the release of trapped gas. Veterinary advice should be sought.

In an emergency a RUMENOTOMY may be performed or a trocar and cannula used.

Frothy bloat With the frothy type of bloat, puncturing the rumen with a trocar and cannula in an emergency may do more harm than good –

The normal rumen with gas able to escape

Gross distension of rumen

Acute frothy bloat – stable foam fills the rumen.

not releasing gas and perhaps causing leakage of some solids into the abdominal cavity.

This frothy type of bloat is the more important from an economic point of view, as it can occur simultaneously in a number of animals, with a fatal outcome. The second diagram shows the rumen distended by foam, with bubbles of gas trapped and unable to escape.

Signs The left side of the body, between the last rib and the hip bone, is seen to be swollen; the whole abdomen gradually becoming tense and drum-like. There is obvious distress on the part of the animal which appears restless. Breathing is rapid. (See TYMPANITIC RESONANCE IN CATTLE.)

Prevention Frothy bloat may be prevented by limiting access to pasture, avoiding fine milled feeds and/or including an anti-foaming agent such as poloxalene ('Bloatguard'). Dimethicone ('Birp') may also be used in the treatment of frothy bloat. A solution of sodium bicarbonate, 150 g in 1 litre (5 oz in 2 pints) of water, administered by stomach tube, is also useful.

Low-protein, low-energy supplements decreased the incidence of bloat in cattle on a high clover sward, compared with a control group.

Bloat in Chinchillas

This is due to a sudden change of diet especially if fed fruit and green vegetables to excess. The

VetBooks.ir

condition has to be relieved by stomach tube or by trocharisation.

Bloat in Pigs

Bloat in pigs affects not the stomach but the small intestine, excluding the duodenum. It is sometimes referred to as 'colonic bloat' or 'whey bloat'. This is usually due to the fermentation of lactose in the large intestine. It occurs when whey is introduced suddenly into the diet. (See HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Block, Nerve

Applying local anaesthesia to the nerve(s) supplying a specific area to remove sensation in that part of an animal.

Blonde D'aquitaine

A French breed of cattle, for which there is an English breed society. (See BEEF BREEDS AND CROSSES.)

Blood

Blood is a slightly alkaline fluid which serves as a carrier of nutrients from the digestive system to the various tissues, transports oxygen from the lungs and carbon dioxide to the lungs, carries hormones from the endocrine glands, maintains a correct water balance in the body and assists with temperature control, carries waste products to the kidneys, and has an important role in the defence of the body against bacteria, viruses, etc. By its ability to clot (see CLOTTING OF BLOOD), blood has its own built-in safety factor for use in the event of damage to the blood vessels. Blood also assists in the maintenance of the correct pH of tissues.

Composition Blood consists of a fluid portion, or plasma, in which blood-cells are suspended. They are of three chief varieties: red blood-cells (erythrocytes or corpuscles), white blood-cells (leukocytes) and platelets (thrombocytes).

Plasma forms about 66 per cent of the total amount of the blood and contains three protein groups – fibrinogen, serum globulin and serum albumin. Fibrinogen is important in assisting blood coagulation.

When shed from blood vessels, plasma separates into two parts: a liquid, which is called serum, and a solid, which is the fibrin clot. Blood serum is, therefore, plasma which has lost its fibrinogen, the latter having gone to form the fibrin of the clot; but it contains two newly-formed proteins – fibrino-globulin and nucleo-protein. These are derivatives of fibrinogen which are split off from the fibrinogen when it forms the fibrin clot. (See GAMMA GLOBULIN.)

Besides the proteins mentioned above, the plasma contains non-protein nitrogenous material such as amino acids; waste products such as urea; glucose; fats; inorganic salts of sodium, potassium, calcium, magnesium, etc.

Red blood-cells (blood corpuscles; erythrocytes) constitute about 32 per cent of the total amount of the blood. Seen under the microscope they appear as biconcave discs, circular in shape (oval in camelids) and without a nucleus – having lost it before entering the circulation. (*Note*. The red blood-cells of birds, fish and reptiles possess a nucleus.)

Red cells are soft, flexible, elastic envelopes containing the red blood-pigment known as haemoglobin (see below), which is held in position by a spongy lacework of threads called stroma. They are present in large numbers in the blood. In the horse they number about 7 to 9 million per cubic millimetre, and about 6 million in the ox, on average.

The red blood-cells are destroyed after three or four months in the circulation. New red blood-cells are formed in the red marrow of the bones, and appear first of all as nucleated red cells, called erythroblasts.

Packed cell volume The height of the column of red cells, as a percentage of total height, of a sample of centrifuged blood in the tube. The red cells lie at the bottom; the middle layer consists of the white blood-cells and platelets; and the top layer is the serum.

Blood platelets or thrombocytes, reduce loss of blood from injured vessels by the formation of a white clot. (For a deficiency of platelets, see under THROMBOCYTOPENIA.)

Haemoglobin – a complex substance – has the power of absorbing oxygen in the lungs, parting with it to the tissues, receiving carbon dioxide in exchange, and finally, of yielding up this carbon dioxide in the lungs. When haemoglobin carries oxygen it is temporarily changed into oxyhaemoglobin, and when it is carrying carbon dioxide it is known as carboxyhaemoglobin. The process of oxidation and reduction proceeds with every respiratory cycle.

'Haemolysis' is a process by which the haemoglobin of the red blood-cells becomes dissolved and liberated from the cell-envelope. Anything which kills the cell or destroys the envelope can result in this. Natural serum of one animal can act as a haemolytic agent when injected into the body of another animal of a different species. The serum from a dog is haemolytic to the red blood-cells of a rabbit, but if this serum be

heated to 57° C (135° F) it loses its haemolytic powers. The heat has destroyed the agent which caused the haemolysis.

'Agglutination' is the process by which the red cells of the blood are collected together into clumps, under the action of an agent in the blood called an 'agglutinin'. It sometimes precedes haemolysis. (See AGGLUTINATION.)

White blood-cells (leukocytes; leucocytes) can be seen in among the red cells when blood is examined under the microscope. They are larger and fewer than the red cells, and nucleated, and possess the power of amoeboid movement. They exist in a varying proportion to the red cells, from 1 to 300, to as few as 1 to 700, and their numbers are liable to great fluctuation in the same animal at different times.

White blood-cells comprise the following:

Neutrophils, in which the cytoplasm contains granules which – with stains containing eosin and methylene blue – are not coloured markedly red or blue. The nuclei are of many shapes, and the term polymorphonuclear leukocytes is applied to neutrophils. They can migrate from the blood-vessels into the tissues and engulf bacteria (phagocytosis); are found in pus; and are very important in defence against infection.

Eosinophils have red-staining granules, contain hydrolytic enzymes, and have been observed to increase in numbers during the course of certain chronic diseases.

Basophils have blue-staining granules containing histamine which is secreted during allergy. Basophils and mast cells have receptors for IgE antibodies, and when basophils with IgE antibodies on their surfaces are stimulated by antigen (usually of parasitic origin) they release histamine. In severe reactions the animal may die.

Monocytes have very few granules, engulf bacteria, and are important in less acute infections than those dealt with by neutrophils. When they migrate from blood-vessels into surrounding tissues, they increase in size and are called macrophages.

Lymphocytes also have few granules and are likewise formed in lymphoid tissue, e.g. lymph nodes, spleen, tonsils. B and T cells are concerned with antibody formation and form barriers against local disease. (See B CELLS.)

Coagulation (See under CLOTTING OF BLOOD.)

Temperature The temperature of the blood is not uniform throughout the body. It is coolest near the surface, and hottest in the hepatic veins. It varies from 38° C to 40° C (100° F to 105° F).

Blood, Diseases of

(See ANAEMIA, and the blood disorders given under that heading; also LEUKAEMIA; THROMBOCYTOPENIA; FOALS, DISEASES OF - HAEMOLYTIC DISEASE; THROMBASTHENIA; CANINE HAEMOPHILIA; LEUKOPENIA; HAEMOLYSIS; VIRAEMIA; PYAEMIA; TOXAEMIA; SEPTICAEMIA.)

Blood-Brain Barrier

The barrier separating the blood from the brain tissue except at the HYPOTHALAMUS. There is limited permeability and usually it keeps out many drugs and infections. However it does allow entry of water, carbon dioxide, oxygen, glucose, alcohol and general ANAESTHETICS. Some AMINO ACIDS are transferred by specific mechanisms but many ELECTROLYTES cannot penetrate it.

The system also prevents certain medicines, such as penicillin, from treating brain infections such as bacterial meningitis. A similar barrier in the placenta protects the fetus.

Blood Enzymes

See creatine kinase, under CREATINE KINASE for a reference to diagnosis. Other blood enzymes, now routinely used in diagnosis, include: aldolase, alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, acetycholinesterase, gamma glutamyltransferase, glutathione peroxidase, α-hydroxybutyrate dehydrogenase, lactate dehydrogenase and superoxide dismutase.

For information on their activities in fresh serum, as compared with those in plasma containing anticoagulants and preservatives, see Jones, D. G. *Research in Veterinary Science,* **38**, 301.

Bloodhound

A large breed of dog with pendulous ears and a lugubrious expression, possessed of an acute sense of smell; have been much used as police tracker dogs in consequence. The amount of loose skin on the face leads to both entropion and ectropion. May inherit elbow joint problems (ununited anconeal process) and posterior paralysis (Stockard's disease). GASTRIC TORSION is not uncommon.

Blood Parasites of British Cattle

Piroplasms	*Babesia divergens* (Redwater agent)
	B. major
	Theileria mutans
	T. sergenti
Rickettsiae	*Cytoecetes (=Ehrlichia) phagocytophila* (Tick-borne fever agent)
	Haemobartonella bovis
	Eperythrozoon wenyoni
	E. tuomi
	E. teganodes
Flagellate	*Trypanosoma theileri*

VetBooks.ir

Blood Poisoning

Commonly used term for bacteraemia (bacteria in the blood), toxaemia (toxins in the blood) or septicaemia, the same with signs of illness.

Blood Spots in Eggs

A vitamin A supplement for hens has been suggested as a means of ridding eggs of this unappetising but harmless defect.

Blood Transfusions

Blood transfusions may be used in veterinary practice in cases of anaemia and certain other blood disorders. Transfusions may also be life-saving where it is necessary to replace blood loss caused by accident, haemorrhage and shock. Plasma-substitute fluids and modified gelatin solutions, however, are often more convenient where rapid restoration of normal fluid volume is the main concern.

Blood donors must be healthy animals of the same species. Up to 10 per cent of the blood volume can usually be taken without ill effect. As a rough guide, 1 per cent of the donor's body weight (300 ml for a 30 kg dog) may be taken. In dogs, which have 8 blood groups, adverse reactions due to incompatible blood types are rarely seen. Cats have 3 blood types: A and B, in the ratio 3:1, and AB (less than 1 per cent). Matching of donor and recipient blood should be done before transfusion, if possible.

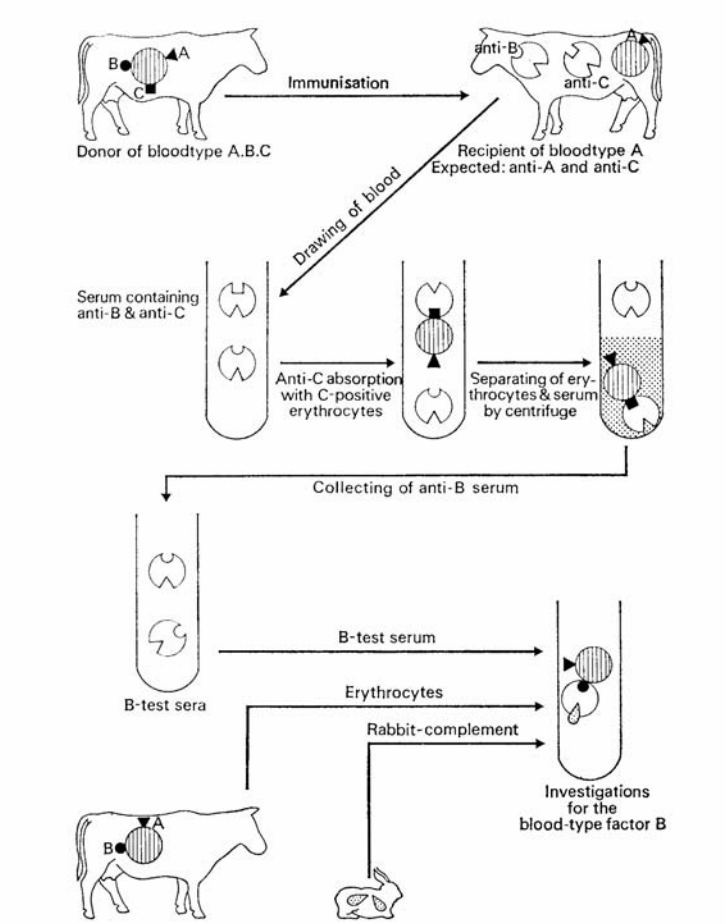
Blood is conveniently collected from the jugular vein. Donors should be sedated and the skin in the area shaved and cleaned. A hypodermic needle or catheter is inserted and blood collected into a blood bag (dog) or 50 ml syringe (cat) containing an anticoagulant such as sodium citrate or acid citrate dextrose. Collected blood may be stored for up to 4 weeks if refrigerated; it should be warmed to body heat before administration. This should be via a jugular or cephalic vein.

In cattle, donor and recipient are usually in the same herd, a fact which lessens the risk of introducing infection. Blood is collected from the jugular or other vein (after the skin has been cleaned and precautions taken to ensure asepsis) by means of a suitable needle (e.g. 13 swg) and allowed to flow into a blood bag or sterilised bottle containing anticoagulant. This may be made by dissolving 60 mg of sodium citrate in a little water, for every 100 ml blood collected. The bottle should be shaken gently during collection. The donor's blood is then transferred to the recipient's vein. Transfusion reactions rarely occur during a first transfusion.

In the newborn foal suffering from haemolytic disease, exchange transfusion has been the means of saving life. Up to 5500 ml of the foal's blood is removed and replaced by up to 7000 ml of compatible donor's blood. The process takes up to 3 hours and requires special apparatus. See also DEXTRAN; GELATIN, SUCCINYLATED; also under FELINE INFECTIOUS ENTERITIS; DEHYDRATION.

Blood Typing, Cattle

In Canada, extensive use is made of blood typing in respect of cattle, and results of a blood test have been accepted as evidence in court in a case where a man was convicted of falsifying a pedigree. The basis of this evidence was that to prove parentage of an animal, all the factors found in the blood of a calf must be present in the blood of either the sire or the dam. If certain factors found in the blood of the calf could not be found in the blood of either the sire or the dam, then that calf could not have been of that particular mating – as was proved in this case. DNA 'finger-printing' is now used.



Blood typing is also used in the diagnosis of freemartins. In one series 228 freemartins were found out of 242 sets of twins.

Blood typing has been used to decide the paternity issue in a heifer calf born to a cow inseminated twice in the same heat period with semen from two different bulls; to reveal discrepancies in pedigrees; and to allay or confirm suspicion on the part of a Breed Society asked to register a calf born following a very short or a very long gestation period. Again DNA 'finger-printing' can now be used.

The work falls into two categories: commercial and research. In the former category there are routine pedigree parentage cases involving one bull, one cow and one calf. In a series of 403 such cases, 26 (or 6.5 per cent) were found to be incorrect. Checking the parentage of bulls to be used in ARTIFICIAL INSEMINATION (AI) as well as typing bulls being used in AI is carried out. It can be used to show parentage of calves where they need registration but are unidentified. Other applications include the diagnosis of freemartins, and the control of egg transplantation – i.e. checking that the offspring is from the egg put in and not from the host cow's own egg.

Blood typing is of service in the policing of screening tests, e.g. for brucellosis. It is not unknown for lazy or unscrupulous people to fill several sample tubes with blood from the same animal and label them as coming from several animals. If several tubes are found to have identical types, fraud is virtually certain to have occurred, since the likelihood of two samples, other than from identical twins, having the same blood type is negligible.

Thoroughbred horses must all be blood-typed as an aid to identification. (See also EQUINE BLOOD TYPING.)

The principles of producing a test serum and its use in blood grouping. (With acknowledgements to Dr J. Moustgaard, Royal Veterinary and Agricultural College, Copenhagen.)

The Preparation of Test Sera containing antibodies, or blood-group reagents, is based on the injection of blood corpuscles from one animal into another of the same species, or into one of a different species. The first procedure is called iso-immunisation, the second hetero-immunisation. As a result of both procedures, the recipient animal produces antibodies to the antigenic factors associated with the donor blood corpuscles, provided that these factors are not already present in the recipient animal. (No animal can produce both an antigen and its antibody.) The diagram demonstrates the principle of iso-immunisation in cattle.

It shows that the donor possesses blood-group factors A, B and C while the recipient has only blood-group factor A. On immunisation, the recipient will therefore form antibodies to blood group factors B and C. The antibodies thus formed are called anti-B and anti-C. A serum containing several blood group antibodies is known as a crude serum. This serum will react with red corpuscles not only from the donor, but also from all cattle with the blood group factor B or C.

To obtain a blood group reagent which reacts with only one blood group factor – for example B – the anti-C antibody must be removed. To do this, the prepared crude serum is mixed with blood corpuscles which are C-positive but B-negative. The anti-C is then bound to the blood corpuscles and can be removed by centrifuging, as illustrated. This procedure is called antibody absorption. As the figure indicates, a specific B-reagent prepared in this way can be used to decide whether the blood

VetBooks.ir

group factor B is or is not present in a cow or bull, provided that rabbit complement is also present.

To obtain sufficiently high concentration of antibodies, donor blood corpuscles are injected into the recipient once a week for 4 to 6 weeks. The antibody concentration of the recipient's blood serum, or its titre, is estimated by determining the power of the serum to react with donor blood corpuscles, or with blood corpuscles possessing a similar antigenic structure. In some cases, one single period of immunisation is inadequate to achieve a satisfactorily high antibody concentration in the recipient's blood. This can often be achieved, however, by repeating the immunisation a few months later (reimmunisation). (See also TRANSFERRIN; EQUINE BLOOD TYPING; monoclonal antibodies under GENETIC ENGINEERING; ELECTROPHORESIS.)

Blood Urea Nitrogen (BUN)
Used as a measure of urea in the blood.

'Bloody Gut'
A common name used for cattle with JEJUNAL HAEMORRHAGIC SYNDROME, often considered to be a clostridial infection.

Blouwildebeesoog
The Afrikaans name for BOVINE MALIGNANT CATARRHAL FEVER, a disease of sheep, cattle and horses, characterised by enlargement of the eyes leading to blindness. It occurs in Africa, and is apparently spread by blue-wildebeest.

Blow-fly
Insects of the family Calliphoridae.

Blow-Fly Eradication
Sterile genetically engineered blow-fly maggots have been used in attempts to eradicate blow-fly infestation.

Blow-Fly Strike
Infestation of the skin with the maggots of blow-fly; cutaneous myiasis.

Blowpipe Darts
(See PROJECTILE SYRINGE.)

'Blows'
Distension of the caecum in the rabbit as a result of excessive gas formation. The rabbit assumes a huddled posture.

Bluebottle
Blowfly.

Blue Comb
Another name for 'PULLET DISEASE'.

Blue Cross
A charity devoted to caring for and rehoming sick and unwanted animals. Address: 1, Hugh Street, London SW1V 1QQ. Telephone: 0300 777 1897; website: www.bluecross.org.uk

'Blue-Ear' Disease of Pigs
Also known as PORCINE REPRODUCTIVE RESPIRATORY SYNDROME (PRRS). This devastating disease was first recognised in Europe and the USA in the late 1980s.

Cause A virus of the arterivirus genus. The infection can be wind-borne.

Signs Cyanosis of the extremities (hence the name 'blue-ear' disease) but the sign is uncommon and affected up to 2 per cent only of dry sows in the UK. An increase in abortions occurred in up to 3.3 per cent of sows. Premature farrowings in up to 20.6 per cent were recorded; mortality in neonatal and pre-weaning piglets was as high as 88 per cent, with a low mortality in fattening pigs. It often results in an upsurge of other latent infections in the herd, with respiratory problems being common.

Once the disease is established in a herd, little can be done. Immunity tends to build up but susceptibility may recur. A live freeze-dried vaccine is available. As with other infectious diseases, 'all in, all out' management is advisable to control PRRS.

Diagnosis Confirmation of the disease is by serological tests.

'Blue Eye'
(See CANINE VIRAL HEPATITIS.)

Blue Eyes
Some animals have from birth one or both eyes apparently blue in colour. This is quite common in certain species such as the dog, horse and pig. In dogs, it is more common in those with a MERLE coat colouring. The blue colour affects the iris and is due to the suppression of the pigment cells (MELANOCYTES). (See also WALL EYE.)

Blue-Faced Leicester Sheep
A long-woolled sheep originating (in spite of its name) from Northumberland. The rams weigh up to 110 kg (240 lb) and the ewes up to 89 kg (195 lb) with a fleece of 1 kg to 3.5 kg (2.2 lb – 7.5 lb). The face is blue-grey, as is the skin. The male is often used as a sire for MULES; these include a Blue-Faced Leicester ram crossed with a SWALEDALE ewe to produce a north country MULE or the ram can often be crossed with a SCOTTISH BLACKFACE. The crosses assist with

meat production. Semen was exported in the 1970s to Canada and the breed is used in North America.

B

Blue-Fin Tuna

A species of fish which, in the wild, preys on cephalopods and smaller fish. They maintain their body temperature at 27° C irrespective of the temperature of the water. They are now being farmed in sea cages around Australia and fed on an artificial diet that also prolongs the shelf life of the tuna fish in shops.

Blue Fur Disease

Secondary infection of moist skin and fur in rabbits by *Pseudomonas aeruginosa*. Affected fur should be clipped away and topical antiseptic applied. Systemic antibiotic therapy may be required. The cause of the moistness must be determined.

Blue-Gray Cattle

The offspring of a GALLOWAY or of an Aberdeen Angus crossed with a Beef Shorthorn bull. Often used as suckler cows in bleaker areas of Britain.

Blue-Green Algae

(See CYANOBACTERIA.)

Blue Iris

Called *Iris spuria* and the Larger Blue Iris (also called The Harlequin Blueflag) *Iris versicolor*. Both are members of the Family Iridaceae. They can contain the glucoside IRIDIN.

'Blue-Nose' Disease

'Blue-nose' disease is a form of PHOTOSENSITISATION occurring in the horse, following the eating of some particular meadow plant. The name arises from the blue discoloration observed in some cases on the muzzle (but not, for example, on the same animal's white socks). Sloughing of the non-pigmented skin occurs, and there is often intense excitement amounting to frenzy – during which the horse may injure itself.

Blue Sac Disease

A condition of unknown cause found in fish fry. The yolk sac increases in size and the contents become blue in colour. If left untreated, the fry cannot swim. The problem can be alleviated by increasing the water flow.

Bluetongue

A viral disease of ruminants formerly confined mainly to Africa but which has spread to North America and Australia, Portugal, Spain and Cyprus and, more recently, Italy, France and the UK. There are 24 strains of the virus which are antigenically different and so there is little cross immunity. Bluetongue is a NOTIFIABLE DISEASE throughout the EU.

Infection is carried by biting midges and probably the mosquito, and consequently outbreaks are commonest near the breeding haunts of such insects – damp, marshy regions.

Cattle may be carriers and can be infected in utero by transplacental infection.

To prevent entry of bluetongue to the EU from Canada, cattle must have a negative blood test in January; they can then be exported to the EU if they leave Canada between February 1 and April 15. This procedure ensures that they were not infected the previous summer and move out of the country before the midges carrying the infection become active.

A major outbreak occurred in 2006 with strain 8 producing severe signs and involving countries including the Netherlands, Denmark, Germany, France, Belgium and Luxembourg. In August 2007 the UK was infected and overall there were 149 confirmed premises infected in England and Wales. Vaccination with dead bluetongue virus (BTV) 8 began in 2008 in the UK. Several strains (including 1, 4, 8) are still present in parts of Europe and other parts of the world. According to meteorological reports, approximately 100 hours of suitable wind current each month are conducive to bringing midge vectors to the UK from mainland Europe. The UK was declared free of the disease in July 2011.

Cause An orbivirus.

Signs In sheep, a rise in temperature up to 41.5° C (107° F), and after a week or 10 days, eruptions on the tongue, lips, and dental pads – with a swelling and blueness of these parts – mark the typical appearance of an attack. Both the mouth and nose show a discharge, and there is an accompanying smacking of the lips. In spite of the soreness of the mouth the sheep are inclined to feed, but loss of flesh is very rapid, particularly when diarrhoea sets in. In 3 to 5 days, the mouth lesions begin to heal, and the disease is seen in the feet. These become sore; sheep are stiff, and feed from the kneeling or recumbent positions. Diagnosis may be confirmed by viral isolation. In cattle and goats signs can be similar to those in sheep, but usually they are milder.

In cattle, sheep and goats the disease may be subclinical.

Treatment Isolation of the affected animals into shady paddocks, sheds, or orchards, where they are immune from disturbance, antiseptic mouth washes, good feeding of a soft, succulent quality, the provision of a clean water-supply and salt-licks. Dipping has given good results.

VetBooks.ir

Prevention Vaccines for specific strains are used, when permitted by national legislation. They are usually very effective against the specific strain (only). A stockpile of quadrivalent vaccine is maintained at various sites in the EU.

Blue Wool

A form of LUMPY WOOL caused by *Pseudomonas indigofera*.

BNP

(See BOVINE NEONATAL PANCYTOPENIA.)

Boarding Kennels

(See ANIMAL BOARDING ESTABLISHMENTS ACT 1963.)

Boar Taint

Meat from older or mature male pigs can produce an unpleasant odour (caused by compounds including ANDROSTENONE and SKATOLE) when the meat is cooked. While not all people can smell it, it may cause the meat to be rejected. A vaccine was introduced in Europe in 2009 and besides reducing the taint after death, it lowers aggressiveness and mounting behaviour in boars and thereby improves daily liveweight gain. The vaccine contains gonadotrophin releasing factor (GnRF) analogue and by producing antibodies in the pig it produces a temporary immunological suppression of testicular function.

Bobtail

A short tail either natural or from DOCKING.

Body-Scanner

(See under X-RAYS; MRI.)

Boer Goats

A breed from South Africa imported into Europe in the 1980s. They are large, docile and graze well, producing milk and, primarily, meat. There are several meat-producing herds in Britain. The male weighs 150 kg (330 lb) and the doe 100 kg (220 lb). The bucks are often used as TERMINAL SIRES.

Bog Asphodel

(*Narthecium ossifragum*) A cause of light sensitisation in sheep. Ears, face and legs of white lambs may all be affected. Skin necrosis may follow the inflammation. In severe cases, jaundice may be a complication.

Cows have been fatally poisoned by the plant as a result of necrosis of kidney tissue.

In one case, cattle forced by drought to graze swampy ground where bog asphodel grew suffered 137 deaths out of 232 cattle affected. The clinical signs included depression, anorexia and diarrhoea. Extensive kidney damage was caused. Reduced grazing pressure on moorland grazings is allowing this plant to spread.

Bog Spavin

An old name for chronic synovitis of the hock (*tarsus*) of horses. It often shows as a swelling of the front of the hock joint caused by fluid. It seldom causes lameness. (See also BONE SPAVIN.)

BOHB

(See BETAHYDROXYBUTYRATE.)

Bollinger Bodies

(See FOWL POX.)

Bolus

A roughly spherical mass of food, which has been chewed and mixed with saliva, ready for swallowing. Bolus also means a cylindrical mass, 3.8 to 7.5 cm (1½ to 3 in) long, and up to 1.3 cm (½ in) in diameter, of a medicine in paste or solid form for administration to horses and cattle. It is also known as a 'ball' – hence 'balling gun'. Slow-release boluses which are retained in the rumen for the administration of anthelmintics or trace elements over a period are available in a variety of forms.

(See WORMS, FARM TREATMENT AGAINST - ADMINISTRATION.)

Bombay Cats

A breed of cat developed in the USA by crossing black American shorthairs with Burmese cats. The breed has totally black, silky fur that is difficult to keep in good condition.

Bonamiosis

A NOTIFIABLE DISEASE in the UK and other parts of the EU; it affects shellfish, notably oysters, and is caused by the protistan parasite, *Bonamia ostrea*. Lesions occur in the connective tissue of the gills, mantle and digestive gland. The intrahaemocytic protistans quickly become systemic with overwhelming numbers coinciding with the death of the oysters. The parasite occurs throughout the year but infection intensity increases in the warm season. It is controlled in the UK by the Fish Health Regulations 1997.

Bone

Bone is composed partly of fibrous tissue, partly of phosphate and carbonate of lime. Since the bones of a young animal are composed of about 60 per cent fibrous tissue, and those of an old animal of more than 60 per cent of lime salts, one readily understands the toughness of the former and the brittleness of the latter. Two kinds of bone are noteworthy: dense bone, such as forms the shafts of the long bones of the limbs, and cancellous or spongy bone, such as is found in the short bones

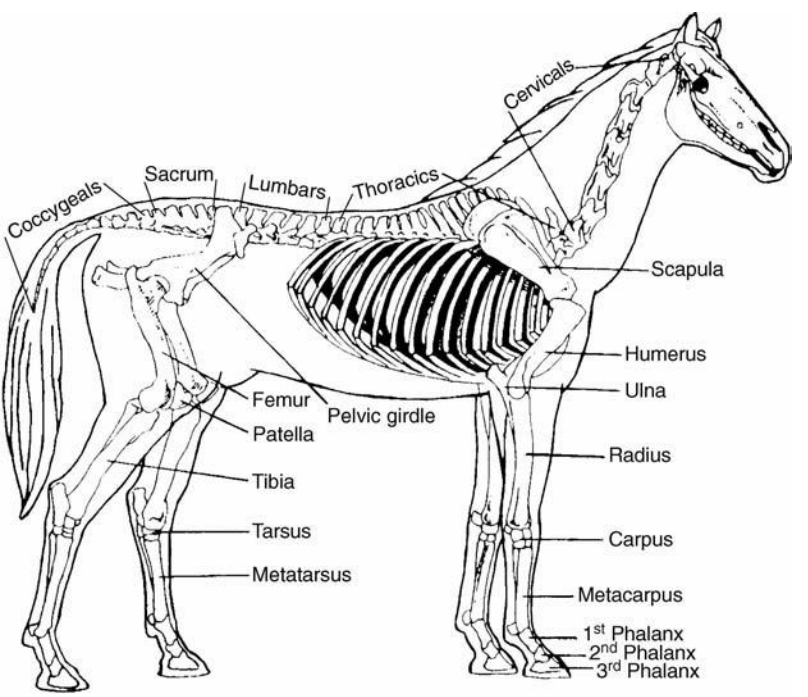
and at the ends of the long bones. Dense bone is found in a tube-like form, with a central cavity in which normally yellow marrow is found, composed mainly of fatty substances; the walls of the tube are stout and strong, and the outer surface is covered by 'bone membrane' or periosteum. Cancellous bone has a more open framework, is irregular in shape, and, instead of possessing a cavity, its centre is divided into innumerable tiny spaces by a fine network of bony threads, which support the important red marrow. (See MARROW.)

All bone is penetrated by a series of fine canals (Haversian canals), in which run blood-vessels, nerves, lymph-vessels, etc., for the growth, maintenance, and repair of the bone.

Varieties of Bone Apart from their structural classification, bones are arranged according to their external shape into: (a) long bones, like those of the limbs; (b) short bones, such as those of the 'knee' and hock; (c) flat bones, such as those of the skull and the shoulder-blade; (d) irregular bones, such as those of the vertebral column; and (e) the 'spongy' bones of the feet of horses and cattle and the claws of other animals.

The Skeleton has: (1) an axial part, consisting of the skull, the vertebrae, the ribs with their cartilages, and the sternum or breast-bone; and (2) an appendicular portion, consisting of the four limbs. In addition to these divisions, certain parts of the skeleton are embedded in the substance of organs, and are described as the visceral skeleton, e.g. the bones in the heart of the ox, the snout of the pig, the penis of the dog, etc.

Bone, Diseases of



Growth-plate disorders The growth-plate is a layer of cartilage between the DIAPHYSIS and the EPIPHYSIS of a long bone. Failure of chondrogenesis leading to cessation of growth is commonly the result of trauma to the plate, occasioned by a fracture or crush injury, or too rapid growth or the interruption of the vascular supply to the germinal cells. Diseases such as scurvy, rickets, osteomyelitis and endocrine disorders make the plate more vulnerable to injury and predispose to epiphyseal separation.

Epiphyseal injury in the foal, for example, may be of two types:

Type 1 Separation without fracture. After realignment healing is rapid and the prognosis is good. Femoral head detachment is the exception because if the epiphyseal vessels are damaged, avascular necrosis of the head follows.

Type 2 The most common, involving fracture of a triangular piece of metaphysis. With accurate reduction the prognosis is good.

Such injuries usually involve the epiphyses in the distal radius, distal metacarpus and proximal

Skeleton of horse.

VetBooks.ir

first phalanx. These cases often have the appearance of acute joint sprains but epiphyseal damage should always be suspected because at this age growth-plates are weaker than collateral ligaments. Radiography is essential to identify the type of defect present. Prompt and accurate replacement of the epiphysis is required, followed by stapling the epiphyseal plate or stripping the PERIOSTEUM. (See VALGUS for picture.)

Acute inflammation of bone is divided into acute periostitis, or inflammation of the surface of the bone and its covering membrane, the periosteum; acute osteitis or ostitis, inflammation of the bone substance itself; and acute osteomyelitis, inflammation in the bone and the central marrow cavity.

Acute inflammation of the bone surface almost always results from external violence. Osteomyelitis is usually due to bacteria gaining access either through the blood- or lymph-streams, or through the broken tissues resulting from a deep wound. The mildest types are often due to an inflammation in a ligament or tendon spreading to the periosteum in the near vicinity and causing it to become inflamed as a consequence. (See also RHEUMATISM.)

Complete rest is essential: in fact work, or even walking, is often impossible. Hot fomentations, poultices, soothing and cooling liniments or applications are usually sufficient treatment for mild cases. The more severe cases, in which infection has reached the bone, call in the first place for antibiotics, or the immediate opening up of the area and the elimination of any pus that has collected. After that, any pieces of dead bone that are present are removed, and the wound treated as an infected open wound.

Chronic inflammation may result from several conditions, e.g. tuberculosis, actinomycosis, etc. Generally speaking, when a chronic suppurative inflammation affects a bone, sooner or later the pus and debris of a liquid nature will burrow through the surrounding tissues and burst on to the surface of the skin. A discharging sinus results which proves intractable to treatment. At the bottom of this sinus lies the dead piece of bone and until it has been removed or absorbed the leakage of purulent material will continue in spite of antiseptic injections and other surface treatment.

The offending dead portion of bone must be removed in the first instance, and the whole sinus tract must be laid open. This is not always an easy matter, and much depends upon the situation of the pieces of dead bone (sequestrum), as well as of the mouth of the sinus. The area afterwards is treated as an open wound, and if all the necrotic parts have been removed, recovery generally takes place.

Exostosis is an outgrowth of rarefied bone tissue upon the surface of a bone. Among the commonest forms of exostoses are the following: certain forms of splints, ring-bones, bone spavins, some side-bones. (See also ACROPACHIA.)

Tumours of bone are sometimes met with. The commonest of these is the osteosarcoma of the limb-bones of dogs. The bony tissue is invaded by the cells that are characteristic of the tumour, and there is swelling and pain.

Rickets is a disease of young animals in which the bones of the limbs are affected, and often small pealike swellings are found at the junction of each of the ribs with its cartilage. (See also main entry for RICKETS.)

Osteomalacia is the equivalent of rickets occurring in the adult animal, especially during pregnancy. (See also main entry for OSTEOMALACIA.)

Osteodystrophic Diseases are due to an incorrect calcium: phosphorus ratio in the diet, or to lack of one or more of the minerals – calcium, phosphorus, magnesium and sometimes manganese; also, if vitamin D has been inadequate in amount in the food eaten for some considerable time (e.g. see FELINE JUVENILE OSTEODYSTROPHY). (See also OSTEODYSTROPHIC DISEASES.)

Porphyria is a rare disease, hereditary in origin, occurring in man, cattle and pigs. It is characterised by brown or pinkish discoloration of the bones and teeth, and by changes in the urine. In cattle a hairless, scabby condition of the skin is also a sign. (See also under HEXACHLOROBENZENE.)

Bone Charcoal

It has been used as an aid in the control of non-specific diarrhoea in cattle and pigs. It can be included with attapulgite. (See also ATTAPULGITE.)

Bone Cyst

A cavity within a bone. It is visible on X-RAY and the outline can, in some cases, be palpated externally. The cyst may be filled with fluid and is sometimes lined by a membrane.

Bone Grafts

(See FRACTURES.)

Bone Marrow

(See MARROW; ANAEMIA; BLOOD - Red blood-cells.)

Bone-Pinning

A method of treating FRACTURES. In medullary pinning, a pointed stainless steel 'pin' is driven down the marrow cavity of the bone concerned; in ordinary pinning, transverse 'pins' are used, driven

through the bone at right-angles to its length, and the pins held in position by a special adjustable metal splint. These methods obviate the use of cumbersome plaster casts, and they also enable cases of serious and multiple fracture (e.g. as caused in a dog or cat knocked down by a car) to be successfully treated – a result often impossible of achievement by older methods. These techniques require a high degree of specialised skill and strict asepsis and, of course, the use of a general anaesthetic. (See illustration on next page see also bone-plating in the illustration below; and EXTERNAL SKELETAL FIXATORS.)

Bone Plating

(See FRACTURES.)

Intramedullary pinning. Two views of the fracture of the femur in a dog. (Beaumont Animals' Hospital.)

Bone-pinning – Plating. This is another technique used in veterinary practice. The radiographs show a fracture of the tibia of a dog and the use of a metal plate screwed into the bone. (Beaumont Animals' Hospital.)

VetBooks.ir

The insertion of a metal pin down the marrow cavity of the bone.

Bone Spavin
Osteitis or arthritis of the lower hock-joints of the horse. The animal is often lame; there may or may not be a hard, bony swelling.

Bonham
An Irish piglet.

Boran Cattle
An East African type of Zebu cattle.

Border Collie
A medium-sized, longish-haired dog originally bred for herding sheep. It is said that one well-trained sheepdog can do the work of seven men. The breed is susceptible to COLLIE EYE ANOMALY (choroidal hypoplasia), CEROID LIPOFUSCINOSIS and LENS LUXATION. Inherited deafness may be linked to coat colour. Osteochondritis dissecans may also be inherited. OSTEOCHONDRITIS DISSECANS, TRAPPED NEUTROPHIL SYNDROME and RETINAL PIGMENT EPITHELIAL DYSTROPHY may also be inherited. CANINE MULTIDRUG SENSITIVITY (DNA test available) is found in the breed. They can be susceptible to AVERMECTIN endectocides and INFLAMMATORY BOWEL DISEASE.

'Border Disease' of Sheep
A disease occurring on the English–Welsh border, and first described in 1959. Affected lambs are known as 'hairy shakers' and are congenitally infected.

Cause The virus which causes the disease in lambs is classified as belonging to the family Togaviridae, genus *Pestivirus* and antigenically related to BOVINE VIRAL DIARRHOEA and classical SWINE FEVER viruses.

Signs The birth-coat is altered; the amount of hair in the fleece being increased. Lambs are smaller than normal, and grow more slowly. The shape of the head is slightly abnormal – likewise the gait which, however, shows only a slight swaying motion. Mortality is very high; most lambs die during their first few weeks.

The disease has been recognised in New Zealand, the USA and Switzerland.

A feature of the disease is acute necrosis of the placenta associated with abortion.

It appears that there is an immunological relationship between Border disease, mucosal disease, and swine fever, with all three caused by closely related viruses. In-contact goats may be infected by sheep with Border disease.

Border Inspection Posts

The only authorised entry points for animals entering the UK from outside the EU. Animals imported into any EU member state through one of its Border Inspection Posts and found to be free from infectious or contagious disease may move on to the UK, or from the UK to another EU member state, without hindrance. Quarantine may be imposed in some cases; for example, alpacas from South America. Locations and the regulations affecting the posts may change. In 2011 the British Border Inspection Posts, and what they could import, were as follows:

Gatwick Airport	All animals except ungulates and registered equidae.
Heathrow Airport	All ungulates, registered equidae and other animals.
Manchester Airport	All fish, reptiles, amphibia and invertebrates only.
Prestwick Airport	All ungulates and registered equidae.
Stansted Airport	Ungulates and registered equidae.

Registered equidae are animals registered with a breed society, or a registered thoroughbred. Under the PET TRAVEL SCHEME entry documents are screened by the port authorities and the registered ports are the ferry posts as animals are expected to arrive in the UK by car.

Animal products can enter the United Kingdom at specific BIPs according to their nature (see table below).

Border Leicester Sheep

The breed is primarily a meat animal. It is a polled, long-woolled large sheep. The rams weigh 140 kg to 175 kg (310 lb to 390 lb) and ewes 90 kg to 120 kg (200 lb to 260 lb). The wool is sheared twice, with 3.2 kg (7 lb) of wool at each shearing. The Border Leicester was developed in 1767 in Northumberland from foundation stock (TEESWATER or CHEVIOT ewes) with Disley Leicester rams (LEICESTER LONGWOOL). They provide 50 per cent of genetics in the Australian Gromark breed and the rams are used to produce MULES.

Border Terrier

A small dog bred originally for hunting foxes and vermin. It weighs about 5 kg to 7 kg (11 lb to 15.5 lb) and has a wiry red, wheaten or tan coat. It has become popular since the 1990s in towns as well as in the country. It is usually a good family pet, as it is normally even-tempered, although it is strong willed. The breed can show HIP DYSPLASIA, LEGG-CALVÉ-PERTHES DISEASE, CATARACTS and PROGRESSIVE RETINAL ATROPHY, all of which may be inherited. They can also have various heart problems and seizures. Some dogs suffer from CANINE EPILEPTOID CRAMPING SYNDROME (CECS).

Belfast Airport	Packaged animal products not intended for human consumption which are imported under ambient and chilled temperatures.
Bristol Airport	Frozen animal products for human consumption. Frozen animal products not intended for human consumption.
East Midlands Airport	Packaged, chilled animal products for human consumption. Packaged animal products for human consumption imported at ambient temperatures. Packaged animal products not intended for human consumption imported at ambient temperatures.
Falmouth Port	All products for human consumption.
Felixstowe Port	All animal products for human consumption. Animal products not intended for human consumption at frozen or ambient temperature only.
Gatwick Airport	Packaged animal products for human consumption. Packaged animal products not intended for human consumption.
Glasgow Airport	Currently suspended.
Grimsby-Immingham Port	Frozen animal products for human consumption.
Heathrow Airport	Packaged animal products for human consumption. Packaged animal products not for human consumption.
Kingston-upon-Hull Port	All animal products for human consumption. Animal products not intended for human consumption at ambient temperatures.
Invergordon Port	Processed animal proteins only.
Liverpool Port	All packaged animal products for human consumption. All packaged animal products not intended for human consumption.
Manchester Airport	Packaged animal products for human consumption. Packaged animal products not intended for human consumption.
Peterhead Port	Frozen packaged fishery products only.
Southampton Port	All animal products for human consumption. All animal products not intended for human consumption.
Stansted Airport	Packaged animal products for human consumption imported at ambient temperatures. Packaged animal products not intended for human consumption imported at ambient temperatures.
Thamesport Port	All packaged animal products for human consumption. All packaged animal products not intended for human consumption.
Tilbury Port	All animal products for human consumption. Animal products not intended for human consumption at frozen and ambient temperatures only.

(See also IMPORTING/EXPORTING ANIMALS; HORSES, IMPORT CONTROLS; BIRD IMPORT CONTROLS; RABIES; QUARANTINE; PET TRAVEL SCHEME.)

VetBooks.ir

Bordetella spp.

(See under BACTERIA). *B. bronchiseptica* is a secondary invader complicating cases of canine distemper, and may also produce respiratory disease (see KENNEL COUGH) in the dog independently of viruses. This bacterium is also the cause of chronic respiratory disease in many other animals. It is an important factor in atrophic rhinitis. (See RHINITIS, ATROPHIC.)

Bordetella bronchiseptica A common bacterium found in pigs. It causes a mild rhinitis in pigs but often combined with toxic producing strains of Pasteurella multocida they cause ATROPHIC RHINITIS. It is also involved in the PORCINE RESPIRATORY DISEASE COMPLEX.

Borna Disease

Mainly a disease of horses, but occurs also in sheep, llamas, cats and humans.

Cause A virus which is closely related to those causing EQUINE ENCEPHALITIS occurring in various tropical, subtropical and temperate regions; the diseases bearing such names as Near Eastern encephalitis, Venezuelan, Eastern, Western and Japanese B. encephalitis.

Transmission Mosquitoes, midges, and ticks can transmit the virus, of which birds are also hosts.

Signs Depression and fever. Recovery may follow without involvement of the central nervous system, but probably in most cases such involvement does occur. Signs then include walking in circles, or pressing the head against a fixed object, a facial twitch, hanging of the head, ataxia, and paralysis.

Diagnosis depends upon a fluorescent antibody test or the detection of Joest-Degen antibodies. A differential diagnosis of Borna disease in sheep must take into account louping-ill, maedi/visna, rabies, listeriosis, scrapie, cerebro-cortical necrosis, poisons, etc.

Borogluconate

The salt of calcium used in 25 per cent or 40 per cent solution for intravenous or subcutaneous injection in cases of hypocalcaemia (milk fever) in cattle and sheep. It should not be given to small animals except as a 5 per cent or 10 per cent solution intravenously as a treatment for eclampsia. High doses can result in boron poisoning.

Boron

An element that is essential for plants and some insects. It has been reported that a deficiency in mammals causes impaired bone formation. It is believed to have an influence on the metabolism of calcium, phosphorus, magnesium and vitamin D, possibly indicating a role in bone and cell membrane formation.

Borrelia

A species of SPIROCHAETE, causing disease in fowls in the tropics, and also human tick-borne relapsing fever. The distribution of the latter is, with the exception of Australia, almost worldwide. The signs include fever, erythema, sometimes jaundice. *B. burgdorferi* causes LYME DISEASE, a disease of dogs, horses and humans characterised by arthritis, headache, lethargy and sometimes meningitis or encephalitis. It is endemic in certain parts of the USA and is seen throughout the UK.

Borreliosis

A disease of dogs characterised by lameness, swollen joints and fever.

Cause *Borrelia burgdorferi*.

Boss Cows

(See BUNT ORDER.)

Boston Terrier

Originating in the USA, this small short-haired dog has erect ears and prominent eyes. It is prone to a number of inherited conditions including achalasia of the oesophagus, cleft palate, cataract, CORNEAL ENDOTHELIAL DYSTROPHY, CRANIOMANDIBULAR OSTEOPATHY, incomplete development of the vertebrae (HEMIVERTEBRAE), RETROGNATHIA (undershot jaw) and patellar luxation. The shape of the pelvis makes whelping difficult and assistance may be required.

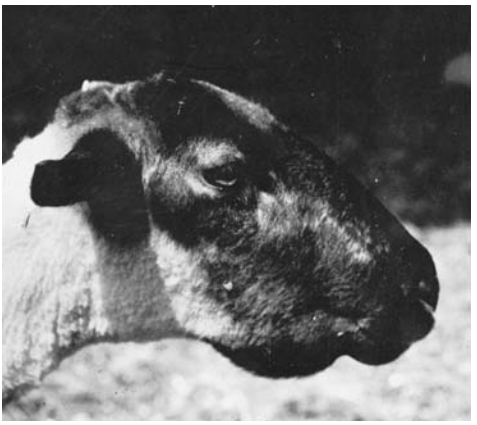
Bot-Flies

(See under FLIES.)

Bothriocephalus

Bothriocephalus is one of the parasitic tapeworms.

Botryomycosis



A suppurating granulomatous infection usually caused by *Staphylococcus aureus* (see GRANULOMA).

'Bottle-Jaw'

Oedema of the lower jaw (see illustration on next page). Also found with liver-fluke infestations in sheep and, occasionally, cattle; and with JOHNE'S DISEASE in cattle, occasionally anaemia and heart disease can cause bottle jaw in all species.

Botulism

A form of food poisoning, often fatal, caused by *Clostridium botulinum* toxins, types A to G, which produce paralysis. Botulism occurs worldwide, but

'Bottle-jaw'. Oedema of the lower jaw caused by Haemonchus contortus, a parasitic worm found in the abomasum of sheep and goats. It is also a cause of severe anaemia. (Reproduced by permission of Dr M. A. Taylor, Central Veterinary Laboratory, Weybridge; Crown copyright reserved.)

is especially common in the tropics. Toxin types C and D are most commonly found in birds and most mammals including cattle; A, B, E and F in people. Detection of toxin in affected animals is usually difficult. A flaccid anus is PATHOGNOMONIC.

Cattle and sheep Large numbers may die in regions where they suffer from mineral deficiencies (especially of phosphorus) and are driven to eating the bones of dead animals to obtain the minerals they need.

Cl. botulinum may inhabit the alimentary tract of a healthy animal without ill effect. However, in a decaying carcase, rapid multiplication of the bacterium, with toxin production, occurs. Carrion is therefore the main source of botulism in animals, but proliferation can also occur in decaying vegetable matter. Carcases may pollute well-water or forage, and in Britain botulism in cattle has been associated with the use of broiler litter on grazing land – such waste containing a few carcases. The worst outbreak was probably that in Queensland, Australia, where more than 5,500 steers died, as a result of infection from poultry litter.

Signs Large doses of toxin may result in sudden death, but often the illness lasts a few days; the animal becoming first stiff and dejected, and then recumbent, lying on the sternum with the cow's head turned to one side or resting on the ground, the tongue is flaccid. Salivation may be profuse, swallowing difficult or impossible, so that botulism has to be differentiated from rabies when making a diagnosis.

Control The use of mineral supplements where osteophagia occurs (see LAMZIEKTE), or of vaccines. Treatment is usually very disappointing but antiserum, if available, might help. Remove from source of toxin.

Horses The signs are ataxia, difficulty in swallowing, and posterior paralysis; or sudden death. In the UK cases have occurred in horses fed big-bale silage. Contamination of the silage by soil (which may contain *Cl. botulinum* B), or by rodent carcases, has been suggested as the source of botulism in horses. In the USA, contaminated alfalfa (LUCERNE) caused deaths of 7 out of 8 horses which showed signs of progressive muscular weakness.

Signs Difficulty in chewing and swallowing; in some outbreaks tongue paralysis has been seen; dilated pupils. Sudden death.

Dogs Botulism has occurred in packs of fox-hounds fed infected meat such as farm animals found dead.

Birds Type C botulism has been reported in Britain among both chickens and waterfowl; also pheasants. It is not uncommon in hot dry summers as water levels reduce, allowing access to mud. (See also MAGGOTS.)

Signs of botulism in an outbreak among captive birds included a characteristic statuesque behaviour; some individuals stood motionless for over one hour despite activity of other birds around them; paralysis, ranging from a single dropped wing to bilateral leg paralysis; inability to swallow; and terminal gasping.

Fish Botulism in fish causes high mortality. It is usually due to feeding wet trash fish to farmed fish without cleaning out the machinery between batches. The Danish name for the disease translates as 'bankruptcy disease'.

For botulism in mink, see MINK, DISEASES OF. For botulism in South African cattle, see LAMZIEKTE.

Public health Human (and also animal) botulism may occur as the result of imperfectly preserved food or when cooked food is allowed to stand and later re-heated. Although there have been very few cases of human botulism in Britain, a high proportion of trout in fish farms may be contaminated with *Cl. botulinum* type E, which can multiply at temperatures as low as 5° C (41° F), whereas the more common types A and B will not normally multiply at temperatures below 10° C (50° F). As most bird and mammal case are type C, risk assessments have downgraded its importance for humans.

Boutonneuse Fever

A ZOONOSIS which is transmissible from dogs to people. The cause is *Rickettsia conori*. There is a rash. Wrists, ankles, and then other parts of the

VetBooks.ir

body may be affected. The dog tick *Rhipicephalus sanguineus* is the vector.

Bouvier Des Flandres

A medium-sized, short-tailed dog with grey or fawn coat. It has few reported inherited defects, but LARYNGEAL PARALYSIS is inherited as a dominant trait and primary glaucoma is inherited by an unknown mechanism.

Bovine Atopic Rhinitis

A discharge from eyes and nose, with some ulceration of nasal mucosa (and formation of nasal granuloma), are signs in common with those of bovine infectious rhinitis. It is often the result of an acute hypersensitivity reaction, particularly in Channel Island breeds. Recovery usually follows housing.

Bovine Atypical Interstitial Pneumonia

(See FOG FEVER.)

Bovine Autoimmune Haemolytic Anaemia

A heifer died within two days of showing anaemia and dyspnoea, and the diagnosis was bovine autoimmune haemolytic anaemia, based on autoagglutination (which increased on Coombs' testing) and the presence of antibovine IgG on red blood cell surfaces.

Acute haemolytic anaemia may be due to many other causes, including water intoxication, delayed copper toxicity (COPPER, POISONING BY), brassica poisoning (BRASSICAE SPECIES), BABESIOSIS, LEPTOSPIROSIS and BACILLARY HAEMOGLOBINURIA.

Bovine Embryo Collection And Transfer Regulations 1993

These apply within the UK and other member states of the EU.

Bovine Encephalomyelitis, Buss Disease

Bovine encephalomyelitis (Buss disease) occurs in the USA, Australia and Japan. In the USA it is a disease mainly of the summer and autumn months, and cattle under two years old are mainly susceptible.

Cause *Chlamydophilia psittaci*.

Signs A fever, which lasts a week or more. With loss of appetite, the animal loses condition and becomes weak. A nasal discharge or diarrhoea may be seen. Pushing the head against a wall, walking in a circle, hyperaesthesia and convulsions are signs of which one or two may be seen. Economically the disease has a low incidence and generally a low mortality, but in some herds losses may be serious.

Autopsy findings include pleurisy, pericarditis and peritonitis, apart from any brain lesions.

Public health Man is susceptible.

Bovine Enzootic Leukosis

A virus-produced form of cancer, characterised by multiple malignant growths as well as, in some cases, leukaemia. The disease was first recorded in Britain in 1978, is fairly common on the European mainland, and is a NOTIFIABLE DISEASE. Occasionally, cattle show signs before they are two years old, but four to eight years is a more common age. Digestive disturbance, anaemia and loss of condition result

The virus is a type C oncornavirus of the retrovirus family.

In Britain the enzootic bovine leukosis (EBL) attested herds scheme was introduced by MAFF in January 1982 to encourage the establishment of EBL-free herds, as a first step towards eradication of the disease.

Great Britain was recognised as being free of the disease in July 1999; the last case was detected in December 1996. Feeding colostrum substitutes from abroad has led to some calves passively acquiring antibodies to EBL. The sporadic form is seen in younger cattle but must be differentiated from EBL.

Testing for enzootic bovine leukosis

Breeding cattle may only be moved from one member state of the EU to another if they originate from herds which are recognised as free from EBL in accordance with the terms of the EU directive.

Bovine Ephemeral Fever

(See EPHEMERAL FEVER.)

Bovine Herpes Mammillitis

An ulcerative disease of the cow's teats and udder, caused by a herpes virus. (See also VIRAL INFECTIONS OF COWS' TEATS.)

Bovine Immunodeficiency-Like Virus (BIV)

This causes a progressive wasting condition of cattle, with intercurrent diseases, poor milk yield and enlarged lymph nodes. Infection is stated to be present in North America and Europe. There is limited evidence of the degree to which BIV is present in Britain, but antibodies have been found in the majority of at least one herd with possible signs. Antibodies have been found in some animals in other herds.

Bovine Infectious Petechial Fever

Also known as Ondiri disease, this affects cattle in Kenya, and is characterised by haemorrhages of the

visible mucous membranes, fever and diarrhoea. There may be severe conjunctivitis and protrusion of the eyeball. Death within one to three days is not uncommon, though some animals survive for longer, a few recovering. The cause is a rickettsia, *Ehrlichia ondiri*, believed to be spread by a biting insect or a tick. The bushbuck provides a reservoir of infection.

Bovine Lactoserum

In a concentrated form it can be given to calves that have not received sufficient colostrum. It will reduce the mortality in calves due to *E. coli* strains that have the K99 adhesin.

Bovine Leukocyte Adhesion Deficiency (BLAD)

An inherited problem of cattle resulting in inability to resist disease. Affected cattle usually die by one year old. It was discovered in the USA in 1989, and has since been found in many European countries, including the UK. Animals usually have very high leukocyte counts.

Bovine Leukosis, Bovine Leucosis

There are two forms, sporadic and ENZOOTIC BOVINE LEUKOSIS. Sporadic is seen in cattle up to about two years old and takes various forms including thymic (a lump in front of the brisket), or a swelling in some or most lymph nodes. Enzootic Bovine Leukosis is a NOTIFIABLE DISEASE and is caused by a lentivirus. It can be detected by a blood test. In 2014 it was not present in Britain but it occurs in Europe and the USA where it can reduce milk production.

Bovine Malignant Catarrhal Fever (MCF)

This infection, also known as malignant catarrh, may occur not only in cattle but also in sheep, farmed deer and antelopes. It is most common in Africa, but cases have been recorded in the UK, other EU countries, Australasia and North America. Usually, one animal is affected but there can be outbreaks. In Africa it is also seen in wildebeest.

Cause A celaphine herpes virus.

Signs Enlarged lymph glands, inflammation of the mucous membrane of the mouth, drooling of saliva, gastroenteritis, keratitis (followed in some cases by blindness, and sometimes ENCEPHALITIS). Most affected animals die.

Bovine Neonatal Pancytopenia (BNP)

'Bleeding Calf Syndrome' A condition, also known as Ideopathic Haemorrhagic Diathesis, first reported in Germany in 2009. Other cases occurred across much of Europe including UK. Signs followed the ingestion of colostrum from one or a few specific cows within a herd. Epidemiological studies showed that most, but not all, cases were associated with use of BVD vaccine (Pregsure BVD, Pfizer). The company voluntarily withdrew the vaccine from Europe in 2010 without accepting any culpability. The vaccine is still available in some other parts of the world. There appears to be a link between BNP and antibodies against the major histocompatibility complex class 1 (MCH I) proteins.

Signs Signs occur at between two and 28 days old. There are three forms of problem: sudden death, with pale mucous membranes, diagnosed post mortem; calves that are ill and die in 24 hours (most common form); and signs remaining for three to four days. Live calves often have a raised temperature, are dull, and have bleeding from one or more points on the skin, often, but not necessarily where the skin has been punctured by flies, injection sites, etc., producing 'blood sweating'. Mucous membranes are usually pale and often show haemorrhages; faeces are often heavily blood stained. If calves survive for a time they may develop secondary infections.

Post mortem signs: Multiple external and internal haemorrhages, often on organ surfaces including bladder, liver, lungs, spleen; also bleeding into gut and on joint surfaces. There is bone marrow hypoplasia.

Control Other calves should not receive colostrum from dams whose calves have had the disease. Also if the cow remains in the herd her next calf should not receive her colostrum.

Bovine Papular Stomatitis

This pox was first described in Germany and during recent years has been reported in the UK, Australia, East Africa, etc. The disease is not accompanied by fever or systemic upset.

Characteristically, papules form in the mouth on the mucous membrane lining the cheek. Early lesions are rounded areas of intensive congestion up to 1.5 cm in diameter which, in pigmented mucous membrane, are visible as roughened areas with greyish discoloration. The centre of such areas becomes necrotic and in a later stage shows a depressed centre. Removal of the caseous material leaves a raw granulating ulcer but normally epithelial regeneration occurs in three to four days. A feature of the disease is the occurrence of concentric rings of necrosis and congestion. Secondary lesions of mouth, muzzle or nostril may prolong the disease over a period of months. However, it is unusual for the animals to show signs of illness.

VetBooks.ir

Cause The virus involved is the same as, or is related to, that causing pseudo-cowpox. (See also VIRAL INFECTIONS OF COWS' TEATS.)

Bovine Parvovirus

A cause of diarrhoea in calves.

Bovine Pleuropneumonia, Contagious CBPP

A NOTIFIABLE DISEASE in the UK and worldwide. It is an important disease in Africa. Affected animals have a high temperature (41.5° C [107° F]), difficulty in breathing and are anorexic.

Cause *Mycoplasma pleuropneumoniae.*

Control Diagnosis is difficult except at post mortem examination. Affected animals are slaughtered

Bovine Pulmonary Emphysema

(See FOG FEVER.)

Bovine Quintuplets

Bovine quintuplets, all dead, were produced by a Charolais cow in the UK, which went on to conceive again within a normal period of time.

Bovine Respiratory Disease Complex (BRD)

(See ENZOOTIC PNEUMONIA OF CALVES; 'SHIPPING FEVER'.)

Bovine Rhinotracheitis, Infectious

(See RHINOTRACHEITIS, INFECTIOUS BOVINE.)

Bovine Somatotropin, Bovine Somatotrophin

The growth hormone found in cattle. The natural product is a chain of amino acids produced in the pituitary gland but it may be produced by recombinant DNA technology. The recombinant somatotropin is used in milk producing animals, but is banned in the EU, Australia, Canada, New Zealand and Japan. It increases milk production and also muscle production in beef animals.

Bovine Spongiform Encephalopathy (BSE)

'Mad cow disease'. A NOTIFIABLE DISEASE in which microscopic spaces (vacuoles) develop in the brain tissue, in the manner of a sponge.

Signs Cattle become nervous and hypersensitive to noise, and when approached or touched. They appear frightened and may be aggressive. Dairy cattle show a reluctance to enter milking parlours and may resent attempts to apply milking clusters. The gait becomes abnormal, with hind-limb swaying. The head is lowered. When the animal is at rest, regular or spasmodic muscle twitching may be seen.

BSE was first recognised in 1986 although individual cattle were probably affected in the 1960s and 1970s. A policy of slaughter and incineration of carcases was introduced. The heads were removed to confirm diagnosis.

Its origin is unknown but it is possible that the disease developed in a single cow following genetic mutation.

Fortuitously, a link between BSE and the use of meat and bone-meal in bovine diets was established in 1987. It was at first thought that the meal responsible contained material from scrapie-infected sheep. However, the Phillips inquiry into BSE concluded that this was not the case. Current opinion favours the probability that a BSE-infected cow entered the rendering process that produces meat and bone-meal, infecting cattle which spread the disease when their carcases were in turn processed into meat and bone-meal. Meat and bone meal was banned from bovine diets in 1988 but could still be used in diets for other species. However, this created the potential for meal intended for cattle to be infected by contamination with that prepared for other species in the same mill. Meat and bone meal is now banned from use in all animal feeds; its possession in an animal feed plant is a criminal offence.

Specified bovine offals were prohibited from human consumption; they include brain, spinal cord, spleen, thymus and small intestine lining. All British beef exports were banned, with catastrophic effects for the farming economy. The ban could not be lifted until the UK adopted measures to lessen any risk to humans.

A new form of Creutzfeldt-Jakob disease in (mainly) young persons (called variant CJD) has been confirmed as being linked to BSE. The UK government has introduced a scheme to aid victims and their families.

Incidence At its peak in 1992, 36,681 cases had been confirmed representing about 0.3 per cent of the national herd; the disease has been declining since then. By 1996, the number had fallen to about 8,000, about 0.07 per cent of the national herd. In 1997, a cull of cattle, instigated by the EU, removed those cows which could have eaten the same contaminated feed as the proved cases in the same herd. A second cull, in 1998, removed female calves born to cows around the time they showed clinical signs of the disease. In 2010 there were no clinical cases in the UK, but 11 were detected by active surveillance, and there were two clinical cases in Eire.

Eradication As a further precaution against the possibility of endangering public health, the

carcases of animals over 30 months of age were incinerated and not used for human consumption. In 2011 it was proposed that healthy cattle are accepted into the human food chain without BSE testing if they are less than 72 months old. The incidence of BSE is now so low that all cattle born after 1998 can enter the food chain.

Cause It is generally accepted that the cause of BSE is a PRION, a self-replicating infectious protein (PrP). However, it is not known how this produces the disease. Theories that BSE resulted from a change in the rendering process used to produce meat and bone-meal, that it is a bovine form of scrapie or that it is an autoimmune disease have been discounted. The Phillips inquiry also discounted claims that BSE was caused by exposure to organophosphorus pesticides although it acknowledged the possibility that this might increase susceptibility to the disease.

Differential diagnosis BSE has to be differentiated from other disorders such as acetonaemia (in which short periods of delirium may occur); from listeriosis (in which cattle may become violent in the terminal stages); from hypomagnesaemia and hypocalcaemia.

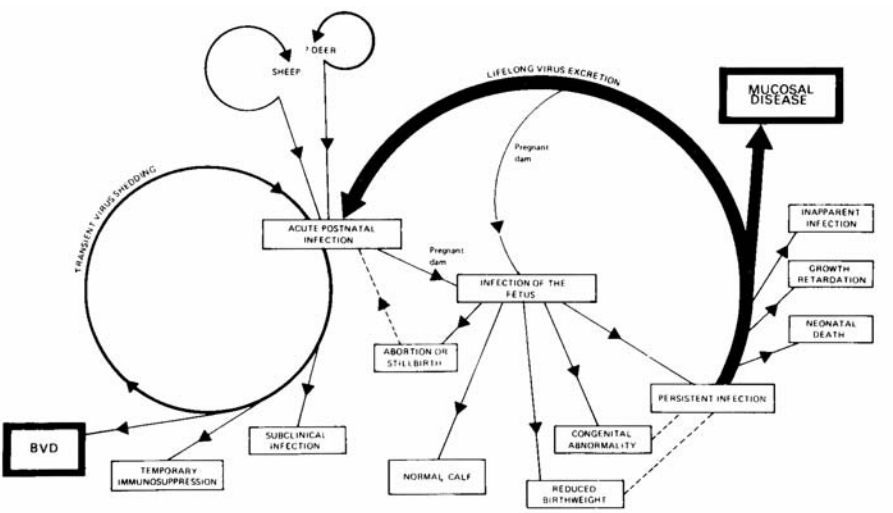
Prevention Ruminants are not allowed to consume animal protein.

Other species BSE has been recorded in several species of antelope in zoos and there is some evidence of infection in sheep. Pigs have developed BSE only after infective material was injected into the brain; they did not develop the disease when fed contaminated feed. There may be a link with FELINE SPONGIFORM ENCEPHALOPATHY as some big cats in zoos had developed a spongiform encephalopathy after having eaten bovine heads, before BSE was recognised as a disease. BSE is experimentally transmissible to mice and monkeys. (See also SCRAPIE.)

Bovine Syncytial Virus

A retrovirus which may have an involvement with bovine and bovine enzootic leukosis as well as immunodeficency-like virus respiratory diseases. (See PNEUMONIA.)

Bovine Tuberculosis



(See TUBERCULOSIS.)

Bovine Viral Diarrhoea/Mucosal Disease (BVD/MD)

Bovine viral diarrhoea (BVD) and mucosal disease (MD) are two clinically dissimilar conditions caused by the same virus.

BVD is the result of an acute infection in susceptible cattle which may occur at any age in post-natal life, and is usually a trivial illness of a few days' duration and negligible mortality. Infection in cows in early pregnancy may result in abortion, resorption of the fetus, or the birth of more persistently viraemic calves.

By contrast, MD is almost invariably fatal. It occurs in cattle which have a persistent BVD/MD viral infection acquired as fetuses. Susceptible animals are unable to produce antibody to the

Bovine virus diarrhoea and mucosal disease: infection cycles. (Reproduced with permission from *Veterinary Record*, **117**, 245, MAFF/HMSO. Crown copyright.)

VetBooks.ir

infecting virus. The disease develops, after the loss of passive immunity given by colostrum, usually when the animals are six to nine months old.

In Britain BVD/MD virus is widespread. More than 60 per cent of adult cattle have significant levels of serum neutralising antibody.

Cause The BVD/MD virus belongs to the *Pestivirus* genus, and is a small RNA virus of the Togavirus family. There are at least 13 strains, some more pathogenic than others. The strains may show ANTIGENETIC DRIFT. The virus can survive storage at 4° C (39° F) for at least 16 months; also repeated freezing and thawing.

Signs In affected animals in the very mildest cases, there may be a few ulcers in the mouth, perhaps also in the nostrils, but little else. More often, however, the animal runs a temperature of 40° C or 40.5° C (104° F or 105° F) with loss of appetite, scouring, and a drop in milk yield. There may be ulcers in the cleft of the foot, and lameness can be a prominent feature of the disease. With mucosal disease, signs are of severe disease with mucosal sloughing in the mouth, oesophagus and possible other parts of the alimentary tract.

Infection in early pregnancy may cause abortion, embryonic death or congenital deformities. Mid-pregnancy infection may result in apparently normal calves which may succumb to mucosal disease. These animals are persistently infected with BVD virus and this results in immunosuppression. They maintain infection in the herd. Many cattle at some time after six months old develop infection with a cytopathic form of virus and develop fatal mucosal disease. Animals infected in late pregnancy produce calves born with antibodies to the disease produced by the fetus.

Diagnosis BVD/MD has to be differentiated from foot-and-mouth disease, Johne's disease, cattle plague, and other conditions. An ELISA test is available.

Prevention Various vaccines, live and inactivated, have been used in North America, with mixed results. In 1995, an inactivated ('killed') vaccine was developed from a prototype created at the Institute for Animal Health, Compton, which was demonstrated as being effective. Several killed vaccines are now available. In Scotland, an eradication programme uses a combination of vaccination and culling.

Bowel, Oedema of the

This disease affects mainly piglets of eight to 14 weeks old, though occasionally it is seen in the newborn and in pigs of up to five months. It is usually associated with a change in management such as moving or mixing with others, but especially with a change in diet. In most cases a gelatinous fluid is found in the thickness of the stomach wall and other parts. The disease can be experimentally transmitted by inoculation of this fluid.

Cause *E. Coli*, mainly serotypes 0138, 0139 or 0141.

Signs The finding of a dead pig – often the best in the litter – is usually the first indication. Puffy eyelids, from which there may be a discharge, and puffiness of snout and throat may be observed, together with leg weakness and convulsions. Severely affected pigs die. Post mortem examination shows oedema in the stomach wall.

Treatment Administer antibiotics by injection to affected pigs, and by injection or in feed or water to others in the group. Feed should be reduced and, if provided from hoppers, roughage should be added. Return to normal feed should be gradual.

Prevention After weaning, keep on same feed for at least two weeks. Change of diet should be gradual over three to five days.

Bowels

(See INTESTINES.)

'Bowie'

A disease of unweaned lambs, resembling rickets, in New Zealand. A supplement of phosphates appears to be effective.

Bow-Legs

Legs curved outwards from the knee occur normally in some breeds of dogs, such as the pug and bulldog, but in other breeds they are usually the sign of RICKETS. The shafts of the long bones become softened and bend outwards under the weight of the body, so that the fore-limbs especially become curved outwards. The condition is also seen in poultry and farm animals.

Bowman's Capsule

A part of the nephron – the unit of structure of the kidney. Fluid passes from the glomerulus into the capsule as the first stage of filtration and urine formation.

Boxer Dogs

A medium-sized, short-coated, short-nosed (brachycephalic) breed of dog; usually brown in colour with white and black markings; a few are all white. The skull structure leads occasionally to breathing difficulties. ACHALASIA OF THE OESOPHAGUS,

AORTIC STENOSIS, ATRIAL SEPTAL DEFECT, CALCINOSIS CIRCUMSCRIPTA, CLEFT PALATE, CORNEAL ENDOTHELIAL DYSTROPHY, CORNEAL EPITHELIAL DYSTROPHY, HYPERPLASTIC GINGIVITIS, PATELLAR LUXATION, SPONDYLOSIS DEFORMANS and PROGRESSIVE AXONOPATHY can all be inherited. The breed shows a higher than usual incidence of SKIN CANCER and HISTIOCYTIC ULCERATIVE COLITIS occurs in this breed. They are susceptible to CRUCIATE LIGAMENT RUPTURE, CORNEAL LIPIDOSIS, DEGENERATIVE MYELOPATHY, and VON WILLEBRAND'S DISEASE. White boxers tend to be deaf.

'Box Wetting'

A name for compulsive polydipsia in horses. (See COMPULSIVE POLYDIPSIA.)

Boxwood Poisoning

Boxwood poisoning may sometimes occur through farm animals gaining access to gardens where the plant grows, or by eating the trimmings from box hedges along with other green food taken from the garden. The plant, known botanically as *Buxus sempervirens*, contains several toxic alkaloids, the chief of which is buxine. When large quantities have been taken, or if the beast is not able to vomit, nervous signs, lameness, muscular twitching, dizziness, diarrhoea and acute abdominal pains are seen. In very severe cases there is the passage of blood-stained motions, great straining, convulsions, delirium, unconsciousness, and death. Pigs are the most susceptible of the farm animals.

BPEX

(See BRITISH PIG EXECUTIVE.)

Brachial

Brachial is a word describing an association with the forelimb. The brachial plexus is an important group of nerves supplying the shoulder and forelimb. Tumours arising here are usually malignant. They are seen most often in dogs and cause a progressive lameness of one forelimb together with atrophy of the muscles; also signs of pain which cannot be localised. Injury to the brachial plexus involving damage to NERVES results in paralysis of the affected forelimb.

Brachycephalic

The word is applied to the short skulls of such dogs as the BULLDOG, toy spaniel or PUG. In such the forehead is more domed than normal, the skull broad, and the face foreshortened with the lower jaw protruding in front of the upper jaw. This may lead to breathing difficulties. (See BRACHYGNATHISM, DOLICHOCEPHALIC SKULL, MALOCCLUSION, PROGNATHISM).

Brachydactyly

A congenital shortness of the hands or feet.

Brachygnathism

(adjective, Brachygnathic)

A condition in which the lower (mandible) is abnormally short and behind the upper jaw, i.e. the jaw is said to be OVERSHOT or PARROT MOUTH.

Brachyspira intermedia

This occurs as a dormant infection in poultry in many parts of the world, but can cause a drop in egg production and increase faecal moisture when wheat-based diets are given.

Brachyury

A MUTATION first described in mice, which affects the tail length and the sacral vertebrae in HETEROZYGOUS animals. In homozygous (see GENETICS, HEREDITY AND BREEDING) mice death occurs at about 10 days gestation due to defects in embryo formation. The name derives from Greek *brakhus* meaning short and *oura* meaning tail. It is seen uncommonly in animal species but is seen in some dog breeds including COCKER SPANIELS.

Bracken Poisoning

The eating of bracken (*Pteris aquilina*) by horses, cattle or sheep may lead to serious illness and death; signs appearing a month or two after the first meal of the plant.

Cause Bracken contains an enzyme, thiaminase, which in the horse and pig causes a thiamine deficiency. In cattle and sheep this vitamin is produced in abundance in the rumen, and bracken poisoning is due not to thiaminase but to the 'radiomimetic-factor' also present in bracken which depresses bone-marrow function. There are complex changes in the blood and bone marrow. Poisoning is more prevalent in dry seasons than in wet weather, and young store stock are more often affected than adult cattle. The rhizomes are said to be five times as poisonous as the fronds – a fact of importance where reclaimed land has been ploughed.

Signs In the horse these take the form of a general loss of condition and an unsteady gait; later on, loss of appetite (but no rise in temperature), nervous spasms and death.

Affected cattle, on the other hand, run a high temperature. They segregate themselves from the rest of the herd and cease grazing. The visible mucous membranes are pale in colour, and numerous petechial haemorrhages are found scattered over the lining of the nose, eyes and vagina. Bracken is

VetBooks.ir

also associated with enzootic haematuria and upper alimentary squamous cell carcinoma (mainly in older suckler cows).

Faeces, passed without straining, are usually blood-stained. Respirations are accelerated, and on the slightest exertion the animals fall and have some difficulty in rising. In many cases a knuckling of the fetlocks, especially of the hind-limbs, is noticeable. In some cases the throat becomes swollen, so that there is difficulty in breathing. The illness lasts from one to six days. In other cases, death may occur much sooner, and be accompanied by bleeding from nose and anus, when the carcases have some similarity to deaths from anthrax. Onset of signs may be delayed for up to two months.

In sheep, ingestion of bracken can also cause bright blindness and mandibular neoplasia.

Treatment DL-Butyl alcohol injections have been recommended for cattle in the early stages of bracken poisoning. For the horse, injections of thiamine are usually successful if the illness is tackled in time.

Prevention Bracken is usually eaten only when no other food is available; avoid the situation in which animals turn to bracken out of sheer hunger or thirst – semi-starvation of livestock is ever a false economy. Especially where the grazing is poor, it is essential to move animals to bracken-free land every three weeks. Avoid the use of green bracken as bedding.

Bracken and cancer During the investigation of acute bracken poisoning in cattle, it was found that certain constituents of the plant were carcinogenic in rats and mice. In 1975 one of at least two bracken carcinogens was identified as shikimic acid, a constituent of many other plants also, and it has been shown to cause lethal mutations and to be a very potent cancer-producer in mice.

Both in the UK and in Japan young bracken shoots have been eaten by people as a vegetable. A link has been established in Japan between long-term bracken fern ingestion and stomach cancer.

In some parts of the world, cancer of the bladder is an endemic condition in cattle, and in most places – states the World Health Organisation – it is associated with bracken. (See also BRIGHT BLINDNESS.)

Bradshot

Another name for BRAXY.

Bradycardia

Bradycardia means slowness in the beating of the heart, with corresponding slowness of the pulse-rate. (See also HEART DISEASES Functional disorders; PULSE.)

Bradykinin

Damaged tissue releases the polypeptide bradykinin, a powerful vasodilator and stimulator of smooth muscle and of pain receptors, possibly as part of the inflammatory response to injury.

Braford

A breed of cattle formed by crossing the Brahman and the Hereford.

Brahma Chickens

A breed originating from India, believed to originate from JUNGLE FOWL (*Gallus gallus*) and the COCHIN. They are calm birds and the male weighs 5.5. kg (11 lb) and the hens 4 kg (9 lb). There are three colours: light, dark and buff. The eggs are white with about three produced per week. There are bantam varieties.

Brahman

Cattle of this name in the south of the USA were developed from a mixture of several zebu breeds (*Bos indicus*) plus some Shorthorn or Hereford content.

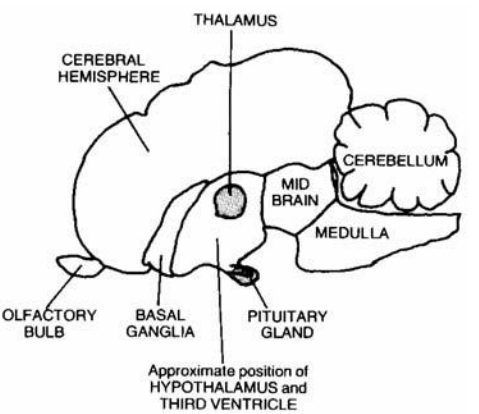
Brailing

A means of temporarily preventing flight in pheasant poults, etc., by means of leather straps.

Brain

The brain and the spinal cord together form what is called the CENTRAL NERVOUS SYSTEM.

Parts of the brain In the domestic animals, as in man, the principal parts of the brain (front to back) are as follows:



1. The cerebrum. This is by far the largest part, and consists of two hemispheres separated by a deep cleft. The surface of the cerebrum is increased by numerous ridges or gyri and by furrows called sulci. The hemispheres are joined by the fibres of the corpus callosum.

   Each hemisphere is divided into sections or lobes, and its surface has a layer of grey matter – the cortex. At the front of each hemisphere is the olfactory bulb, which relays impulses from the olfactory nerves of the nose to the brain, and is concerned with the sense of smell.

   Within the cerebral hemispheres lie the basal ganglia. At the base of the cerebrum is the thalamus. Below is the hypothalamus, containing nerve centres for the control of body temperature, and connected by a stalk or pedicle with the pituitary gland.

The lateral ventricles are located within the corresponding hemispheres and are spaces filled with cerebro-spinal fluid, and communicating with the third and fourth ventricles.

2. The brain-stem consists of nerve tissue at the base of the brain and includes the mid-brain (of which the largest structures are the two cerebral peduncles and four quadrigeminal bodies), the pons, and the medulla oblongata.
3. The cerebellum, which has two hemispheres and a middle ridge – the vermis. The cerebellum, with the pons, and the medulla oblongata are often spoken of as the hind-brain. The pons is a bridge of nerve fibres from one hemisphere of the cerebellum to the other. The medulla continues backwards as the spinal cord.

Brain of dog.

Structure The brain is composed of white and grey matter. In the cerebrum and cerebellum the grey matter is arranged mainly as a layer on the surface, though both have grey areas imbedded in the white matter. In other parts the grey matter is found in definite masses called 'nuclei'.

The cells vary in size and shape in different parts of the brain, but all of them give off a number of processes, some of which form nerve-fibres. The cells on the surface of the cerebral hemispheres, for instance, are roughly pyramidal in shape, and each one gives off numbers of nerve-cell projections, called 'dendrites', from one end, and a single long process, called an 'axon', from the other. The white matter is made up of a large number of nerve-fibres, each of which is connected to a cell in the grey matter.

In both the grey and the white matter there is a framework of fibrous tissue cells, extremely fine and delicate, which acts as a supportive structure for the fibres and nerve cells, to which the name 'neuroglia' is applied. Permeating the grey matter is a complex system of blood-vessels, and in the white matter there are also vessels but to a lesser extent.

Meninges The brain proper is covered over by a thin membrane called the 'pia mater', the bones of the cranium are lined by a thick membrane called the 'dura mater', and between these is an irregular network called 'the arachnoid'. Between the arachnoid and the pia mater is a small amount of fluid, which serves as a kind of water-bed in which the brain floats.

Size The brain varies very much in different animals and in different breeds, but the following table gives the average relation of the weight of the brain to the weight of the body:

Cat	1 to 99
Dog	1 to 235
Sheep	1 to 317
Pig	1 to 369
Horse	1 to 593
Ox	1 to 682

From this it will be seen that the cat has proportionately to the size of its body the largest brain.

Nerves There are 12 pairs of nerves coming from the surface of the brain. They are known as cranial nerves:

1. Olfactory, to the nose (smell).
2. Optic, to the eye (sight).
3. Oculomotor
4. Trochlear } to the muscles of the eyes.
5. Trigeminal, to the skin of the face, etc.
6. Abducens, to the muscles of the eye.
7. Facial, to the muscles of the face.
8. Auditory, to the ear (hearing).
9. Glossopharyngeal, to the tongue (taste).
10. Vagus, to heart, larynx, lungs, and stomach.
11. Spinal accessory, to muscles in the neck.
12. Hypoglossal, to the muscles of the tongue.

Blood-vessels The brain obtains its blood-supply from four main sources: two internal carotids and two occipital arteries. These branch and unite to form an irregular circle under the brain within the skull, called the 'circle of Willis'. From this, numerous smaller branches leave to supply the whole of the brain substance. By such an arrangement any possibility of deficiency of blood is obviated, for should one of the main branches become cut or occluded, the others enlarge and the same amount of blood is still supplied. The blood leaves the organ by means of

VetBooks.ir

large venous sinuses situated in the membranes covering the brain, and finally finds its way into the jugular veins of the neck.

Functions The cerebrum is concerned with memory, initiative, volition, intelligence, and, as well as these, it is the receiving station of the impulses that originate from the organs of sight, smell, taste, hearing, and touch. Fear, anger, and other emotions originate in the grey nerve cells of the cerebrum, which is also concerned with voluntary control of the skeletal muscles.

Sensations on the right side of the body, and muscular control in the right side, are dealt with by the left cerebral hemisphere; the right hemisphere being concerned with the left side of the body.

The cerebellum is concerned with unconscious control, with balance, and with co-ordination of complex muscular movements. Each half of the cerebellum controls the muscular system of its own side of the body, and is in communication with the opposite side of the cerebrum. It closely communicates with the nerves, internal ear, and with certain nerves of muscle-sense, monitoring the state of muscle contraction.

The hypothalamus controls many body functions including hunger, thirst, body temperature and sleep.

The thalamus acts as a vital relay station between the sensory nerves (except the olfactory nerves) and the cerebral cortex.

The basal ganglia help to control much muscular activity.

The medulla contains nerve centres for the control of involuntary, or reflex, actions such as respiration and heart-beat rates, coughing, vomiting, and the reflex part of swallowing.

Brain Diseases

Brain diseases include the following:

Abscess Infective micro-organisms may enter through an injury to the bone, through the medium of the ear (especially in the pig and dog), or may arrive by the bloodstream. Sometimes a foreign body, such as a needle that has become lodged in the throat, may pass upwards into the brain and set up an abscess. The condition may be produced during the course of pneumonia, metritis, endocarditis, etc., when the bacteria invade the bloodstream and get carried to the brain among other tissues.

For signs and first-aid, see under MENINGITIS; ENCEPHALITIS.

Cerebral haemorrhage Bleeding into the cranial cavity, usually as a result of trauma or a vascular problem. It may result in loss of consciousness and death. Residual signs on recovery may include hind limb instability or convulsions.

Concussion The temporary loss of consciousness resulting from a head injury. Temporary blindness may occur after the animal has regained consciousness.

In domestic animals long-term effects include changes in behaviour, such as aggressiveness and excessive libido. Fits (epileptiform convulsions) may be a sequel to a head injury in dogs. (See EPILEPSY.)

Encephalopathy Any disease of the brain, particularly one involving structural changes.

Inflammation (See ENCEPHALITIS; MENINGITIS.)

Necrosis This can occur and can be a specific area and affect one or both sides of the brain.

Oedema of the brain is seen in salt poisoning in pigs, and in polioencephalomalacia CEREBROCORTICAL NECROSIS. Blindness and convulsions are produced.

(See also 'DAFT LAMBS'; HYDROCEPHALUS; CHOREA; RABIES; EQUINE ENCEPHALITIS; 'SLEEPER' SYNDROME of cattle.)

Parasites of the human brain, of animal origin, include nematodes, such as larval hookworms, *Strongyloides*, ascarid worms (*Toxocara*), filarial worms, rat lungworm (*Angiostrongylus cantonensis*), and *Gnathostoma* spp.; trematodes, such as *Fasciola hepatica* (liver fluke), *Schistosoma japonicum*, and *Paragonimus* spp. (lung fluke); the cestodes of hydatid disease, cysticercosis, and sparganosis; and fly maggots such as Tumbu fly of East and Central Africa (*Cordylobia anthropophaga*), tropical warble fly of South America (*Dermatobia hominis*), sheep botfly of parts of Russia and the region and the Mediterranean (*Rhinoestrus purpureus*), and cattle bots and warble fly in Europe (*Hypoderma bovis* and *lineatum* of cattle and *H. diana* of deer) (*Lancet*). Such parasites may similarly occur in the brains of farm and domestic animals. (See COENURIOSIS and HEARTWORM; the latter being especially important in cats.)

Transmissible encephalopathies such as scrapie and BSE.

Tuberculosis of the brain (See TUBERCULOSIS.)

Tumours of the brain may cause a variety of signs, according to the part affected. For example, changes in character, loss of house training,

seizures (cerebrum), circling movements, nystagmus (vestibular system), loss of coordination (cerebellum), a staggering gait (medulla), metabolic problems (hypothalamus). Decreased activity, drowsiness and blindness in cats are seen as a result of a meningioma. Of the 11 per cent suspected of having bovine spongiform encephalitis (BSE) in which the disease was not confirmed, brain tumour was the commonest explanation for the signs.

Brain Surgery

In veterinary practice this is performed to treat COENURIOSIS. (See under TAPEWORMS for the technique of the operation in sheep, and for the signs suggestive of this disease.) It may be necessary in small animals following a road traffic accident or to remove brain tumours.

For example, a 12-year-old cat referred to the Ohio State University's teaching hospital, had been walking in circles, aimlessly pacing, and, purring almost continuously; however, the cat was only intermittently responsive to human attention, and kept his tongue protruded from his mouth.

Under a general anaesthetic, after computerised tomography of the skull to indicate the exact site of the lesion, a hole was drilled and through it the tumour (a meningioma) gradually removed. The cat made a perfect recovery.

Bran

This is the waste product from wheat milling, used as a feedstuff for herbivores and a medium for rearing and transporting MEAL-WORMS. A bran diet is deficient in calcium and high in phosphorus. *Osteodystrophia fibrosa* is seen in horses fed predominantly on bran. (See HORSES, FEEDING OF; MIDDLINGS; OSTEODYSTROPHIC DISEASES; BRAN DISEASE; WEATINGS.)

Branding

The application of an identifying mark to, usually, horses and cattle. Traditionally, a hot iron was used to sear the hide, leaving a permanent mark. A less painful method is freeze-branding. In this technique, a copper branding 'iron', cooled to –70° C (-94° F) with dry ice and alcohol, is applied to a clipped or shaved area for about 27 seconds.

When the branded area thaws, the hair falls out. The new hair which grows in two or three weeks is white, and therefore shows up well on a darkish animal. For a white animal, the brand has to be left on longer to kill the hair roots. The brand-mark then resembles a hot-iron brand, but the hide damage may be less. (Early claims that 'there is no damage to the hide' have been disproved.)

Laser beams have been used for branding cattle in the USA. It is claimed that 'with the 5,000° C temperature of the branding beam, the speed of branding is faster than the pain reflex of an animal'.

Where a permanent brand is not necessary, it is a simple matter to apply black hair dye or hair bleach, according to whether the animal is light or dark in colour.

Bran Disease

Osteodystrophia fibrosa; it is seen in horses predominantly fed bran. Such a diet is deficient in calcium and contains excessive phosphorus. Bone deformities are seen, particularly swelling of the upper and lower jaws, with loosening of the teeth, and lameness. It may also occur in other animals fed a diet too high in phosphorus.

Bran Mash

Made by adding boiling water to a tablespoonful of salt and two double handfuls of bran and stirring to a porridge-like consistency; cool for 15 to 30 minutes, then give feed. Traditionally given to sick horses.

Brassicae Species

Plants of the *Cruciferae* family – kale, cabbage, Brussels sprouts and rape. Excessive consumption can lead to haemolytic anaemia, with haemoglobinuria, especially if other foods are not available or if the kale is frosted. Certain species of brassica contain thiocyanates and produce iodine deficiencies and goitre. In tortoises, excess feeding leads to GOITRE. (See under KALE.)

Braxy

Also known as BRADSHOT – a disease of sheep characterised by a very short period of illness, by a seasonal and regional incidence, and, in the natural state, by a high mortality. It occurs in various parts of Scotland, Ireland, the north of England, Scandinavia, etc., chiefly on hilly land. It attacks young sheep under the age of two years, weaned lambs being very susceptible; the best members of the flock are more liable to become attacked than poorly nourished sheep, and it is most frequently seen during a spell of cold, severe weather with hoar frosts at night.

Causes *Clostridium septicum.* It affects the mucous membrane of the fourth stomach (abomasum) of sheep and from there invades the tissues. It gains entrance to the alimentary canal by way of the mouth along with the grass from a 'braxy pasture'.

Infection with *Cl. septicum* is characterised by gas gangrene and may occur in animals other than sheep – including man.

VetBooks.ir

Signs These – loss of appetite, abdominal pain, diarrhoea, with a high temperature and laboured breathing – are seldom in evidence for more than five or six hours; death being sudden. A characteristic odour is perceptible from the breath and body fluids. Decomposition is very rapid. The lesions are those of a gastritis in the 4th stomach (abomasum).

Prevention Vaccination at the beginning of September, so that the animals have time to establish an immunity before the frosts begin, has given good results. On farms where the losses have been very heavy a second vaccination 14 days later may be needed. (See also under VACCINATION.)

BRD

A term coined in USA to designate BOVINE RESPIRATORY DISEASE COMPLEX, formerly concerned with respiratory disease in feedlots (See 'SHIPPING FEVER'). The term is now used for all types of respiratory disease in cattle.

Breast Blisters

Mainly seen in chickens (broilers, layers) and turkeys. A swelling of the keel bone (see BURSAE). There are many causes including trauma, wet litter, lack of perching space, leg weakness and then often staphylococcal infection.

Breathing

(See RESPIRATION.)

Breathlessness

Breathlessness may be due to any condition that hinders the thorough oxygenation of the blood, the opposite of hypopnoea.

Hyperpnoea is increased depth of breathing.

Tachypnoea is the name for an increase in the rate of respiration. This may arise from such diverse causes as anaemia, heat stress, heart disease, pneumonia, bronchitis, and paraquat poisoning. Opposite of bradypnoea.

Dyspnoea means laboured breathing, or breathing accompanied by pain or distress, such as may occur with oedema of the lungs, pneumonia, bronchitis, pleurisy, emphysema, and paraquat poisoning.

Breda Virus

A cause of diarrhoea in calves in the USA, and of respiratory disease in 2-day-old calves which very soon died.

Breech Presentation

(See PARTURITION.)

Breeding, Controlled

(See CONTROLLED BREEDING.)

Breeding and Sale of Dogs (Welfare) Act 1999

This amended the above two Acts. Bitches must not be mated if they are less than 1 year old; and a bitch can have not more than 6 litters in her lifetime. Records of breeding have to be kept and dogs must be identified by a tag bearing a code identifying the premises of birth.

Breeding of Dogs Act 1973

The Breeding of Dogs Act 1973 makes it unlawful for anyone to keep a dog-breeding establishment unless it has been licensed by the local authority. A breeding establishment is defined as 'any premises (including a private dwelling) where more than two bitches are kept for the purpose of breeding for sale'.

Breeding of Dogs Act 1991

This extended powers under the 1973 legislation, which permitted local authorities to inspect only those premises already licensed, or those for which a licence application had been made. Under the 1991 Act the local authority or a veterinary surgeon could apply to a magistrate for a warrant to enter and inspect the premises. Obstruction is a criminal offence.

Breeding of Livestock

Information about animals coming 'on heat' or being 'in season' is given under OESTRUS. Other information is given under PREGNANCY AND GESTATION and PARTURITION.

Number of females per male varies. The stallion when he is four years old and upwards and in good condition will serve from 80 to 120 mares during a season. A three-year-old can take up to about 50 or 60, and from 15 to 20 are enough for a two-year-old. From 60 to 80 cows are sufficient for an average adult bull, but he should not serve more than 35 or 40 between one and two years of age. Twenty to 30 ewes are as many as the ram lamb will successfully serve, but shearlings may have as many as 40 to 50. Adult rams may successfully impregnate 80 ewes or more. The year-old boar should not be allowed more than 20 sows during a season, but when he is older he may have up to 30 or 35. In this connection it must be remembered that when a large number of females are served by a male, those served at the later stages are not so likely to prove fruitful as those served earlier.

When synchronisation of oestrus (heat) is practised, more males are required; for instance, one ram for 10 ewes.

In old age There are few reliable data, but mares have bred foals when over 30 years, cattle and sheep up to 20 years and cats till 14 years old. These, however, were all animals that had bred regularly in their younger days. It is difficult to breed from an aged female that has not previously been used for stud purposes. (See also under REPRODUCTION; ARTIFICIAL INSEMINATION.)

Brewer's Grains

Brewer's grains are a by-product of brewing used as animal feed. They consist of the malted barley after it has been exhausted. In both wet and dry forms they are used for feeding cattle, while dry grains are sometimes fed to folded sheep. If fed wet they must be fresh or they become fermented; acidosis may then result when fed. Mould can occur if stored. In the dry they can be kept for a considerable length of time without harm. They are rich in proteins and carbohydrates, but must not be fed to excess.

Some samples become infected with *Bacillus cereus*. (See BACILLUS.)

Briard

A large, long-haired dog, black, fawn or grey in colour. Many heritable defects have been eliminated by selective breeding but progressive retinal atrophy and RETINAL PIGMENT EPITHELIAL DYSTROPHY are probable inherited traits. HIP DYSPLASIA may be due to a variety of factors. Night blindness has also been reported as inherited in this breed.

Bridle Injuries

They take the form of: (1) injuries to the poll; (2) injuries to the chin, caused by the curb-chain; and (3) injuries of the mouth from the bit. Damage is generally only superficial but in a few cases infection sets in, and pus forms. This may burrow down into the ligamentous tissue of the poll and produce 'POLL EVIL'. In ordinary cases it suffices to protect the damaged skin by winding a piece of sheep-skin round the strap that is causing the injury, and dressing the abraded areas with an antiseptic powder each night. Those injuries to the chin that are caused by the curb-chain are usually only slight, and mainly affect young horses when they are being broken in. When they learn to answer the reins and acquire what is called a 'soft mouth', the chafed skin is allowed to heal and the condition passes off. In older horses that have 'hard mouths' and that constantly require the use of the curb-chain, the skin becomes thickened and calloused, and the surface of the bone may become irritated with a resulting deposition of new bone in the groove of the chin. Injury may be obviated by using a leather curb for young horses that have very tender skins, and by changing the bit for older animals. Care in driving of the horse, avoiding all sudden or severe pulls on the reins, will often do more to 'soften' a horse's mouth than the use of more drastic measures. Bit injuries consist of the abrasion of the mucous membrane of the lower jaw, just opposite the corners of the lips, where the bit crosses. Sometimes the membrane becomes actually ulcerated and a foul-smelling discharge escapes, but in the majority of cases the injuries are slight and heal in a few days.

Bright Blindness

This, a prevalent condition in Yorkshire hill sheep, was first described in 1965, and is characterised by progressive degeneration of the retina. The disease is of considerable economic importance in some flocks.

Cause Consumption of bracken over a period. Bright blindness has been found in several breeds of sheep, in Scotland and Wales as well as in Northern England. In some flocks the incidence may be 5 per cent to 8 per cent among the ewes, with a peak incidence in those two- to four-years-old. The blindness is permanent.

In ewes moved to bracken-free grazing before the disease is well advanced, the condition will not progress further.

Brisket Disease

Another name for 'MOUNTAIN SICKNESS'.

British Alpine Goats

A black and white breed of goat, with markings of a Swiss, developed in Britain. It is used for milking producing 4.1. kg (9 lb) daily with 3.8 per cent butterfat and 2.7 per cent protein.

British Blonde Cattle

The British bred cattle of the Blonde d'Aquitaine breed. Although a dual-purpose animal it is used for beef. They are a light yellow colour and of an even temperament.

British Blue Cattle

The beef breed originating from the imported BELGIAN BLUE. This breed was first imported to Britain in 1982 and a 'British Type' of Blue was recognised; 25 years later, in 2007, the British Herd Book name was changed. (See BELGIAN BLUE CATTLE.)

British Cats

The term applied to any breed of cat indicates that the animals are stockily built with round heads. For example, the British blue is stocky and round faced; the Russian blue has a bony structure more

VetBooks.ir

similar to the Siamese. British short-hairs are prone to femoral neck fracture.

British Cattle Movement Service (BCMS)

Curwen Road, Workington, Cumbria CA14 2DD. The organisation set up by the UK government to maintain a register of births, deaths and imports of cattle, issue cattle passports and process cattle movement information from farmers.

British Cattle Veterinary Association (BCVA)

The address is Unit B4, Pure Offices, Kestrel Court, Waterwells Drive, Quedgeley, Gloucestershire G12 1AT. Telephone: 01452 260125; email: office@cattlevet.co.uk; website: www.bcva.eu.

British Dane

A breed established by the Red Poll Cattle Society in the UK following the import of Danish Red cattle.

British Equine Veterinary Association (BEVA)

The address is Mulberry House, 31, Market Street, Fordham, Ely, Cambridgeshire CB7 5LQ. Telephone: 01638 720250; website: www.beva.org.uk.

British Friesian Cattle

The breed established a society in 1909 to record the black and white cattle, imported from Holland. There is still a British Friesian Breeders Club. Following the popularity of the Holstein it changed the breed evaluation. The British Friesian Cattle Society became the Holstein Friesian Society in 1988. Compared with the Holstein, the British Friesian is smaller and more stocky. It produces less milk but is more adapted to production from grass and the calves are better for beef rearing.

British Friesland Sheep

(See FRIESLAND SHEEP.)

British Goats

A group of goats registered with the British Goat Society, but which are not classed as a pedigree breed, although they may be used for 'grading up'. They can be of any colour, often have HYBRID VIGOUR, and are often the highest yielding animals.

British Guernsey Goats

(See GOLDEN GUERNSEY GOATS.)

British Horse Society (BHS)

Address: British Horse Society, Abbey Park, Stareton, Kenilworth, Warwickshire CV8 2XZ. Telephone: 02476 840500 or 0844 848 1666; website: www.bhs.org.uk

British Landrace Pigs

A breed originating from an import of Scandinavian LANDRACE PIGS. They are white with drooping ears and a long back. It is a popular breed for using purebred or for crossing.

British Milksheep

A polled medium-sized sheep breed with white wool, face and fine boned. They produce large litters and are used for milk production.

British Pig Executive (BPEX)

This is now part of the AGRICULTURE AND HORTICULTURE DEVELOPMENT BOARD. It is based at Stoneleigh Park, Kenilworth, Warwickshire CV8 2TL.

British Rabbit Council

Address: The British Rabbit Council, Purefoy House, 7 Kirkgate, Newark, Notts NG24 1AD. Telephone: 01636 676042; email: info@thebrc.org; website: www.thebrc.org.

British Saanen Goats

This dairy breed has been developed in the UK mainly from imported SAANEN GOATS. The breed is white in colour but patches and flecks of colour are allowed. It is longer legged and heavier than the Saanen. They have usually long lactations and produce daily about 5.2 kg (11.5 lb) at 3.5 per cent butterfat and 2.6 per cent protein.

British Saddleback Pigs

The breed was created in the 20th century from the Essex and Wessex Saddleback breeds. The Essex is a black pig with a clear band of white over the shoulders and front legs, white feet and tip of tail. The Wessex is black except a continuous white band over the shoulders and forelegs. They can be used for pork (but dark skin), bacon and heavy pigs (over 100 kg [220 lb]).

British Shorthorn Cattle

The breed was developed in North East England in the late 18th century. They are red, white and roan (mixture of red and white hairs) and some are all white. At one time they were dual purpose, producing milk and meat. Usually all cattle are now used for beef. They are crossed with GALLOWAY producing the BLUE-GRAY.

British Toggenburg Goats

The breed is a brown-and-white dairy goat with a short coat although slight fringing is allowed. Daily, they produce about 4.5 kg (10 lb) milk with 3.7 per cent butterfat.

British Veterinary Association (BVA)

Address: 7 Mansfield Street, London W1G 9NQ. Telephone: 0207 636654; email, bvahq@bva.co.uk; website: www.bva.co.uk. The veterinary surgeons' professional representative body. Its principal objects are the advancement of veterinary science in all its branches, the publication of scientific and clinical material, and the promotion of the welfare of the profession. It is intimately concerned with all matters of professional policy, and maintains contact with many outside bodies and government departments. It publishes the weekly journal the *Veterinary Record* and the monthly *In Practice*, which have an international circulation.

The BVA's Animal Welfare Foundation is a charity devoted to the promotion and protection of animal welfare; address as above.

British Veterinary Profession

(See VETERINARY PROFESSION.)

'Brittle Bones'

This is an inherited condition; animals affected are very likely to suffer fractures. It is seen in cattle, sheep and dogs. It is also known as paper bone disease or juvenile osteoporosis. (See OSTEOGENESIS IMPERFECTA.)

Broad-Breasted Bronze Turkeys

This is a brown coloured breed which has been bred to have large breasts for meat; it is unable to breed naturally and so is maintained by ARTIFICIAL INSEMINATION. The weight of a stag is about 16.4 kg (36 lb) and hens weigh 9 kg (20 lb). For about 20 years they were the main type of meat turkey in the USA. Curled tongue may occasionally appear in this breed.

Broad-Breasted White Turkeys

A widely-used breed of commercial turkeys in America. They have shorter legs and breasts than standard white breed. They cannot breed naturally and require ARTIFICIAL INSEMINATION. They can grow up to 22.7 kg (50 lb) and average weights are typically 38 kg to 40 kg (17 to 18 lb).

Brodifacoum

A second generation anticoagulant rodenticide (see RODENTS). They can result in accidental poisoning of dogs and wildlife including OWLS.

Broilers

Good quality table chickens of either sex, about five to eight weeks old, and weighing about 1.5 kg (3½ lb) (liveweight).

Mortality If the chicks and their management are good, the total mortality for a broiler crop should be less than 5 per cent, frequently only 3 per cent. Most of these deaths will take place during the first fortnight. In fact, a 1.5 per cent mortality is normal and to be expected during the early period.

For commercial reasons there is often the temptation to overcrowd broilers in their houses, and this practice will inevitably increase stress and hence the liability of disease – the effects of which may be the more severe. (See also under BATTERY SYSTEM; NEWCASTLE DISEASE; POULTRY AND POULTRY KEEPING.)

Broiler ascites and colisepticaemia lesions in the pericardium and liver are causes of carcase rejection at processing plants; as is 'swollen head syndrome' (subcutaneous oedema). Both are caused by *E. coli*.

'Broken Mouth'

'Broken mouth' is the name given to the mouths of old sheep that have lost some of their teeth. Loss of incisor teeth is not uncommon in hill sheep and is of economic importance because a ewe needs her incisors if she is to support herself and a lamb on the hill.

The condition involves resorption of bone from the jaw following premature loss of the incisor teeth. Often there are also problems with the cheek teeth. It is already known that, in the rat, demineralisation of the skeleton can result from protein or mineral deficiency.

Broken incisors were seen in 6- to 8-month-old sheep wintered for 6 to 12 weeks on swedes or turnips. Towards the end of this period up to two-thirds of the hoggets were in poor condition. The crowns of several incisors had fractured leaving short irregular brown stumps. The enamel was normal but there was softening and loss of dentine between the apical end of the enamel and the gum margin. It was suggested that this resulted from the effects of acids produced by bacterial action on the carbohydrates in the turnips and swedes.

Signs Difficulty in feeding, dropping some of the food back into the trough and 'quidding'.

'Broken Wind', 'Heaves'

'Broken wind' and 'heaves' are both are outdated expressions applied to horses with long-standing respiratory diseases, it was then usually referred to as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) and now RECURRENT AIRWAY OBSTRUCTION (RAO). 'Heaves' is the colloquial name for a condition in which double expiratory effort is a feature. This particular sign may arise from several different pathological processes in the lungs, not all of which are chronic or irreversible;

VetBooks.ir

e.g. allergic reactions, such as immediate-type hypersensitivity (as in bronchial asthma) and extrinsic allergic alveolitis (as in 'farmer's lung'), chronic bronchiolitis following bacterial or viral infections and, very rarely, lung tumours. In every case there is widespread bronchiolitis which initially gives rise to generalised over-inflation of alveoli (so-called 'functional emphysema'). This lesion is reversible but eventually there is destructive emphysema in which there is an increase beyond normal in the size of the air-spaces with destructive changes in the alveolar walls. These changes are irreversible and lead to progressive respiratory disability and eventual failure.

Signs The clinical sign of double expiratory effort consists of an initial passive normal expiratory movement followed by an active contraction of the chest and abdominal muscles to expel the remaining air. In advanced cases this leads to hypertrophy of the rectus abdominis muscles, and the formation of a 'heaves line' beneath the posterior aspect of the rib cage – a feature characteristic of long-standing obstructive pulmonary disease in the horse.

A cough – typically dry, short, hollow and low-pitched – sometimes becomes paroxysmal after stabling or exercise; also faster breathing, audible wheezing, nasal discharge, and intolerance of exercise.

Differential diagnosis of these chronic respiratory disorders with a double expiratory effort depends upon detailed clinical evaluation, responses to corticosteroids and other drugs, the results of serological tests with appropriate antigens and, ultimately, autopsy. Infestation with the equine lungworm *Dictyocaulus arnfieldii* tuberculosis, and hydatid cysts should also be considered. Another related condition occurring in the summer is Summer Pasture-Associated Airway Obstruction (SPAAC).

Treatment Try to remove from the cause of the problem. Often horses are best kept outside. Corticosteroids can help reduce the inflammatory changes and bronchodilators such as clenbuterol hydrochloride assist. Theophylline is used orally and sodium chromoglicate can be inhaled. Mucolytics are used but probably only provide some symptomatic relief.

Control Vaccination against equine influenza, since many cases appear to originate from an episode of acute respiratory disease. Place on a spore-free and dust free bedding. Housed animals must have good ventilation. The feeding of haylage rather than hay and bedding with shavings rather than straw also.

(See also CHRONIC OBSTRUCTIVE PULMONARY DISEASE; EMPHYSEMA.)

Bromelain

An enzyme found in pineapple juice; when fed daily to cats with a history of vomiting hairballs, there was a reduction in the frequency of vomiting from 62.5 per cent in the first month and 81.3 per cent in the second month.

Bromhexine Hydrochloride

A mucolytic and expectorant; used in most animal species.

Bromides

These are used as fumigation insecticides. Animals exposed to these may show signs of sedation, but they should recover if the exposure has not been prolonged.

Bromocriptin

An ergot alkaloid. (See PSEUDO-PREGNANCY.)

Bronchi

Plural of BRONCHUS.

Bronchial Associated Lymphoid Tissue (BALT), Bronchus Associated Lymphoid Tissue

This is the diffuse local aggregations of LYMPHOID tissue in the MUCOUS MEMBRANES associated with the main airways of the RESPIRATORY SYSTEM in some mammals including rats and rabbits but not mice or humans. They can contain B CELLS, T CELLS, MACROPHAGES and PLASMA CELLS, and are able to produce localised immune responses.

Bronchiectasis

A condition in which there is dilatation of the walls of the bronchioles due to weakening through excessive coughing. The condition is often met with in chronic bronchitis, and the cavities produced are often filled with pus.

Bronchioles

These are part of the tubular structures within the lungs between the BRONCHI and the ALVEOLI. Unlike the bronchi, bronchioles do not contain CARTILAGE. They form part of the LOWER RESPIRATORY SYSTEM.

Bronchiolitis

Inflammation of very small bronchial tubes (bronchioles).

Bronchitis

Bronchitis is inflammation of the mucous membrane lining of the bronchi. It is a very common disease of all animals in temperate or cold climates. It may occur as an extension of inflammation of the trachea (tracheitis) and it may be followed by pneumonia or pleurisy, or both.

a. Acute bronchitis This may follow exposure to smoke from a burning building, or be the result of careless administration of liquid medicines which then 'go the wrong way'. More commonly acute bronchitis may occur during the course of some virus infections, following colds and chills, and may affect farm animals housed in badly ventilated buildings. In the dog, bronchitis often occurs during the course of distemper, and in the horse it may be associated with influenza or strangles. Acute bronchitis in cattle and sheep may be parasitic. (See PARASITIC BRONCHITIS; WORMS, FARM TREATMENT AGAINST.) In pigs, too, parasitic worms may cause bronchitis. (See also under COUGHING.)

Signs A rise in temperature, accompanied by faster respiration, loss of appetite, a cough and nasal discharge are seen. The cough is at first hard and dry, but becomes softer and easier in the later stages. The breathing may often be heard to be wheezing and bubbling in the later stages.

Treatment Attention to hygienic conditions is of first importance. The bronchitic horse should be removed to a loose-box, provided with a plentiful supply of bedding, rugged if the weather demands, given plenty of clean water to drink, and fed on soft foods. It must on no account be drenched, for there is nearly always difficulty in swallowing, and a great risk of some of the medicine entering the trachea and complicating an already serious case. In animals suffering from bronchitis due to parasitic worms, suitable anthelmintics must be used. Where the cause is bacterial – secondary, very often, to a virus infection – the use of appropriate antibiotics is indicated. Liquid medicines should not be given. In housed livestock, attention must be paid to the ventilation. For the dog, a jacket of flannel or similar material may be made. (See NURSING OF SICK ANIMALS; KENNEL COUGH.)

b. Chronic bronchitis This may follow the acute form, or it may arise as a primary condition. The smaller capillary bronchial tubes are affected and not the larger passages.

Chronic bronchitis is often seen in the old dog, very occasionally in association with tuberculosis. The latter may also cause chronic bronchitis in cattle and other animals. In the horse, chronic bronchitis may lead to EMPHYSEMA. (See also 'BROKEN WIND'; CHRONIC OBSTRUCTIVE PULMONARY DISEASE; RECURRENT AIRWAY OBSTRUCTION.) Parasitic worms may be associated with some long-standing cases of bronchitis in animals.

Signs A loud, hard cough, often appearing in spasms, respiratory distress on the least exertion, an intermittent, white, clotted, or pus-containing nasal discharge, which is most in evidence after coughing or exercise, and a gradual loss of condition, characterises this form of bronchitis.

c. Bronchitis in chickens (See under INFECTIOUS BRONCHITIS OF CHICKENS.)

Bronchopneumonia

Inflammation of the bronchi and lungs.

Bronchoscopy

Examination of the bronchi by means of a bronchoscope, a tubular optical instrument with a small lamp attached which is passed through the trachea. The technique is used in cases in which clinical and radiological examinations fail to provide a diagnosis.

Bronchus

(plural, Bronchi), Bronchial Tube

Bronchus, or bronchial tube, is the name applied to tubes into which the windpipe (trachea) divides, one going to either lung. The name is also applied to the later divisions of these tubes distributed throughout the lungs. Bronchioles are very small bronchial tubes. The bronchi are lined by MUCOUS MEMBRANE and have CARTILAGE in their walls. They are part of the upper RESPIRATORY SYSTEM. Bronchioles are very small bronchial tubes and do not have cartilage present.

Bronopol

An antifungal compound, which is used as a wash for fertilised salmonid eggs and/or a treatment for adult salmonids. It is active against *Saprolegnia* spp. which are important pathogens of salmon returning from the sea to spawn. It must not be used for alevins. Eggs and fish are treated for 30 minutes and then the medicated water is removed. The dose must be carefully measured and there needs to be a discharge consent from the appropriate environmental agency when used. There is no withdrawal period after treatment of fish.

Bronze Turkeys

The bronze turkey, so called because of its coppery bronze colour, is very popular in Britain. The broad-breasted (meat) Bronzes are more common than standard Bronzes. The Standard Bronze stags weigh 13.6 kg to 18.1 kg (30 to 40 lb) and hens 8.2 to 11.8 kg (18 – 26 lb).

Broth

A liquid medium used for micro-organism culture.

Brown Fat

(See FAT.)

VetBooks.ir

Brown Leghorn
Originating from Italy, it was first introduced from the USA in 1872. It is a prolific egg layer of white eggs. The hens weigh 2.0 kg to 2.3 kg (2.2 lb to 5 lb) and the males 2.4 kg to 2.7 kg (5.3 lb to 6 lb). They can be crossed with the SUSSEX LIGHT CHICKENS.

'Brown Mouth'
A syndrome characterised mainly by gum necrosis and dysentery, occurring as a complication of virus diseases in the dog.

'Brown Nose'
A form of LIGHT SENSITISATION in cattle.

Brown Swiss
A breed of dairy cattle producing milk with a high protein level. It is a dual-purpose breed and can be used for beef production (also known as the Braunvieh); in the past it has been used as a draught animal. It is a common breed in some countries.

Brucellosis
A NOTIFIABLE DISEASE, this is an infection with *Brucella*. Five species of this genus of bacteria are important, namely: *B. abortus* (the main cause of abortion in cattle but now eradicated in Britain); *B. melitensis*; *B. suis*; *B. ovis* and *B. canis*.

Public health Human brucellosis may be caused by any of the five species of *Brucella*, as mentioned above. Infections with *Brucella* species are reportable diseases under the Zoonosis Order 1989. It often takes the form of 'undulant fever', with characteristic undulating fluctuations of the temperature. Human infection with *B. abortus* may follow the drinking of raw milk or the handling of infected fetal membranes. Infected uterine discharge drying on the cow's skin may be inhaled. It was formerly not uncommon in farm and abattoir workers, and veterinary surgeons. Britain was declared Officially Brucellosis Free in 1985. Since then occasional instances have occurred from the import of infected animals.

For signs, see UNDULANT FEVER IN MAN.

What was formerly known as Malta Fever in man is due to *B. melitensis*, an infection of goats and sheep, occasionally cattle. Its only occurrence in the UK was limited to one outbreak resulting from imported infected cheese.

The American strain of *B. suis* (found in pigs and hares) is also pathogenic for man, causing undulant fever and arthritis.

B. canis, which infects dogs, can also cause illness in people.

B. ovis, which infects sheep, rarely causes human illness.

None of those strains is found in the UK.

Horses *B. abortus* may cause fistulous withers and lameness due to infection of other ligaments. Occasionally, after heavy exposure there is systemic illness.

Cattle (See BRUCELLOSIS IN CATTLE.)

Dogs In the UK, *B. abortus* was isolated from the urine of a dog which had shown signs of stiffness and orchitis. At autopsy, cystitis and an abscess of the prostate were found. Such a dog would be a public health risk and a danger to cattle. Abortion is another sign. The infection has been found in kennels, following the feeding of meat from stillborn calves. Brucellosis in dogs is probably more common than generally realised. In Chile a survey showed that 40 per cent of dogs, on farms where the dairy herds were infected with *B. abortus*, were infected.

B. canis was first isolated in 1966. In the USA it has caused outbreaks of severe illness in laboratory beagles; it causes also illness in man.

A unique feature of *B. canis* infection is lack of fever. Another feature is the duration of bacteraemia, which usually lasts for several months, but can last three or four years.

In males, epididymitis, scrotal dermatitis and testicular degeneration may occur, although it is not uncommon for male dogs to be 'silent' carriers.

Sheep Formerly, brucellosis was an important disease of sheep in the UK.

B. ovis gives rise (in Australasia, the USA and Europe) to infertility and scrotal oedema in rams. Abortion may occur in infected ewes. (See also RAM EPIDIDYMITIS.)

Goats In Britain, brucellosis is not a serious problem in goats.

A survey of sheep flocks and goat herds is carried out yearly to determine whether Britain remains free from brucellosis in those species. The results are sent to the EU Veterinary Directorate. The cause is *Brucella melitensis*.

Pigs In Britain, brucellosis is not found. Overseas, abortion in pigs is caused by *B. abortus suis*.

Deer There is no evidence that deer, infected with *B. abortus*, have infected cattle grazing the same pasture.

Poultry Chickens are susceptible to *B. abortus* infection, which they have transmitted to cattle.

Wild animals The harbour porpoise around Britain may carry *Brucella maris*, which reacts with *B. abortus*. Cattle by the shore coming into contact

with porpoise material may then show a positive reaction to the brucella test. *B. suis* has caused orchitis in hares abroad and, in Africa, *B. abortus* has been isolated from a waterbuck and from rodents.

In Argentina foxes are commonly infected with *B. abortus*.

(See also FISTULOUS WITHERS; 'POLL EVIL'; BUMBLE-FOOT; RAM EPIDIDYMITIS.)

Brucellosis in Cattle

(*Brucella melitensis* causes disease in some countries.) 'Contagious bovine abortion', also known as Bang's disease, is a specific contagious disease due to *B. abortus*. Since the infection may exist and persist in the genital system of the bull, *Brucellosis* is to be preferred as a name for the disease. In females it is characterised by a chronic inflammation of the uterus (especially of the mucous membrane); usually, but not invariably, followed by abortion between the fifth and eighth months of pregnancy.

It is important to note that not all infected animals abort. Indeed, in over half of them pregnancy runs to full term. However, any animal that has aborted once may be almost as infectious at its next and subsequent calvings as on the occasion it aborted.

Infection may occur by the mouth or through the vagina during service, when a bull which has served an infected cow is called upon to serve a clean one afterwards, or when the bull is a 'carrier'. Contamination of litter with discharges from a previous case is an important factor in the spread of the disease in a herd. The hand and arm of the man who handles an aborted fetus may also transmit infection.

In the pregnant cow a low-grade chronic inflammatory reaction is set up in the uterus with the result that an exudate accumulates between the fetal membranes and the uterine mucous membranes, especially around the cotyledons. The cotyledons may appear necrotic, owing to the presence of fibrinous adherent masses upon their surfaces, and the fetal membranes may show similar areas after they have been expelled. Quite commonly in cattle the membranes are thickened and tough. The fetus may be normal or may show a dropsical condition of the muscles and the subcutaneous tissues, and there may be fluid present in the cavities of chest, abdomen and cranium. In some cases the fetus undergoes a process of mummification, and when it is discharged it is almost unrecognisable as a fetus.

Cows at pasture may become infected by older 'carrier' cows (which are liable to harbour the organisms in their udders) or by wild animals (e.g. foxes), dogs or birds, which have eaten or been in contact with infected membranes or discharges upon other farms near by where the disease already exists.

Signs Abortion may occur without any preliminary signs, and except that the calf is not a full-term one, may be practically the same as normal calving. Most cows which have aborted once will carry their next calf to full term, or practically to full term, while only very few cows will abort a calf three times. Some calves born to infected cows will be persistently infected.

As a rule, if abortion occurs early in pregnancy the fetal membranes are expelled along with the fetus, but if towards the end of the period there is almost always retention of these. A continuous reddish-brown or brownish-grey discharge follows, and persists for about 10 to 20 days (often for about two weeks). In some instances it slowly collects in the cavity of the uterus, little or nothing being seen at the vulva, and then it is discharged periodically, often in large amounts at a time. In the bull signs of infection may be very slight or absent, and laboratory methods are usually necessary to establish a diagnosis.

Brucellosis is not the only cause of abortion in cattle due to an infective agent, and in arriving at a diagnosis it must be differentiated from infections listed under ABORTION.

Immunity Infected animals gradually produce an immunity in themselves against further abortions. The organisms may persist in the system for long periods, and a cow which does not herself subsequently abort may spread infection to other cows in the herd. This natural immunity, however, is wasteful, both in the matter of calves and milk supply, so that methods have been adopted in which an effort is made to provide animals with an artificial immunity.

Testing Bulked milk from herds is routinely tested by the MILK RING TEST or an ELISA. Periodic biennial blood tests are made of suckler herds; formerly the ROSE BENGAL PLATE TEST was used but this has been replaced by an ELISA. All cows calving at 270 days' gestation or less must be reported and are investigated by blood and milk samples from the dam, examination of placenta, abomasal contents and sera of the fetus. (See also COOMBS TEST.)

Eradication In October 1985 Britain was declared officially brucellosis-free. Occasional cases have occurred following the importation of cattle. Brucellosis has been successfully eradicated from many overseas countries, including Denmark, Sweden, Norway, Finland, the Czech Republic, Slovakia and Eire. Farmers' cooperation and discipline played an important part.

VetBooks.ir

Precautions All calvings under 270 days' gestation must be reported to DEFRA and may be investigated. The greatest care must be taken in handling and disposing of an aborted fetus, fetal membranes, discharges, etc., both in the interests of human health and in order to prevent the spread of the disease among cattle. It is worth having a veterinary surgeon examine the cause of any abortion. There can be danger from the infected cow that has carried a calf to full term. Avoid buying in replacements from non-Accredited herds. Infected farm dogs can spread infection.

Brucellosis in Sheep
(See RAM EPIDIDYMITIS.)

Brucine
An alkaloid found in the seeds of *Strychnos nux-vomica* which are used to produce NUX VOMICA. Its action is similar to, but milder than, that of STRYCHNINE.

Bruised Sole
Bruised sole is a condition of bruising of the sensitive sole of the foot, due to a badly fitting shoe, or the result of the horse having stood upon a projection, such as a stone, etc. Its character and its treatment do not differ from what is given under CORNS, except that while the corn has a more or less definite position in the foot, bruising of the sole may occur anywhere.

Bruises
The discoloration caused by bleeding under unbroken skin following a blow or other trauma. (See also HAEMATOMA.)

Bruit and Murmur
Bruit and murmur are words used to describe several abnormal sounds heard in connection with the heart and arteries on auscultation.

Brush Border
On the free surface of some cells, the wall may be modified to provide finger-like projections: the brush border. This is seen, for example, in the convoluted tubule of the kidney and in the alimentary canal.

Brushing and Cutting
Brushing and cutting are injuries to the horse caused by the inside of the fetlock joint or coronet being struck by the hoof or shoe of the opposite limb; although bad shoeing may be responsible in a few instances, the cause is usually faulty conformation.

A brushing boot should be fitted, and an attempt made to avoid the future occurrence of brushing by skilful shoeing. (See also SPEEDY-CUT.)

Brussels Sprouts
Cattle strip-grazing these for 6 weeks, without other food, became ill with anaemia and haemoglobinuria. The illness caused by members of the *Brassicae* species is said to be more serious near to the time of calving. (See BRASSICAE SPECIES.)

Bruxism
Grinding, gnawing or clenching of the teeth; seen mainly in cattle.

BSE
(See BOVINE SPONGIFORM ENCEPHALOPATHY.)

BST bST
(See BOVINE SOMATOTROPIN.)

bTB
Abbreviation of BOVINE TUBERCULOSIS. (See TUBERCULOSIS.)

Bubonic Plague
Bubonic plague is an infectious disease of man, rats and mice and rabbits caused by *Yersinia pestis*. Foci of infection exist in several parts of the world, including the western United States. Rats, rabbits and cats and dogs may be involved in transmitting the infection to man, usually by means of fleas.

In man bubonic plague takes one of two forms: (l) After an incubation period of two to seven days, the usual signs include the sudden onset of fever, rigors, muscular pain, headache and prostration. Within a few days the characteristic buboes (swelling of the lymph nodes in the groin and armpits) usually appear. These are accompanied by oedema, erythema and great pain. (2) Pulmonary plague has an incubation period of two or three days. Besides the sudden onset of fever there is a cough (usually with bloody sputum), headache, rigors and prostration. When untreated this form of plague usually results in death within two to five days.

Various antibiotics are effective in treatment if given early enough.

The intermediate link between the infected rat and man is the rat flea.

Buccal
Related to the cheek.

Buccal Cavity
The mouth.

Buccostomy
An operation to remove cheek teeth in horses.

B

Buchu
The dried leaves of *Barosma* spp. plants. It is found in herbal remedies and acts as a weak diuretic and urinary antiseptic.

Buck
Term for the male of many species, e.g. deer, ferret, goat, hare, kangaroo.

Budd-Chiari Syndrome
A rare disorder affecting dogs, cats and other mammals. Blood entering the liver has difficulty leaving as the organ and its blood vessels, usually the posterior vena cava, are affected. The liver enlarges and there is tenderness in the abdominal region. Ascites may occur and leg oedema. Portal hypertension may occur with blood vessels to the heart distended and they may become varicose and rupture. Treatment is required before liver failure occurs. Diagnosis involves X-ray angiography or venography or using ultrasound. Surgical treatment is by removing the blockage or, if it cannot be removed, rechannel the blood supply around the blockage.

Budgerigar Fledgling Disease, 'French Moult'
A disease of young birds causing failure of feather growth, with hepatic and renal necrosis. It is caused by a polyoma virus. While often fatal, survivors have symmetrical feather abnormalities with a lack of down feathers. The primary wing feathers and those of the tail may be totally lacking and so affected chicks are often referred to as 'runners' as they cannot fly. In the USA a vaccine is available for breeding birds to provide passive immunity during the susceptible period.

Budgerigars
(See CAGE AND AVIARY BIRDS, DISEASES OF.)

Buffalo
The Asiatic water buffalo *Bubalus bubalis* is farmed in Britain for the production of mozzarella cheese. This large bovine animal is used as livestock in the Indian subcontinent, South America, southern Europe, the Middle East, North Africa and elsewhere. In 2000 there were estimated to be 158 million water buffalo in the world with 97 per cent of them in Asia.

The American 'buffalo' is the bison (*Bison bison)* and is farmed in the UK for meat. (See WATER BUFFALOES.)

Buffalo Fly
This is *Lyperosia exigua*, a parasite of importance in Australia and in India and Malaysia. Swarms of these, which breed in running water, attack cattle and can make them stampede. They produce serious bites which may lead to death. It causes great irritation and even anaemia. Man is also attacked by these black flies (*Simulium* species) (See FLIES.)

Buffalo Gnat
Swarms of these, which breed in running water, attack cattle, often causing them to stampede, and producing serious bites which may lead to death. Man is also attacked by these black flies (*Simulium* species).

Buffalo-Pox
A contagious disease of buffaloes which is of considerable economic importance. The infective agent is distinct from cowpox virus. (See also under POX.)

Buffer
A substance which, when added to a solution, causes resistance to any change of hydrogen ion concentration when either acid or alkali is added.

Buffing
Buffing is a term applied to the striking of the inside of one hoof at the quarter with some part of the opposite one. It is due to the same causes as BRUSHING, but it occurs in horses that do not lift their feet very high. Less damage is done than in brushing, and it is not so likely to cause stumbling or lameness.

Buff Orpington Chickens
The breed originated in Orpington, Kent, England. It is of large size and usually has some white neck colour. They seldom fly away, as they are heavy, and they can become broody. The male weighs 4.5 kg (10 lb) and hen 3.6 kg (8 lb). They have a medium-sized comb and produce light brown eggs. They were originally produced by William Cook by crossing Minorcas, Langshans and Plymouth Rocks. The original colours were black, white, buff, blue and splash. There is a bantam form, larger than many other bantams, seen in a variety of recognised colours (black, blue laced, white, buff, red, buff laced, barred, buff Columbian, birchen).

Bufotalin
The principal poisonous substance present in the skin and saliva of the common European toad, *Bufo vulgaris*. Very small quantities will cause vomiting in dogs and cats, and 0.00917 mg per kg bodyweight has caused death from heart-failure in the cat. (See TOADS.)

Buiatrics
The study of cattle and their diseases. The term is often applied to international cattle veterinary conferences.

VetBooks.ir

Buildings
(See HOUSING OF ANIMALS.)

Bulbar Paralysis, Infectious
(See AUJESZKY'S DISEASE.) The term 'bulbar' relates to the medulla oblongata or the prolongation of the spinal cord into the brain.

'Bulgy Eye' in Grouse
This has occurred in red GROUSE due to *Cryptosporidium baileyi* and signs are similar to those of INFECTIOUS SINUSITIS caused by *Mycoplasma gallisepticum*.

Bulla
A BLISTER greater than 5 cm in diameter; plural, bullae.

Bull Beef
This is beef from the entire animal as opposed to the castrate. (See under CASTRATION.)

There is no question that bull beef is a more economic proposition. Feed conversion efficiency is improved, daily weight gain increased and fat deposit reduced compared with steers or heifers. Bull beef is more popular than that from steers in many parts of Europe. In the UK bulls are used in intensive indoor cereal diet based systems and are usually slaughtered around a year old.

Bulldog
A breed of medium-sized, smooth haired, short nosed (brachycephalic) dog which has breathing difficulties. A show of the breed that took place in very hot weather resulted in the deaths of several dogs because the abnormally large soft palate interfered with their breathing in such conditions. Bulldogs are subject to a number of inheritable conditions including CLEFT PALATE, under-developed (hypoplastic) trachea, and narrowing (stenosis) of the aorta and pulmonary system. PULMONARY STENOSIS can add to the breathing difficulties and under-developed vertebrae can also be found. Ingrowing (ENTROPION) or double eyelashes (DISTICHIASIS) are also found. The breed has changed considerably in appearance since the beginning of the 20th century; the dogs have been bred to accentuate the brachycephalic nature of the skull and the squat appearance of the forequarters. These changes have come with other less obvious internal anomalies and have largely contributed to the problems the bulldog suffers from today.

Bull-Dog Calves
In Dexter cattle commonly, and in other breeds occasionally, a hereditary condition known as achondroplasia occurs. Calves are born in a deformed condition in which the short limbs, dropsical swollen abdominal and thoracic cavities, and a marked foreshortening of the upper and lower jaws give the calf an appearance resembling a bulldog. Such calves are usually dead when born.

'Bull-Dogs'
A small metal appliance used temporarily for the restraint of cattle. They are applied to the inside of the nose for holding an animal steady.

'Bullets'
A form of BOLUS. They are administered to cattle and sheep by means of a special dosing 'gun', and are used as a means of supplying the animal with a long-lasting supply of magnesium, cobalt, or selenium. Bullets can be somewhat costly and not always retained, but they are widely used and have proved successful in preventing deficiency disease in sheep. (See also under COBALT.)

Bull Housing
Any bull housing must be secure and designed to prevent injury to the animal or stockman. The pen should be sited so that the bull can see what is happening around him; ideally, he should be able to see other cattle at times. All accommodation should have sufficient escape points to ensure the safety of those attending the bull. There should be a means of capturing and restraining the animal without having to enter the pen. Adequate space for exercise should be provided as well as sleeping accommodation, which could be a loose-box. If service is to be carried out in the pen there must be a means for allowing the cow to be introduced to a service area without risk to either cow or stockmen.

The codes for the welfare of farm livestock recommend that for an adult bull of average size, the sleeping area should be not less than 16 m² (180 ft²). For very large bulls the sleeping area should not be less than 1 m² for each 60 kg liveweight (9 ft² per cwt). The exercise and service area should be at least twice the size of the sleeping accommodation.

The walls of the pen should be built up to a height of 1 m (3 ft 3 in) and extended to 2 m (6 ft 6 in) high with stout tubular steel rails. There should be a fodder rack and feeding trough at the end away from the shelter, provided with sufficient cover to protect the fodder and concentrates, and the animal while feeding, during bad weather. This arrangement encourages the bull to stay out in the open rather than in the box or shelter and is considered beneficial. The entrance to the pen should be convenient to the feeding area.

The feeding trough should be about 60 cm (2 ft) above ground level and should be fitted with a tubular tying arrangement which can be closed on the bull's neck when he puts his head through to the trough, if it is required to catch him. This

equipment is very desirable as an added safety measure, as it permits the bull to be securely held before the attendant enters the pen.

An arrangement which is very useful for dealing with vicious bulls is the provision of a strong overhead wire cable running from inside the house or shelter to the opposite end of the pen. This cable is threaded through a strong ring, about 3 cm (1¼ in) in diameter. This ring, which slides along the cable, is attached to a chain which passes up through the bull's nose ring, then around the back of the horns and is hooked to the upright chain in front of the forehead. In this way, the weight of the chain is carried by the head instead of by the nose ring and considerable discomfort to the animal thereby avoided. The chain should be just sufficiently long to allow the animal to lie down comfortably. The advantage of this arrangement is that a cow can be brought into the pen for service without the necessity of having to release the bull from his tying.

Another safety device which should be provided, where possible, in the walls or railings surrounding the pen, is escape slits. These are upright openings about 38 cm to 45 cm (15 in to 18 in) wide, sufficient to allow the attendant to pass through in case of emergency, but through which a bull could not pass. If, due to the location of the pen, it is not possible to provide these escape slits, the blind corners of the pen should be fenced off by means of sturdy upright steel rails set 38 cm to 45 cm (15 in to 18 in) apart, behind which an attendant could seek refuge.

Bulling

A cow being mounted by another when on heat is said to be 'bulling'. These oestrus cows may also ride other cows and occasionally they mount the head of other cows. (See also OESTRUS, DETECTION OF, IN COWS.)

Bull Management

All bulls should be handled from an early age and become accustomed to being restrained by means of the bull ring. The animals should be routinely groomed and have their feet regularly handled and trimmed. There should always be two people present when the bull is handled or the pen is entered. A bull can be used for service from about a year old, but only sparingly; once a week, or three services in two weeks, until at least about 16 months old. When first using a young bull, he should be used to serve older, experienced cows.

While a bull is often turned out with cows to act as a 'sweeper' after artificial insemination, or where oestrus detection is poor, this makes it impossible to keep accurate records of service.

Because of the work involved and the lack of suitable accommodation, there has been a tendency not to keep bulls on dairy farms. If kept, they are usually beef breeds. Bulls should be selected to provide genetic improvement to a herd and their choice requires considerable care. (See BULL HOUSING; also PROGENY TESTING.)

Bull Mastiff

A large muscular breed with a short coat, and a distinctive appearance, somewhat resembling the original bulldog. It has fewer inherited defects than the bulldog. CLEFT PALATE, OSTEOCHONDROSIS and ununited ANCONEAL PROCESS (ELBOW DYSPLASIA) may be found, but the inherited mechanisms are unknown. PROGRESSIVE RETINAL ATROPHY is a dominant trait while HIP DYSPLASIA is multifactorial. PERSISTENT PUPILLARY MEMBRANE (See PUPILLARY MEMBRANE, PERSISTENT) is also seen.

Bulls, Diseases of

(See CATTLE, DISEASES OF; diseases listed under the word BOVINE; PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Bull Terrier

A medium-sized dog, smooth coated, commonly white, with a distinctive flat head profile. Originally bred for bull-fighting. Protein-losing Y may be congenital and inherited by an unknown mechanism, and deafness is linked to the coat colour. CLEFT PALATE and UMBILICAL HERNIA are also heritable conditions but the mechanism is unknown. (See also MINIATURE BULL TERRIER DOGS; PIT BULL TERRIERS; STAFFORDSHIRE BULL TERRIERS.)

Bumble-Foot

Bumble-foot is a condition of the feet of poultry, waterfowl, wading birds, birds of prey and sometimes cage birds in which there is severe inflammation; an abscess may form on the ventral surface of the foot with lameness. It may be caused by the penetration of some sharp object, such as a piece of glass, thorn, stone, etc., or even by penetration of the skin by the bird's own talons. Many micro-organisms, bacteria (including *Staphylococcus* spp.), and fungi may enter as secondary invaders.

Treatment Often it can be unrewarding; involves antibiotics and removal of causes. Surgery is often necessary to open the pus-containing cavity and evacuate the cheese-like contents. The wound must be covered until healing is complete.

BUN

Abbreviation of blood urea nitrogen. (See KIDNEYS, DISEASES OF.)

VetBooks.ir

Bunostomiasis

Infestation with hookworms of the genus *Bunostomum*.

Bunt Order

Equivalent to the 'peck order' among poultry, this is the order of precedence established by cattle and pigs. With a newly mixed group of these animals there will be aggressiveness or actual fighting, until the dominant ones (usually the largest) establish their position in the social order. Once this is established, fighting will cease and the group will settle down, with the top animal being accorded precedence without having to fight for it. The second animal will be submissive to the first, but will take precedence over the rest; and so on down through the herd, with the bottom animal submissive to all. Occasionally two animals will be of equal rank, or there may be a somewhat complicated relationship between a small group as in the 'dominance circle'.

The bunt order can be important from a health point of view, and it can affect the farmer's profits. If, in large units, the batching of animals to ease management means frequent mixing or addition to established groups, stress will arise, and productive performance will decline. Stress will be reduced in the system whereby pigs occupy the same pen from birth to slaughter time. The health factor – as well as daily liveweight gains and feed conversion ratios – will be involved when there is, for example, insufficient trough space, and those animals at the bottom of the social scale may go hungry or thirsty. Similarly, the dominant animals will be able to choose more sheltered, less draughty places, while their inferiors may be cold and wet. (See also STRESS.)

Bunyaviridae

This group of viruses includes the HANTAVIRUS. Individual species may be zoonotic.

Buprenorphine Hydrochloride

An analgesic used for dogs, cats, birds, rodents and rabbits, and as a premedicant for surgery, radiography, etc. The drug takes effect within 30 minutes of injection, and so it can be administered before the animal regains consciousness. The response to the recommended dose may be variable. Some dogs show salivation, bradycardia, hypothermia, agitation, dehydration and myosis. In cats there may be excessive purring and mydriasis. In both species side-effects resolve within 24 hours. Very occasionally, respiratory depression can occur.

Burdock

The burrs of burdock (*Actium lappa* and *A. minus*) have caused granular stomatitis in dogs, especially in town dogs on holiday in the countryside. Treatment is by curettage under general anaesthesia.

Burial of Pet Animals

In 1992 the Environment Minister ruled that dead pets could be returned to their owners for burial, despite the 'Duty of Care' Regulations 1991. In the case of pets suspected of having a NOTIFIABLE DISEASE and dying whilst under suspicion, the carcase will be disposed of by AHVLA. In cases where a pet dies of an infection that may be a serious risk to humans or other animals, then it should be disposed of under the Hazardous Waste Regulations, and veterinary surgeons are obliged to inform the clients that this must be done.

Burmese Cats

A short-hair oriental breed of cat similar to the Siamese but round headed, and having more coat colour. Different colours are recognised from the original brown including red, blue and lilac. Burmese can be affected with congenital unilateral peripheral vestibular disease which is evident at birth or soon after. Some affected cats adapt and can lead a reasonably normal life. Other conditions encountered include gangliosidosis, feline orofacial pain, KINKY TAIL, elbow osteoarthritis, hypokalaemia, and flat-chested syndrome. The breed may show head defects, peculiar to this breed. There is a DNA test for GM_2 GANGLIOSIDOSIS.

Burns and Scalds

Though the former are caused by dry heat and the latter by moist heat, their lesions and the treatment of these are similar.

In animals a burn is usually easily recognised by singeing of the hair, or its destruction, but with a scald there may be little to be seen for several hours or even days. Moreover, a scalded area may remain concealed by a scab.

Burns and scalds are extremely painful and will give rise to shock unless they are slight. After a few hours the absorption of poisonous breakdown products from the damaged tissues may give rise to TOXAEMIA; while destruction of skin affords means of entry for pathogenic bacteria, against which the burned tissues can offer little or no resistance. Death is a frequent sequel to extensive burns – the result of shock, toxaemia, or secondary infection.

Burns and scalds are not uncommon in captive reptiles due to the animal having direct access to a heater. They may lie there on a hot surface and stay there even to the extent of permitting the penetration of the body cavity (coelom) without any signs of discomfort or pain.

First aid Scalds are mainly suffered by dogs, cats, and other domestic pets as a result of mishaps in the home. Placing dogs, cats and reptiles **immediately** under cold, running water will

reduce the temperature of the affected area, and is likely to reduce also the pain and subsequent skin damage. This applies to burns also. Scalds from hot oil are best treated with other (cool) oily substances or emulsions such as milk. Fur-covered mammals such as chinchillas and rabbits, and birds, should not be treated with oils. Emulsions are best for such species.

Treatment Where the burn or scald is at all extensive, no time should be lost in consulting the veterinary surgeon, who will have to administer an analgesic or anaesthetic and perhaps fluid therapy before local treatment can be attempted (and in order to relieve pain, and lessen shock). This also facilitates clipping the hair to expose the affected area.

In an emergency occurring where no first-aid kit is available, a clean handkerchief (or piece of linen) either dry or soaked in strong tea may be applied as a first-aid dressing to a burn. The part should be covered, the animal kept warm and offered water to drink.

The object of treatment is to reduce pain, to form a coagulum of protein rapidly on the surface of the burned area and to diminish absorption of those altered proteins from the damaged tissue, which give rise to toxaemia; and to prevent infection to which the damaged tissue is very susceptible. Tannic acid (the useful constituent of the strong tea mentioned above) helps to form the desired coagulum. A tube or two of tannic acid jelly or bottle of Proflavine emulsion should be included in every first-aid kit for dealing with small burns. It should not be applied over large areas.

Where the animal-owner cannot obtain professional assistance, subsequent treatment must aim at avoiding sepsis, the damaged tissues being very prone to infection. Sulfathiazole or sulfanilamide powder may be dusted lightly on to the area before a first or second application of tannic acid jelly. Subsequent irrigation of the part may be carried out with a weak hypochlorite or bicarbonate solution.

For burns caused by caustic alkalis use vinegar or dilute acids; for phenol and cresol burns, swab with cotton-wool soaked in alcohol and then smear with Vaseline, oil or fat.

The application of choice to a burn is a cream containing silver and sulphadiazine (silvadene). Both of the ingredients have antimicrobial properties. The preparation is used in humans but not specifically registered for veterinary use (2012).

Burnt Sole

Burnt sole is a condition which results from the fitting of a hot shoe to the horse's foot when the horn has been reduced to too great an extent, or when the hot shoe has been held to the foot for too long a time. It is most likely to occur when the horn is naturally thin, and when the sole is flat or convex. The heat penetrates through the thickness of the horn, and burns or blisters the sensitive structures below. It causes great pain and lameness. Professional advice should be sought.

Bursae
(singular, Bursa)

Bursae are natural small cavities interposed between soft parts of the structure of the body where unusual pressure is likely to occur. They are found between a tendon or muscle, and some underlying harder structure, often a bony prominence, between fascia and harder tissue, and some are interposed between the skin and the underlying fascia. They are lined by smooth cells which secrete a small quantity of lubricating fluid. (See BURSITIS.)

Bursal Disease

(See INFECTIOUS BURSAL DISEASE of poultry.)

Bursa of Fabricius

A lymphoid organ in birds, located dorsal to the cloaca, and having a similar role in immunity to that of the thymus of mammals. (See T-LYMPHOCYTES.)

'Bursati'

(See ROUNDWORMS – Horses.)

Bursitis

Inflammation within a bursa.

Acute bursitis is generally due to external violence. In horses, it commonly occurs after runaway accidents, falls, continued slipping when driven at fast paces, and after kicks in the shoulder, where the bursa of the biceps tendon is involved.

Chronic bursitis The blemishes resulting are very commonly seen in all the domestic and many wild animals. The walls of the bursa increase in thickness, more fluid than usual is poured out, leading to a soft, almost painless swelling. Later this becomes hard, and fibrous tissue invades the clotted material. 'Capped elbow' and 'capped hock' in the horse are instances of the condition due to lying on hard floors for a long period, or in the case of the elbow to the calkins of the shoe; 'lumpy withers' are of the same nature, due to the pressure of a badly fitting saddle, and often lead to fistulous withers; hygromata or 'big knees' in cattle result either from a shortage of bedding at the front of the stall, or from the animals continually striking their knees on a too high feeding trough

VetBooks.ir

when rising; in dogs the same conditions are often seen on the knees, hocks, sternum, and stifles, particularly in old and very lean individuals which lie a lot; monkeys, both in captivity and in a free state, develop similar lumps on the points of their buttocks.

Buserelin

A synthetic analogue of the releasing hormones for both luteinising and follicular-stimulating hormones. It is indicated in infertility of ovarian origin in cattle, improving pregnancy rate and synchronising of oestrus within a herd. It can reduce the calving to conception interval. The product can also be used in mares to allow ovulation of a mature follicle and in rabbits it is used to induce ovulation and improve conception rates. The drug has also be been used to facilitate the stripping and reduction of mortality due to egg binding in female rainbow trout.

'Bush Foot'

'Bush foot' is a severe lesion associated with foot-rot in pigs in New Zealand, Australia, the UK, etc. The infection involves *Fusobacterium necrophorum* and spirochaetes in the UK. (See FOOT-ROT OF PIGS.)

Bush Sickness

A cobalt deficiency disease occurring in certain sheep-rearing districts of North Island, New Zealand. It is characterised by inability to thrive, emaciation, anaemia and ultimate prostration, and affects probably all herbivorous animals, although sheep and cattle suffer most. One of the greatest sources of loss is the difficulty experienced in getting females to breed in a bush sick area.

The type of soil is usually blown coarse sand, coarse-textured gravelly sand, or 'sandy silt', and the disease is always worst on land that has been recently cleared and burnt.

The cause is a deficiency in the soil, and consequently in the herbage, of the small amounts of cobalt, which is the trace element needed to enable the body to utilise iron needed for the formation of the haemoglobin of the red blood cells. In this respect, bush sickness is very similar to conditions which are called by other names in various parts of the world such as 'Pining', 'Vanquish' or 'Vinquish' in Scotland; 'Nakuruitis' in Kenya; 'Coast disease' in Tasmania; and 'Salt sickness' in Florida.

Cobalt pellets, which disintegrate slowly in the (usually fourth) stomach, give protection for nine months or so. (See 'BULLETS'.)

Buss Disease

(See BOVINE ENCEPHALOMYELITIS.)

Butazolidine

(See PHENYLBUTAZONE.)

'Butcher's Jelly'

(See 'LICKED BEEF'.)

'Bute'

A commonly used colloquial name for PHENYLBUTAZONE.

Butenolide

A fungal toxin which can cause gangrene of the feet in cattle. (See FESCUE.)

Butorphanol

It is a synthetic opiate acting as a sedative and analgesic when given by injection in dogs, cats and horses. It may be combined with detomidine in the horse and with medetomidine in dogs and cats. Given orally in dogs, it is used to relieve cough. It is often combined with α-2 agonists for use in other animals such as horses and camelids.

Buttercup Poisoning

The common buttercups seldom cause poisoning, although all contain a poisonous oil, protoanemonin, to a greater or lesser degree. Species most likely to cause poisoning include *Ranunculus scleratus* and *R. acris*.

Signs Stomatitis, gastroenteritis, abdominal pain; faeces are blackish. Eyelids, lips and ears may show tremors; with convulsions (and rarely death) following. (See also WEEDKILLERS.)

Butterfat

(See DIET AND DIETETICS - FIBRE; also MILK.)

Butylscopalamine

A spasmolytic and analgesic agent with special activity in the smooth muscle of the digestive tract. It can be indicated in equine colic, for the control of diarrhoea in cattle, horses, and dogs and for the control of pain associated with urinary obstruction in horses, dogs, sheep and goats.

Butyric Acid

This is a VOLATILE FATTY ACID produced during CARBOHYDRATE digestion in the rumen by micro-organisms. Butyric acid is also a fermentation product in silage making. (See SILAGE.) When fed at 0.2 per cent of the diet it helped maintain carcase quality and performance in broilers that had been vaccinated against coccidiosis when challenged with *Eimeria* spp. Used in poultry, it also reduces *Campylobacter* infection by making the gut wall more resistant to adherence and invasion.

BVA

(See BRITISH VETERINARY ASSOCIATION.)

B Value

It is the buffering value of a feedstuff. B-values are calculated as ml of 0.1M hydrochloric acid solution needed to reach a pH of 5 in a feed-in-water slurry of 10g of material in 100 ml of water. A low B-Value is advantageous in young animals and those under stress as it can reduce digestive disorders.

B Virus

This is a herpes virus found in monkeys which gives rise in man to an encephalitis with an almost 100 per cent mortality. It may be transmitted to man from monkeys – especially newly imported rhesus and cynomolgus monkeys. Lesions on the face and lips of monkeys should arouse suspicion of this condition.

It is believed that B virus, herpes simplex virus, and Aujeszky's disease virus have a common origin.

C

Cabbage
Excessive quantities of cabbage (*Brassica oleracea capitata)* should not be fed to livestock. It contains a goitrogenic factor and may cause goitre if it forms too large a proportion of the diet over a period. In cattle, it may lead to anaemia, haemoglobinuria and death.

Cabergoline
A dopamine agonist derived from ergot. It is used to suppress prolactin production, suppressing lactation and treating false pregnancy in bitches.

Cachexia
(adjective, Cachectic)
A severe form of malnutrition resulting in debility and general ill-health.

Caderas, Mal De
(See MAL DE CADERAS.)

Cadmium (Cd)
A metallic element whose salts are poisonous. It can be present in sewage cake used as fertiliser when contaminated with industrial effluent. Aerial pollution or accidental contamination of feed with fungicides, etc., containing cadmium leads to signs including hair loss, bone weakening and kidney damage. As little as 3 parts per million of cadmium in the diet of young lambs causes an 80 per cent reduction in the copper stored in the liver within two months. (See EARTHWORMS.)

Cadmium Anthranilate
Cadmium anthranilate has been used as a treatment for ascarid worms in the pig. It has been replaced by less toxic preparations.

CAE
(See CAPRINE ARTHRITIS-ENCEPHALITIS.)

Caecal Resonance in Rabbits
This is a clinical procedure to assess caecal health in rabbits. The animal is held with its abdomen exposed and a hand holding and separating the two front legs, and the other supporting the lower part of the body between the two hind legs. The abdomen is percussed by the clinician caudal to the sternum. A resonant sound indicates the extent and position of gas in the caecum. A normal amount of resonance is said to occur in an area in the caudal abdominal quadrant. Displacement may indicate the presence of a space–occupying lesion in the abdomen. An excessive area of resonance indicates an imbalanced, excessively fermentative diet, or dental abnormality contributing to secondary dietary imbalances. (See STOMACH, DISEASES OF - RABBIT - DILATION OF THE STOMACH.)

Caecotrophs
Soft brown pellets produced in the caecum of rabbits. They are a source of vitamins and are ingested by the rabbit usually in the evenings. Caking of caecotrophs around the perineum can lead to fly strike. A high fibre diet with low concentrates will treat the condition; it can take several months to resolve. (See CAECOTROPHY.)

Caecotrophy
The (normal) ingestion of specialised faecal pellets called caecotrophs directly from the anus of rabbits and many species of small rodent herbivores. This second passage through the gastrointestinal tract allows the absorption of nutrients (proteins, vitamins) synthesised in the caecum, thereby completing the digestive process. (See also COPROPHAGY.)

Caecum
(plural, Caeca)
Caecum is the pouch-like blind end of the large intestine. (See INTESTINES.) Its relative size varies greatly between the species. Dilatation of the caecum is usually an acute illness. Dilatation or displacement of the caecum may often be identified by rectal examination in horses and cattle and by ultrasonography in small animals.

Caesarean Section, Caesarian Section
An operation in which the fetus is delivered by means of an incision through the wall of the abdomen and uterus. It is chiefly performed in bitches, sows, cows and ewes; it is performed occasionally in the mare, although it can be indicated in many species. (For reptiles see OVARIECTOMY and POOS.) The operation is undertaken when the pelvic passage is for some reason unable to accommodate and discharge the fetus; when the fetus has become jammed in such a position that it cannot pass through the pelvis, and its delivery cannot be effected; when the value of the progeny is greater than the value of the dam; and when the dam is *in extremis* and it is believed that the young is or are still alive. (In this latter case the dam is usually killed and the abdomen and uterus are opened at once. There is a possibility of saving the fetus in the mare and the cow by this method, provided that not more than two minutes elapse between the time when the dam ceases to breathe and when the young animal commences.

The foal or calf will die from lack of oxygen if this period is exceeded.)

Other indications for Caesarean section are: cases of physical immaturity of the dam, failure of the cervix to dilate, torsion of the uterus, the presence of a teratoma and, perhaps, pregnancy toxaemia.

Caesium (Cs)

(See RADIOACTIVE CAESIUM.)

Caffeine

Caffeine is a white crystalline alkaloid obtained from the coffee plant. It is almost identical with theine, the alkaloid of tea. Caffeine has been used as a central nervous system stimulant and a diuretic. It can be given either hypodermically or by mouth. The use of caffeine as a stimulant in greyhound or equine competitions is an offence.

Cage and Aviary Birds, Diseases of

The most common diseases of budgerigars, canaries, parrots and other birds kept in cages and aviaries are very often a consequence of nutritional deficiencies. Lack of vitamin A makes the bird more susceptible to infections such as PSITTACOSIS, BUMBLE-FOOT, respiratory and sinus infections and impaction. Calcium deficiency can lead to tetany or bone diseases such as rickets or osteomalachia in intensively bred species, especially cockatiels and African grey parrots.

Congenital and inherited conditions are also quite common. They include feather cysts (hard yellow swellings under the skin of the back). Fatty tumours and malignant growths may also occur, especially in budgerigars.

The difference in lifestyle between the wild, gregarious parrot, and the singly caged pet parrot accounts for behavioural problems including feather-picking.

Other causes of feather-picking include infestation with mites or lice. These are rare in caged birds but are seen in aviary birds.

Conditions affecting the crop include impaction (which may require surgical treatment) and regurgitation. Regurgitation may indicate inflammation of the crop infection of the intestine (see MEGABACTERIOSIS) or simply a courtship ritual. Injuries to the crop may occur. In the budgerigar, regurgitation is common. There are many causes; they include inflammation of the crop (see INGLUVITIS) caused by bacterial or fungal infection (often candidiasis), trichomoniasis or MEGABACTERIOSIS. Lack of vitamin A may cause the formation of crop crystals. A budgerigar showing the so-called 'RANDY BUDGIE' SYNDROME will regurgitate (chronic sexual regurgitation). Laboratory examination of the crop contents, obtained by a saline wash, is often needed to establish a diagnosis.

Prolapse of the cloaca is fairly common, especially in egg-laying hens, and can also occur without obvious cause in other species, especially cockatoos.

Laboured breathing, associated with rhythmical dipping of the tail, and closing of the eyes while on the perch, suggests systemic infections (e.g. chlamydophilosis), heart disease, internal abscesses or enlarged liver. Gapeworms, mucus, or aspirated food material may block the upper air passages of aviary birds. Air sacs may be punctured by the claws of cats, or other traumatic injury and if infected, can fill with pus or exudate. Birds with ruptured air sacs develop balloon-like swellings under the skin, especially of the base of the neck. Deflation with a needle, or more sophisticated surgery, may be needed.

So-called 'going light' in show budgerigars is a chronic and eventually fatal disease; the precise cause, which may be multifactorial, has yet to be determined. (See also TRITRICHOMONIOSIS - AVIAN TRITRICHOMONIOSIS.) The birds lose weight, though eating well, over a period of weeks or months. Diarrhoea is seen in a few birds; vomiting may also occur. At autopsy, enteritis is found.

Ascarids are frequently encountered nematodes in birds of the parrot family. They are seen most commonly in South Australian parakeets, especially if kept in an aviary with gallinaceous birds such as quail. Generally, nematodes are uncommon in cage birds, unless they have recently been kept in an aviary. Treatment consists of the application of a topical IVERMECTIN preparation to the skin.

Capillaria worms may cause anaemia and diarrhoea.

Worms in the gizzard and proventriculus may cause peritonitis, air sacculitis and sudden death from visceral perforation.

Tapeworms are sometimes seen in aviary finches and in recently imported large psittacines.

Fluke may be found in ornamental waterfowl and occasionally in imported psittacines.

'Scaly face' of budgerigars and cockatiels and 'tassle foot' in canaries are both caused by infestation with Knemidocuptes mites. Topical ivermectin is an appropriate treatment.

Eyeworms can be manually removed.

Fancy pigeons (Columbiformes) are affected by the same conditions as racing or feral pigeons: ascaridiasis, capillariosis, and TRITRICHOMONIASIS. Some treatments for those conditions are sold by specialist suppliers to the racing pigeon fraternity.

Faulty diet, infestation by mites, and injury are among the causes of beak abnormalities, which need correcting at an early stage with fine claw clippers. In the female budgerigar especially, the

VetBooks.ir

nostrils may become blocked by sebaceous or other material. Horn-like excrescences near the eyes may be associated with mite infestation. Congenital beak malformations include 'scissors beak' which, in large psittacines, requires expert attention.

The feet are subject to conditions including bumble-foot, dry gangrene of the feet which may follow a fracture of the limb, unsuitable synthetic bedding material forming a tourniquet round the leg, or poisoning by ergot in the seed. Fractures of the legs result from their being caught in the wires of the cage. Dislocation of the hip is not rare. Overgrown and twisted claws are common and may be associated with mite infestation. (See also PSITTACOSIS; TUBERCULOSIS.)

Coccidiosis, giardiasis and trichomoniasis are protozoan diseases frequently seen in small psittacines. Giardiasis may be associated with feather-plucking in cockatiels.

Viral diseases of cage birds include pox (in canaries, lovebirds, Amazon parrots); papilloma (warts) (dermal in African grey parrots, mucosal in Amazons); Pacheco's disease in Amazons; psittacine beak and feather disease (large psittacines, lovebirds, budgerigars). New viral diseases are discovered regularly.

Poisoning in budgerigars, canaries and other psittacine birds often results from their inquisitive nature. Zinc poisoning from galvanised wire used in cages and lead poisoning from paint or certain plastics are not uncommon. Washing galvanised wire with strong vinegar is a useful preventive. Waterfowl, especially ducks and swans, are liable to suffer lead poisoning from consuming lead weights discarded by anglers.

The over-heating of 'non-stick' frying pans in kitchens gives rise to vapour which can kill budgerigars and other small birds within half an hour. The substance involved is polytetrafluorethylene.

Over-heated fat in an ordinary frying pan may also prove lethal (see 'FRYING PAN' DEATHS). Birds have died after being taken into a newly-painted room.

(See also under ORNITHOSIS; BIRD-FANCIER'S LUNG; and PETS, CHILDREN'S AND EXOTIC.)

Bacterial diseases of cage birds are rare. Contact with other birds may lead to infection with staphylococci (surprisingly lethal in small birds), salmonella, mycobacteria, chlamydophila and pseudotuberculosis. This latter (caused by *Yersinia pseudotuberculosis*) causes sporadic deaths of birds in aviaries – sometimes an acute outbreak, especially in overcrowded conditions. Death may occur from a bacteraemia, or follow chronic caseous lesions in lungs, air sacs, spleen, and pectoral muscles.

In exhibition budgerigars, megabacteriosis was the most common disease in 1,525 birds examined at Liverpool Veterinary School. Trichomoniasis, enteritis, pneumonia, hepatitis and a degenerative disease of the gizzard were also common.

'Cage Layer Fatigue'

A form of leg paralysis in poultry attributed to insufficient exercise during the rearing period. It is common complaint about the battery cage system for egg production. (See BATTERY SYSTEM.) Most birds recover within a week if removed from the cage or if a piece of cardboard is placed over the floor of the cage.

The long bones are found to be very fragile. The condition results in increased culling levels and there is splintering of the bones leading to down-grading of the carcase. The precise cause is obscure. A bone-meal supplement may prove helpful.

Cage Rearing of Piglets

This system of pig management is briefly described under WEANING.

Cairn Terrier

A small, shaggy-coated dog with erect ears; originating in Scotland. The breed is liable to inherit craniomandibular osteopathy, which causes enlargement of bones of the face and cranium, and inguinal hernia. Globoid cell leukodystrophy, causing weakness and eventual paralysis, and haemophilia B (Factor IX deficiency), a sex-linked recessive trait, may be inherited. PATELLAR LUXATION, ABNORMAL PIGMENT DEPOSITION IN THE EYE and INGUINAL HERNIA may be inherited but the mechanisms are unknown.

Cake Poisoning

(See ACIDOSIS; also BARLEY POISONING, LINSEED, GOSSYPOL and CASTOR SEED POISONING.)

Calamine, Carbonate of Zinc

Calamine, or carbonate of zinc, is a mild astringent used to protect and soothe the irritated skin in cases of wet or weeping eczema, and is used in the form of calamine lotion. It has been used in cases of sunburn in pigs.

Calciferol

Calciferol is one of the vitamin D group of steroidal vitamins. (See VITAMINS - VITAMIN D and RODENTS – Rodenticides.)

Calcification

Calcification of a tissue is said to occur when there is a deposit of calcium carbonate laid down. It is a natural process in bones and teeth. Calcification may also occur as a sequel to an inflammatory reaction (e.g. following caseation in chronic tuberculosis). Calcification in the lungs of puppies has led to death at 10 to 20 days old.

Calcined Magnesite
Calcined magnesite contains 87 per cent to 90 per cent magnesium oxide and, being cheaper than pure magnesium oxide, is used for top-dressing pastures (1,250 kg per hectare; 10 cwt per acre) and for supplementary feeding of cattle in the prevention of hypomagnesaemia. In the powder form, much is apt to get wasted, but if the granular kind is well mixed with damp sugar-beet pulp or cake, the manger is usually licked clean.

Calcinosis
(See GOUT.)

Calcinosis Circumscripta
Localised deposits of calcium in nodules in subcutaneous tissues, etc. An inherited condition in dog breeds including BOXERS, GERMAN SHEPHERD DOGS, GREAT DANES, GREYHOUNDS, IRISH WOLFHOUNDS and POINTERS.

Calcitonin
A hormone produced by the thyroid gland. (See also CALCIUM, BLOOD.)

Calcium
An important element found in bone and teeth, milk, and so is essential for growth. It is used in the function of HEART and skeletal muscles, required for blood clotting, control of nerve function, and cell membrane permeability. It is also involved in acid-base metabolism and in ruminants it acts as a rumen BUFFER. It has many interactions, most importantly with VITAMIN D, PHOSPHORUS, and MAGNESIUM.

Calcium, Blood
Levels of calcium (Ca) in the blood are controlled by the parathyroid hormone and by the hormone calcitonin (see table under PARATHYROID GLANDS). Low blood calcium, resulting in milk fever, is frequent in cows at calving and goats at kidding; it is also seen in horses, camelids and dogs at peak lactation. In ewes it mainly occurs during the later stages of pregnancy. It is not seen in pigs. About half the blood calcium is bound to protein and another half is in ionised form. For an insufficiency of blood calcium, see HYPOCALCAEMIA. The calcium/ phosphorus ratio is extremely important for health (e.g. see CANINE and FELINE JUVENILE OSTEODYSTROPHY). Resistance to infection is reduced if calcium levels are inadequate. In rabbits blood calcium levels are related to the amount of calcium in the diet so HYPERCALCAEMIA is often of little pathological significance

Calcium Borogluconate
A solution of calcium, given by subcutaneous or intravenous injection, is the most frequent method of treating milk fever and other acute calcium deficiencies in cattle and other animals. It is also used intramuscularly for the treatment of hypocalcaemic tetany in cage birds. A similar product, CALCIUM GLUCONATE, is preferred in small animals.

Calcium Channel Blockers
A group of drugs that selectively inhibit the movement of calcium ions into cells. They prevent the movement across vascular smooth muscle and myocardial cells. They are used in conditions affecting the heart where blood pressure is raised.

Calcium Deficiency
Occurs quite commonly in African Grey Parrots fed an all-seed diet. Affected birds show weakness and may fall off their perch, they may have tremors, tetany or fits. The diet needs to be corrected and calcium supplementation provided in the short term.

Calcium Gluconate
A solution of calcium salt used as an injectable form to correct calcium deficiencies in small animals, notably bitches with ECLAMPSIA, dogs with hypoparathyroidism and birds with hypocalcaemic tetany. A similar product, CALCIUM BOROGLUCONATE, is preferred in large animals.

Calcium Hypophosphite
Is used only as an intravenous injection for cattle to treat hypophosphataemia and as an aid to raising calcium levels.

Calcium Oxalate
The calcium salt of OXALIC ACID which can be found as crystals in urine. It can be found in some URINARY CALCULI. It also can occur in OXALATE poisoning and lead in chronic cases to NEPHROSIS.

Calcium Phosphate
Here are three types, tribasic and dibasic are sources of CALCIUM used in the body's metabolism, and are the inorganic compound most common in bone and also in milk. Monobasic is used as a fertiliser and as a feed supplement. It commonly occurs in URINARY CALCULI.

Calcium Supplements
These may consist of bone-meal, bone flour, ground limestone, or chalk. **Under BSE controls the feeding of bone-meal or bone flour to ruminants is banned** (see BOVINE SPONGIFORM ENCEPHALOPATHY).

VetBooks.ir

Such supplements must be used with care, for an excess of calcium in the diet may interfere with the body's absorption or employment of other elements. A high calcium to phosphorous ratio will depress the growth rate in heifers. However, after bone injury, calcium is preferentially taken up at the injured site; additional calcium should be provided to maintain blood levels.

In pigs, there is an inter-relationship of zinc and calcium in the development of PARAKERATOSIS and a calcium carbonate supplement in excess can increase the risk of PIGLET ANAEMIA.

Calcium supplements are important in the nutrition of birds and reptiles.

Calcium without phosphorus will not prevent rickets; both minerals are required for healthy bone.

The calcium to phosphorus ratio is also of great importance in dogs and cats and commercial dog and cat foods are usually formulated to maintain a correct balance. (See CANINE and FELINE JUVENILE OSTEODYSTROPHY.)

Calcium alginate, derived from seaweed, has been used as a wound dressing.

Calculi

Calculi are stones or concretions containing salts found in various parts of the body, such as the bowels, kidneys, bladder, gall-bladder, urethra, bile and pancreatic ducts. Either they are the result of the ingestion of a piece of foreign material, such as a small piece of metal or a stone (in the case of the bowels), or they originate through one or other of the body secretions being too rich in salts of potassium, calcium, sodium, or magnesium.

Urinary calculi are found in the pelvis of the kidney, in the ureters, urinary bladder, and often in the male urethra, are collections of urates, oxalates, carbonates, or phosphates, of calcium and magnesium.

Urinary calculi associated with high grain rations, and the use of oestrogen implants, produce heavy losses among fattening cattle and sheep in the feed-lots of the United States and Canada. However, this condition does not seem to present the same problem in the barley beef units in this country, although outbreaks do occur in sheep fed high grain rations. The inclusion of 4 per cent salt (sodium chloride) in the ration may decrease the incidence of calculi. Ammonium chloride may be added to the diet of fattening lambs for a similar purpose: it acidifies the urine. Feeding of long fibre diets is also beneficial. (See also UROLITHIASIS.)

In horses, one study found that calcium carbonate in the form of calcite plus substituted vaterite was the major component of 18 urinary calculi from 14 geldings, two stallions and one mare. In 14 of the cases the calculi were in the bladder. In rabbits, calcium carbonate calculi are common.

Intestinal calculi (enteroliths) are found in the large intestines of horses particularly. They are usually formed of phosphates and may reach enormous sizes, weighing as much as 10 kg (22 lb) in some instances. In many cases they are formed around a nucleus of metal or stone which has been accidentally taken in with the food, and in other instances they are deposited upon the surfaces of already existing coat-hair balls. (See WOOL BALLS IN LAMBS.)

Salivary calculi are found in the duct of the parotid gland (Stenson's duct), along the side of the face of the horse. A hard swelling can usually be both seen and felt, and the horse resents handling of this part. They are seen, albeit rarely, in cattle and dogs.

Biliary calculi are found either in the bile-ducts of the liver or in the gall-bladder. (*Note*. There is no gall-bladder in equines.) They may form around a minute foreign body such as a dead parasite or they may be made up of salts deposited from the bile. They are combinations of carbonates, calcium, and phosphates, along with the bile pigments, and have, accordingly, many colours; they may be yellow, brown, red, green, or chalk-white.

Pancreatic calculi in the ducts of the pancreas have been observed, but are rare.

Lacteal calculi, either in the milk sinus of the cow's udder or in the teat canal, are formed from calcium phosphate from the milk deposited around a piece of shed epithelial tissue. They may give rise to obstruction in milking.

Calf Diphtheria

Cause *Fusobacterium (Fusiformis necrophorus) necrophorum*.

Signs These may vary in severity and may merely involve a swelling of the cheek. Affected calves cease to suck or feed, salivate profusely, have difficulty in swallowing, become feverish, and may be affected with diarrhoea. The mouth is painful, the tongue swollen, and yellowish or greyish patches are seen on the surface of the mucous membrane of the cheeks, gums, tongue, and throat. On removal of one of these thickish, easily detached, membranous deposits, the underlying

tissues are seen reddened and inflamed, and are very painful to the touch. In the course of three or four days the weaker or more seriously affected calves die, and others may die after two or three weeks. Some recover.

Control Isolate affected calves. Antibiotics, particularly penicillin, are helpful for treatment and prevention if used early in an outbreak.

Calf Housing

Housing for calves must be warm but not stuffy (well ventilated), dry, well lit by windows, and easy to clean and disinfect. Individual pens prevent navel-sucking. Bought-in calves, in particular, are at risk of infection when placed in close contact with each other in cramped accommodation; this is exacerbated by the stress of separation from the cow, and often by transportation. (See also under COLOSTRUM.)

In the UK, standards for calf housing must meet the minimum set by the Welfare of Farmed Animals Regulations (England) 2000 (and similar legislation for Scotland and Wales). This requires that in new accommodation, a calf less than 150 kg is given 1.5 sq m of unobstructed floor space; for a calf 150 to 200 kg the space is 2 sq m and for calves more than 200 kg the space is 3 sq m. A calf must be able to stand up, turn around, lie down, rest and groom itself without hindrance and must be able to see at least one other calf unless in isolation for veterinary reasons. The width of any stall must be at least equal to the height of the calf at the withers and the length must be at least 1.1 times the length of the calf measured from the tip of the nose to the caudal edge of the pin bones (tuber ischia). The pen must be built of materials that will not harm the calves and must be able to be cleaned and disinfected. Air circulation, dust level, temperature, humidity and gas concentrations must be within limits that are not harmful to the calves. Ventilation systems must be alarmed, with a back-up system in case of failure; all automatic equipment must be serviced regularly. Calves must not be kept permanently in the dark and the light must be strong enough for them to be inspected and fed at least twice daily. All calves must be supplied with bedding and floors must be smooth but not slippery.

Calf Hutches

Individual portable pens are widely marketed. Among their advantages are the control of transmissible infections such as enteritis and pneumonia by preventing contact between calves. Hutches must be moved to another location and cleaned thoroughly after each occupation. There are welfare considerations in their use; DEFRA offers advice.

Calf Joint Laxity and Deformity Syndrome (CJLD)

A condition, apparently nutritional in origin, very similar to acorn disease (see ACORN CALVES) seen in dairy or suckler calves in herds fed predominantly silage.

Calf Pneumonia

Formerly called virus pneumonia, enzootic pneumonia of calves occurs in Britain, the rest of Europe, and North America. It is multifactorial in origin, with the environment and management often being precipitating causes. Good hygiene and the avoidance of damp, dark, cold surroundings will go a long way towards preventing it. Scours are often associated, probably the result of secondary bacterial infections. Usually, one or more bacteria, mycoplasmas or viruses are involved.

Viral infections include the following:

Parainfluenza 3 – myxovirus
Bovine adenovirus 1
Bovine adenovirus 2
Bovine adenovirus 3
Infectious bovine rhinotracheitis – a herpesvirus
Mucosal disease virus – a pestivirus
Bovine reovirus(es)
Bovine respiratory syncytial virus
Herpesvirus

Mycoplasma, including *M. bovis, M. dispar*, and ureaplasma sp. and bacteria, including *Pasteurella haemolytica, P. multocida, Haemophilus somnus*, and chlamydia, are other infective agents which may cause calf pneumonia. There is a synergism between *M. bovis* and *P. haemolytica* (an important bacterial cause of calf pneumonia). In calves housed in groups, an almost subclinical pneumonia may persist; a harsh cough being the only obvious sign, and although growth rate is reduced there may be little or no loss of appetite, or dullness.

Often problems result from a chronic or CUFFING PNEUMONIA which is usually mycoplasmal in origin. This may be exacerbated into an acute pneumonia by other bacteria or viruses. The change for the worse often occurs following stress resulting from sale, transport and mixing with other calves. Mortality varies; it may reach 10 per cent.

In very young calves, abscesses may form in the lungs during the course of a septicaemia arising from infection at the navel ('navel-ill'). Also in individual calves, an acute exudative, lobular pneumonia may affect calves under a month old; with, in the worst cases, areas of consolidation. (See also PNEUMONIA.)

Treatment A wide range of antibiotics may be effective, depending on the causative organism. Anti-inflammatory agents are also useful, and

occasionally expectorants and diuretics. Affected calves should be moved to prevent spread of infection; good ventilation is essential.

Prevention Allow calves adequate airspace, ensure good ventilation and never house more than 30 together; do not mix age groups. Vaccines, live and inactivated, are available against specific infections.

Calf-Rearing

Calves from dairy herds are usually removed from their dams at a few hours or a few days old. Those intended as heifer replacements or beef are then reared in single or group pens, being fed from buckets or feeders. Colostrum may be all or part of their diet, particularly in the calves removed early. After colostrum, they are given milk (from healthy cows) or a proprietary milk substitute, usually at about 2 litres twice daily when bucket fed. Proprietary milk substitutes must be given in accordance with the manufacturer's instructions. Clean water should be freely available and some form of roughage, which may be straw bedding and concentrates. Weaning usually occurs when a calf is taking 0.7 kg concentrate daily, if single penned, or 1 kg daily if in groups; this is usually at about six weeks of age; ideally, when the birth weight has doubled.

The use of skim milk or whey may, where convenient, be introduced as variants of the systems given above. Under the Welfare of Farmed Animals Regulations 2007 (England), (Wales), 2010 (Scotland) and (Amendment) Regulations 2003 for Northern Ireland, a minimum of 100 g of roughage should be given daily at two weeks of age working up to a minimum of 250 g at 20 weeks old. Concentrates providing an adequate intake of iron should also be given.

Beef calves from the suckler herd are kept with their dams for a period that depends on whether they are to be sold on or reared further. Spring-born calves are usually weaned at 5 to 8 months, the autumn-born at 8 to 10 months. Single suckling is the rule in typical beef herds but multiple suckling on nurse cows is also common practice. Under this system a cow from a dairy herd suckles two or more calves at a time for at least 9 to 10 weeks. Thus, a cow, according to her milk-yielding capacity, may suckle from 3 to 10 calves provided she is fed adequately and is prepared to accept different calves.

Bought-in calves may come from known farms or, more likely, from dealers via markets. Calves under a week old must not be sold at markets unless with the cow; their navels must also have healed and dried. It should be remembered that antibodies received from the dam in the colostrum protect only against infections current in the original environment – not necessarily against infections present on another farm. An early-weaning concentrate should be on offer *ad lib*.

Calf Scours

(See under DIARRHOEA.)

Caliciviruses

Caliciviruses are members of the picorna virus group, and have been isolated from cats, dogs, pigs, and man. (See also FELINE CALICIVIRUS.)

California Mastitis Test (CMT)

CMT (a detergent) for the detection of cows with subclinical mastitis. The test can also be used as a rough screening test of bulk milk; a gel is produced if many cells are present. The test is unsuitable for sheep or goat milk.

Calkins

Calkins are the portions of the heels of horses' shoes which are turned down to form projections on the ground surface of the shoe, which will obtain a grip upon the surface of paved or cobbled streets. Upon modern roads and on the land, they serve no useful purpose and may do harm. If they are too high they lead to atrophy of the frog and induce contracted heels unless the shoe possesses a bar.

Callosity

Callosity means thickening of the skin, usually accompanied by loss of hair and a dulling of sensation. Callosities are generally found on those parts of the bodies of old animals that are exposed to continued contact with the ground, such as the elbows, hocks, stifles, and the knees of cattle and dogs. (See HYGROMA.)

Callus

1. Callus is the lump of new bone that is laid down during the first two or three weeks after fracture, around the broken ends of the bone, and which holds these in position. (See FRACTURES.)
2. Hardening and thickening of the skin over pressure points e.g. point of the elbow. Calluses are particularly common in large breeds of dogs.

Calomel, Mercurous Chloride

Calomel, or mercurous chloride, should not be confused with the much more active and poisonous mercuric chloride. Calomel is a laxative having a special action on the bile-mechanism of the liver. (See also MERCURY.)

Calorie

A unit of measurement, used for calculating the amount of energy produced by various foods. A

calorie is defined as the amount of heat needed to raise the temperature of 1 g of water by 1° C. A kilo-calorie, or Calorie, equals 1000 calories. (See also CARBOHYDRATE; JOULE; METABOLISABLE ENERGY.)

Calves, Diseases of

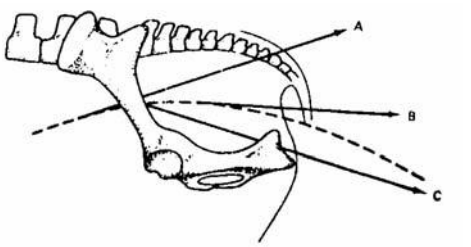
These include BOVINE NEONATAL PANCYTOPENIA; CALF JOINT LAXITY AND DEFORMITY SYNDROME; DIARRHOEA; JOINT-ILL; CALF DIPHTHERIA; TUBERCULOSIS; NECROTIC ENTERITIS; PARASITIC GASTROENTERITIS OF CATTLE; PNEUMONIA; RINGWORM; muscular dystrophy (see under MUSCLES, DISEASES OF); GASTRIC ULCERS; RICKETS; SALMONELLOSIS; HYPOMAGNESAEMIA; PARASITIC BRONCHITIS. (See also CATTLE, DISEASES OF.)

Calves of Predetermined Sex

(See PREDETERMINED SEX OF CALVES.)

Calving

A calving detector which measures internal temperature fall via a ruminal bolus is available. The device incorporates a reader which transfers the information to a computer. (See PARTURITION and under TEMPERATURE, BODY.)



Calving, Difficult, Dystokia; Dystocia

Safety rules for the stockman are: (1) never interfere so long as progress is being achieved by the cow; (2) do not apply traction until the passage is fully open and it has been established that the calf is in a normal presentation; (3) time the traction carefully to coincide with maternal efforts; and (4) never apply that long, steady pull often favoured by the inexperienced.

The force exerted by the cow herself through her abdominal muscles and those of her uterus, in a normal calving, and the forces exerted by mechanical traction in cases of assisted calving, were evaluated by veterinarian J. C. Hindson, who used a dynamometer to measure these forces. He gave a figure of 68 kg (150 lb) for bovine maternal effort in a natural calving. Manual traction by one man was found to exert a force not much greater.

The danger to the cow and calf of excessive force are therefore very real. Obvious risks include tearing of the soft tissues, causing paralysis in the cow, and damaging the joints and muscles of the calf. The latter's brain may also be damaged, so that what appears to be a healthy calf will never breathe.

The diagram shows the cow's pelvis and various directions of traction with the cow in a standing position. (Her failure to lie down may be due to stress, and in itself complicates delivery. Other causes of difficulty in calving include not only a large calf, an abnormal calf (monster), and an awkward presentation, but also a lack of lubrication due to loss of fluid or to death of the fetus, and inertia of the uterine and abdominal muscles – due to stress, subclinical 'milk fever', or exhaustion.)

The cow's pelvis and various directions of traction.

In the diagram, line A indicates the direction of pull which would be the ideal were it not impossible because of the sacrum and vertebrae closing the roof of the pelvis. Line B is a good direction but, again, one usually impossible to achieve. Line C indicates the actual direction of pull, which will vary a little according to the height of the person doing the pulling, and also according to the space available in the calving area. The broken curved line indicates the direction taken by the calf.

The veterinary surgeon attending a delivery will not, of course, rely on traction alone. He or she will correct, if practicable, not only any malpresentation, but will endeavour to make good any fluid loss, treat any suspected subclinical 'milk fever', and endeavour to overcome the inertia if such be present. S/he will also form an opinion as to whether it is physically possible for that calf to pass through that pelvis; if it is not, a Caesarean operation is the likely solution.

Prevention of dystocia To minimise risks, heifers should be at a suitable weight when served; this varies with the breed. For Jerseys, the weight for serving at 15 months for calving at two years old is 215 kg; for Ayrshire, 290 kg; for Friesian, 310 kg; and for Holstein, 330 kg. The respective weights at calving should be: Jersey, 350 kg; Ayrshire, 490 kg; Friesian, 510 kg; and Holstein, 540 kg. Bulls should only be selected if their records revealed less than 2.5 per cent dystocia, their offspring had a below average gestation length and they were the sons of an 'easy calving' bull.

Frequent observation around calving, at least five checks a day, and the provision of exercise facilities should be considered as the incidence of dystocia is lower for cows kept in yards and paddocks than in pens.

VetBooks.ir

Calving Earlier

Over the years, the tendency has been for heifers to calve at a younger age, usually at about two years old. In a herd with an average age at calving of two years, heifers will in practice be calving at between 22 and 26 months. The timing will depend on the maturity of the heifer as well as the time of year at which calving is required.

The Institute of Animal Science in Copenhagen has carried out experiments with groups of Danish Red identical twins, one reared on a special diet designed to give optimum growth rate and inseminated to calve when 18 months old, and the other group at an age of 30 months, and fed at a standard level.

These experiments showed that a heifer's breeding ability depends on her weight rather than on her age. The two groups came into heat for the first time when they reached a weight of between 258 and 270 kg (570 and 595 lb). In the case of the more generously reared twins, this corresponded to an age of 275 days; and with the standard-fed twins, 305 days. More than 50 per cent of the heifers conceived at the first service.

Calving Index, Calving Interval

The ideal is to achieve an interval of 365 days between calvings. This is rarely achieved. As the gestation period is about 284 days, the cow would have to become pregnant again within about 80 days (less than 12 weeks) of calving. To ensure that cows become pregnant in the required time, services should begin shortly after 42 days (6 weeks) after calving so that there are at least two oestrous periods before 12 weeks.

The period up to seven or eight weeks after calving can be regarded as the acclimatisation period when the cow is adapting her feed intake to her milk production. During this time all heat periods should be recorded even though no attempt is made to serve the cow. This allows future heats to be predicted and entered on a wall chart or breeding calendar so that they can be confirmed as they occur. Cows not coming into oestrus regularly can thus be identified and treated so that they will resume normal oestrous cycles by the time breeding commences.

In very high yielding cows, it may not always be advantageous to aim at a 365-day calving interval. In such cases, return to service may be delayed for a time.

Cows that do not come into season regularly generally have cysts or other infertility disorders which, when spotted at an early stage, can be treated by the veterinary surgeon so that they are cycling regularly again before they have been calved more than 8 weeks, thus improving their chances of holding to the first service to calve within the year.

CAM

An acronym for Complementary and Alternative Medicine.

Camborough

A hybrid female developed from Large White and Landrace pigs. Litter size consistently averages 10 or more.

Cambridge Sheep, Cambridgeshire Sheep

A prolific breed of sheep. They have a dark face, are of medium-size, with average quality white fleece. The breed was developed in 1964 at Cambridge University. It was bred by taking foundation stock of very prolific ewes from various British breeds, mostly CLUN FOREST but also LLEYN; with Llanwenog, Radnor, RYELAND, BORDER LEICESTER and SUFFOLK contributed to a lesser extent. Ewes were crossed with FINN rams and the resultant F1 Males back crossed with the foundation stock to produce a breed with 20 per cent Finn blood. The Cambridge is crossed with other breeds or crossbreeds to produce a superior half-bred ewe. The breed is highly prolific and contains a single gene with a major effect on ovulation. (See SHEEP, BREEDS OF - BRITISH BREEDS OF SHEEP.)

Cambridgeshire

A prolific breed of sheep.

Camelidae

This genus includes the llama, alpaca, vicuna, guanaco and camel. South American camelids comprise four closely- related species; all of which can interbreed and produce fertile offspring.

Drug contraindications Camels do not tolerate the trypanocidal drugs diminazine aceturate and isometamidium chloride, at doses harmless to other ruminants.

Anatomy For camel anatomy, see *The Anatomy of the Dromedary* by N. M. S. Shuts and A. J. Bezuidenhout, Oxford University Press, 1987.

Anaesthesia A mixture of xylazine and ketamine or butophenol has been recommended as superior to either drug used separately: administered by intramuscular injection in the hind leg (quadriceps muscle).

Camels

There are two species: the one-humped Dromedary (Arabian), and the two-humped Bactrian (its head carried low). The former are found mainly in the deserts of North Africa, the Middle East, Asia, and Australia. Bactrian camels inhabit rocky,

mountainous regions, including those of Turkey, parts of the former USSR, and China.

Cross breeding occurs, and mating the Dromedary to the Bactrian male produces a superior animal.

Dromedaries Body temperature varies in summer between 36° C and 39° C (97° F and 102° F), according to time of day. Gestation period: about 13 months. Birthweight: 26 kg to 52 kg (57 lb to 115 lb). Puberty occurs in males at four or five years; in females when three or four years old. Life span: up to 40 years (but usually slaughtered for food long before such an age is reached).

In the Sahara camels often go without drinking for a week; and in the cooler months for much longer periods if grazing freely plants with a high water content.

Diseases Camel pox is the commonest viral disease diagnosed. The camel is also important as a carrier of foot-and-mouth disease and Rift Valley fever, although cases of the clinical diseases are rare. Among the bacterial diseases anthrax, brucellosis, salmonellosis, pasteurellosis and tetanus are not uncommon. Tuberculosis is an important disease of Bactrian camels farmed for milk production. Ringworm is the only fungal agent believed to be important and it is widely diagnosed in young animals.

Ectoparasite infections include sarcoptic mange, an important and debilitating disease of camels. The cause is *Sarcoptes scabiei* var. *cameli*. Other external parasites include fleas, lice and ticks. (See also POX; SURRA; HAEMORRHAGIC SEPTICAEMIA; RABIES; BLACK-QUARTER; BILHARZIOSIS; SPEEDS OF ANIMALS.)

Campbell Ducks

(See KHAKI CAMPBELL DUCKS.)

Camptodactylia

A congenital permanent flexion of the fingers and toes (phalanges).

Campylobacter spp. Infections

Campylobacter (formerly known as vibrio) are Gram-negative, non-spore forming bacteria, shaped like a comma, and motile. They are microaerophilic; that is, they require little oxygen for growth. They cause a variety of diseases, from dysentery to abortion, across a wide range of animal species.

C. fecalis causes enteritis in calves.

C. fetus fetus can cause acute disease in animals, including sporadic abortion in cattle, abortion in sheep and bacteraemia in man.

C. fetus veneralis is an important cause of infertility in cattle (see below).

C. coli is routinely found in the intestines of healthy animals and birds; it was believed to be a cause of winter dysentery in cattle, although most are probably due to CORONAVIRUS.

C. fetus jejuni is also found in mammalian and avian intestines and has been implicated in winter dysentery in cattle, although many are probably due to CORONAVIRUS.

Cattle Infertility caused by *C. fetus veneralis* is due to a venereal disease, transmitted either at natural service or by artificial insemination. It should be suspected when many cows served by a particular bull fail to conceive, although usually a few become pregnant at the first mating. The genital organs of the bull, and his semen, appear normal.

One infected bull was brought into an AI centre in the Netherlands, and of 49 animals inseminated with his semen only three became pregnant. Of these three, two aborted and *C. fetus* infection was diagnosed in them. Of the remaining 46 cows, 44 were inseminated with semen from a healthy, fertile bull; and it required six or seven inseminations per cow before pregnancy was achieved. These and many other similar experiences have led to the conclusion that infertility from this cause is temporary – cows developing an immunity some three months after the initial infection. Bulls, on the other hand, do not appear to develop any immunity and may remain 'carriers' for years.

On average, abortion due to *C. fetus* seems to occur earlier than that due to brucellosis, but later than that due to *Tritrichomonas*.

In an infected herd investigated in England, infertility was associated with retained afterbirth, vaginal discharges after calving, stillbirths, weak calves which later died, and a low conception rate. It was also found that abortions occurred between the fifth and eighth month of pregnancy – and not during the initial months of pregnancy as noted above.

Confirmation of diagnosis is dependent upon laboratory methods. A mucus agglutination test devised at the Central Veterinary Laboratory, Weybridge, is of service except when the animal is on heat.

Control A period of sexual rest, use of AI, and treatment of infected bulls by means of repeated irrigations of the prepuce with antibiotic suspensions.

Ewes C. fetus intestinalis and *C. fetus jejuni* may cause infertility and abortion.

Dogs Species of campylobacter have been isolated from dogs suffering from diarrhoea or dysentery, and in some instances people in contact with those dogs were also ill with acute enteritis.

VetBooks.ir

One of the species involved is *C. fetus jejuni*, isolated in one survey from almost 54 per cent of dogs with diarrhoea, but only from 8 per cent without diarrhoea. Feeding poorly prepared chicken meat is considered as a contributing factor.

Pigs *C. sputorum*, subspecies *mucosalis*, has been linked with PORCINE INTESTINAL ADENOMATOSIS, and *C. coli* with diarrhoea in piglets.

Poultry *C. fetus jejuni* is widespread in the intestines of healthy domestic fowl, including ducks and turkeys. Poultry flocks generally become contaminated at around two to three weeks of age and intra-flock spread is rapid with high levels of intestinal colonisation. It is quite likely that some free-range flocks are infected from contaminated water. In artificially inseminated turkeys, infected semen has caused infection in females. The importance of the organism lies in the fact that contamination of the edible parts of the bird at slaughter can cause food poisoning in consumers if the poultry meat is insufficiently cooked.

Public health Farm animals constitute a potential source of campylobacter infection for man. Campylobacters were isolated from 259 (31 per cent) of 846 faecal specimens collected from domestic animals. The highest isolation rate was found in pigs (66 per cent); lower rates were recorded for cattle (24 per cent) and sheep (22 per cent). All porcine isolates were *C. coli* while about 75 per cent of isolates from ruminants were *C. jejuni*. Cases of enteritis in people have been linked to the consumption of milk from bottle-tops that had been pecked by birds. Campylobacters were isolated from 29 out of 37 magpies which had been shot, trapped, or killed on the roads in rural areas around Truro, between June 1990 and February 1991. *Campylobacter jejuni* biotype was isolated from 25 of the birds, *C. coli* from three, *C. jejuni* biotype 2 from two and *C. lari* from one. In 2010 the number of laboratory confirmed human *Campylobacter* cases reached a record level of 70,298 cases, an increase of 8 per cent compared with 2009. The bacterium also overtook *Salmonella* spp. as the most frequently implicated causative agent in reported food-borne illness outbreaks.

Canaliculus

A small channel, e.g. the minute passage leading from the lacrimal pore on each eyelid to the lacrimal sac in the nostril.

Canary

The canary, *Serinus canaria*, is a small seed-eating bird usually yellow in colour. (See under CAGE AND AVIARY BIRDS, DISEASES OF.

Canarypox Vectored Vaccines

These have been used to immunise horses, dogs, cats, ferrets and wildlife against various disease (See VECTORED VACCINES.)

Cancellous

(See BONE.)

Cancer, Neoplasia

Cancer (neoplasia) is perhaps best thought of as a group of diseases rather than as a single disease entity. All types are characterised by uncontrolled multiplication of abnormal cells in the body. Cancer can be malignant (progressive and invasive) when tumours may regrow after removal; or non-malignant (benign) and will not return if removed. In malignant cancer, cells usually have a primary location, but if untreated, secondary growths, called metastases, may develop in other parts of the body by a process called metastasis. Two important types of malignant growth are sarcomas and carcinomas. There are several subtypes of each, classified according to the nature of their cells or the tissues affected.

Sarcomas are, as primary growths, often found in bones, cartilage, and in the connective tissue supporting various organs. Common sarcomas include osteosarcoma, fibrosarcoma, and lymphosarcoma.

Carcinomas are composed of modified EPITHELIUM, and are often associated with advancing age. Primary carcinomas affect the skin and mucous membranes, for example, and the junction between the two, such as lips, conjunctiva, etc.

Cancer can take many forms and the names applied relate to the type, e.g. tumour; the disease caused, e.g. enzootic bovine leukosis, feline leukaemia; or the tissue or organ affected, e.g. melanoma is cancer of the pigmented skin cells, osteosarcoma is cancer of the bones.

Cancer is far from rare in domestic animals and farm livestock. In the latter, however, the incidence of cancer tends to be less, because cattle, sheep and pigs are mostly slaughtered when comparatively young. Nevertheless, sporadic bovine enzootic leukosis may appear in a clinical form in cattle under two years old and cancer of the liver is seen in piglets – to give but two examples.

In the old grey horse a melanoma is a common tumour. In dogs the incidence of tumours generally (including non-malignant ones) is said to be higher than in any other animal species, including the human. (See CANINE TUMOURS.) An osteosarcoma is a not uncommon form of cancer affecting a limb bone in young dogs, particularly the giant breeds. LEUKAEMIA provides another example of cancer. In cats, a survey of 132 with mammary gland tumours showed the ratio of malignant to benign growths to be 9:1. (See FELINE CANCER.) The relative risk in

spayed cats is said to be significantly less than in intact females.

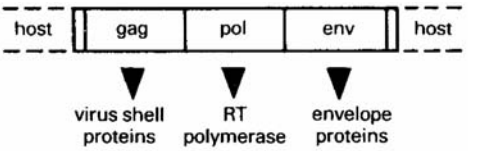
A 'rodent ulcer' is a carcinoma of the skin; less malignant than most in that, while it tends to spread and destroy much surface tissue, it does not as a rule form metastases.

The structure of some carcinomas resembles that of glands, the growth being named an adenocarcinoma. This may occur in the liver, for example.

Causes of Cancer Several different factors can lead to the production of cancer. They include: repeated irritation, by mechanical friction or radiation (e.g. X-rays, ultra-violet rays); chemical carcinogens; hormones; or viruses.

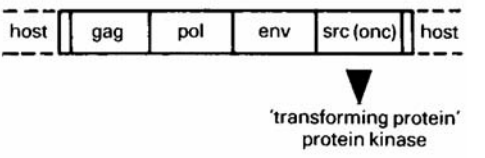
(See also AFLATOXINS; BRACKEN POISONING; HORMONES IN MEAT PRODUCTION; NITROSAMINES.)

Oncogenic Viruses A wide variety of animal tumours are caused by viruses. Several oncogenic RNA viruses have been isolated: the Rous chicken sarcoma virus, the Bittner mouse mammary carcinoma virus, the Gosse mouse leukaemia virus, the Feline lymphosarcoma virus and possibly the Northern European bovine leukosis virus. Of the DNA viruses, several oncogenic viruses have been isolated, but of special importance are the herpes viruses causing Marek's disease in chickens and, recently, a fatal lymphoreticular tumour in monkeys.



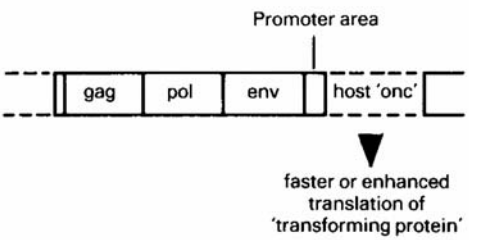
Whatever their nature, all carcinogens have a common factor: they act upon DNA.

When most tumour viruses infect and enter a cell, they have mechanisms for inserting their genes into the DNA of the host cell. In effect, the host has acquired a new set of genes, and when the host cell divides and all of its genes are replicated, so are those of the virus. In this way the virus can produce copies of itself without destroying the host cell, and this is the main difference between a tumour virus and a destructive or lytic virus such as canine DISTEMPER or foot-and-mouth disease virus. One of the virus genes transferred in this way is the oncogene or tumour-producing gene responsible for producing cancerous cells.



Further research led to the discovery of a 'transforming protein' – the presence of which in a cell leads to malignancy.

Diagnosis The type and location of the cancer and the nature of the presenting signs are all factors in diagnosis. The use of endoscopes, scintigraphy and computed tomography, as well as magnetic resonance imaging, may be of considerable assistance.



Treatment Surgical removal of a malignant growth is more difficult than removal of a benign tumour, which normally has a line of demarcation to guide the surgeon. Moreover, incomplete removal of a primary cancer may be followed by cancer elsewhere, as a result of metastases.

Leukaemia virus genes in cell DNA.

Rous sarcoma virus genes in cell DNA.

Leukaemia virus and cell oncogene.

Radium treatment is also used in veterinary medicine.

The most common cancer, the papilloma or wart, is treated by surgical excision or possibly by AUTOGENOUS vaccines.

Chemotherapy is used, under strict control, in dogs and cats. The drugs used are toxic and must be handled with great care; their prescribing and administration should be left to specialist veterinarians.

However, euthanasia is often preferable, on humane grounds.

Control The development of vaccines against MAREK'S DISEASE and FELINE LEUKAEMIA virus was a pioneering step towards the control of other virus-induced cancerous diseases.

(See also CYTOKINES.)

Candida albicans

Candida albicans is a fungus which gives rise to the disease MONILIASIS or CANDIDIASIS; both in humans, in companion mammals, especially in cage birds and in farm livestock. It has caused severe mouth lesions in young HEDGEHOGS.

VetBooks.ir

Candidiasis
Infection with *Candida* species which are YEAST fungi. Often it results in chronic respiratory problems especially in birds that are difficult to treat. It occurs less commonly in mammals.

Cane Corso Dogs
A large heavy-muscled MASTIFF-type Italian breed used as a pet, hunter and guard dog. They weigh 40 kg to 50 kg (85 lb to 110 lb) and stand 62-70 cm (24-27 in) at the shoulder. The head is large with the muzzle a third of the length and broad, the ears drop forward. Often in Europe ears are cropped and tails docked. They have short hair and are black and brown with variations (blue, fawn). Various problems are common including CANINE DILATED CARDIOMYOPATHY, ECTROPION, ENTROPION, !!HIP DYSPLASIA!!, and NICTITATING MEMBRANE GLAND PROLAPSE.

Cane Toad
(See TOADS.)

Canicola Fever
The disease in man caused by the bacterium *Leptospira canicola*, which is excreted in the urine of infected dogs. Paresis may occur and some few cases of this disease may resemble poliomyelitis. Mild conjunctivitis and nephritis accompanying signs of meningitis are suggestive of canicola fever. The bacterium may be harboured by pigs and the disease has been recorded among workers on pig farms and milkers in dairy units. (See LEPTOSPIROSIS.)

Canine
Referring to dogs (Genus *Canis*). Also, a type of tooth found singly on both sides of the upper and lower jaws placed between the incisors and premolars.

Canine Adenovirus Infection
(See CANINE VIRAL HEPATITIS.)

Canine Autoimmune Haemolytic Anaemia
A progressive disease caused by a dog forming antibodies which destroy its own red blood cells. A deficiency of platelets may occur simultaneously. This disease is a clotting disorder caused by a deficiency of blood factor VIII, and is usually fatal in males at an early age.

Signs Pale mucous membranes, lethargy, weakness, and collapse.

Diagnosis A Coombs' antiglobulin test.

Canine Babesiosis, Piroplasmosis
Canine babesiosis (piroplasmosis), which is also called tick fever, malignant jaundice, and biliary fever, is a tick-transmitted protozoan parasitic infection increasingly common in the UK since the advent of the Pet Travel Scheme. Up to 30 per cent of dogs returning with their owners from Europe may be infected. Signs of infection are fever, weakness and malaise. Haemolytic anaemia is followed by haemoglobinurea and thrombocytopaenia. Chronic infection must be confirmed by laboratory tests. Imidocarb dipropionate is effective but must be continued after signs are relieved (in 24 to 48 hours) to ensure that the parasite is all destroyed. *Babesia canis* is the most common cause but *B. gibsoni* is also a possibility; this is more resistant to treatment. Tick-repellent preparations help prevent infection.

Canine Brucellosis
(See BRUCELLOSIS.)

Canine Chronic Hepatitis
A well-recognised condition in the UK with several breeds predisposed to it, usually in middle-aged and older animals. There is lethargy, decreased appetite, vomiting, weight loss, diarrhoea and POLYDIPSIA, and often jaundice. It is common in ENGLISH SPRINGER SPANIELS.

Canine Cognitive Dysfunction Syndrome
A condition mainly seen in older dogs in which there is a loss of some behavioural flexibility such as an inability to switch from one response to another, and to absorb new information, changes in behaviour, disorientation, sleep disorders and house soiling. Feeding a broad spectrum of antioxidants and mitochondrial cofactors may improve the condition, as can mental stimulation. Treatments also include the use of L-CARNITINE with alpha lipoic acid.

Canine Cyclic Neutropenia
An inherited abnormality affecting the haematopoietic stem cells. It results in NEUTROPENIA and animals become more susceptible to infections. It is seen in some dog breeds including BORDER COLLIES, ROUGH COLLIES, SMOOTH COLLIES and is also called canine cyclic haematopoeisis.

Canine Degenerative Radiculomyelopathy
(See DEGENERATIVE MYELOPATHY.)

Canine Dental/Mouth/Tooth Problems
Gum and tooth diseases are common in dogs. (See MOUTH, DISEASES OF; TEETH.)

Canine Dilated Cardiomyopathy
A condition found in large dog breeds such as BOXERS, GREAT DANES, DOBERMANNS, and COCKER SPANIELS. In WEIMARANERS it can progress rapidly.

Canine Distemper
(See DISTEMPER.)

Canine Dysautonomia
A syndrome resembling the Key-Gaskell syndrome in cats has been reported in dogs, and has been tentatively linked with canine parvovirus. (See FELINE DYSAUTONOMIA.)

Canine Ehrlichiosis
A rickettsial infection (*Ehrlichia canis*), formerly confined to the tropics and Southern Europe but increasingly seen in Britain since the introduction of the Pet Travel Scheme. Infected dogs show fever, lethargy, anorexia, lymphadenopathy and thrombocytopenia; urine may be dark in colour. In the chronic form, there may be uveitis and retinal haemorrhage, with gammaglobulinaemia. Diagnosis is confirmed by serological tests. Prompt treatment with doxycycline or tetracycline is usually effective, except in German shepherd dogs, in which pancytopenia is usually irreversible. The disease is transmitted by the ticks *Rhipicephalus* and *Dermacentor* spp. Tick-control preparations help prevent infection.

Canine Epileptoid Cramping Syndrome (CECS)
An inherited condition in BORDER TERRIERS not unlike canine EPILEPSY. Various neurological or other signs are seen singly or in combination, usually in animals between two and six years old; they include trembling, staggering, apparent dizziness and falling over. The muscular signs include exaggerated stretching, slow and or methodical walking or posturing and abdominal and lumbar muscle contractions. The signs can occur rarely or frequently – several times weekly – and last anything from a few seconds to half an hour. Treatment can involve diazepam or butylscopolamine bromide and metamizole.

Canine Fertility
It has been suggested that a total output of 200 million sperms per ejaculate is necessary if a dog is to be regarded as sound for breeding. Individual progressive motility of less than 70 per cent of sperms, and sperm head and midpiece abnormalities in more than 40 per cent of sperms, are associated with infertility.

Canine Filariasis
(See HEARTWORM and TRACHEAL WORMS.)

Canine Genome
The dog genome sequence was completed in 2004.

Canine Haemophilia
This is an uncommon disease of male dogs of virtually all breeds, characterised by an inherited defect causing abnormally slow clotting of the blood, so that bleeding may occur and continue following only a minor injury.

Cause A sex-linked recessive gene (see GENETICS, HEREDITY AND BREEDING). Should the dam carry this, then 50 per cent of her dog pups are likely to be affected and show signs. Bitches, though carriers of the gene, seldom show sign themselves.

Signs These may sometimes be vague and misleading, in that a temporary swelling on the forehead, for example, or transient lameness, may be attributed solely to violence of some kind. The first time that a haematoma is found in the animal, violence may again be thought to be the only cause of the bleeding, and even after repeated episodes it may be thought that the animal is suffering from warfarin poisoning. In some cases the abnormally slow clotting of the blood gives rise to excessive bleeding at teething, or if the toenails are inadvertently trimmed too close.

Diagnosis Confirmation depends upon laboratory tests.

Precautions Affected dogs cannot lead a rough-and-tumble life without bleeding occurring, so the owner must try to prevent knocks and bumps occurring; or agree to euthanasia. A bitch which is known to be a carrier should not, of course, be bred from.

Canine Haemorrhagic Pneumonia
A severe condition seen particularly in GREYHOUNDS with PYREXIA and some respiratory signs. Death occurs in six to 10 hours and there is terminal mouth and nasal haemorrhage. In about half of cases *Streptococcus equi zooepidemicus* has been isolated.

Canine Herpesvirus
A virus isolated from vesicles affecting the genital system of the bitch and associated with infertility, abortion and stillbirths. Infected pups usually die soon after birth. Those that recover may remain carriers of the virus.

Canine Juvenile Osteodystrophy
This is known also by other names, e.g. nutritional secondary parathyroidism. It is also found in cats, when it is referred to as FELINE JUVENILE OSTEO-

VetBooks.ir

DYSTROPHY. It arises from a calcium deficiency which, in conjunction with excess vitamin D, stimulates the release of parathyroid hormone (see the table under PARATHYROID GLANDS). Resorption of bone follows. An excess of phosphorus in the diet will also cause the condition.

Cause The main cause of this disease is feeding the dog a (muscle) meat-rich diet containing little calcium but much phosphorus. Occurrence should be much less likely in dogs fed on 'complete' proprietary diets. (See DOGS' DIET.)

Signs Affected animals are often in good bodily condition but are usually reluctant to move and may cry out in anticipation of being forced to do so. The usual cause of pain is fractures of the thinned bone after a minor injury or even no apparent injury. Short, hesitant steps may be taken. Splaying of the toes is sometimes seen; also swelling at the elbow or carpi.

On radiography, the skeleton appears less dense than normal, indicating demineralisation of the bones.

The bones return to normal when a balanced diet is fed but deformities left by fractures may remain.

Canine Leishmaniasis

(See LEISHMANIA; LEISHMANIASIS.)

Canine Leukocyte Adhesion Deficiency (CLAD)

An inherited disease of dogs in which the animals are unable to deal adequately with infections; any illness tends to be severe. Most die young. It is seen in IRISH RED AND WHITE SETTERS, IRISH SETTERS.

Canine Lipfuscinosis

(See CEROID LIPOFUSCINOSIS.)

Canine Multidrug Sensitivity

An adverse reaction in which some dog breeds are unduly sensitive to certain drugs, for instance ivermectins. The problem is due to mutation in a multi-drug resistance gene (MDR1). It is seen in dogs including AUSTRALIAN SHEPHERD DOGS, BORDER COLLIES, GERMAN SHEPHERD DOGS, OLD ENGLISH SHEEPDOGS, ROUGH COLLIES, SHETLAND SHEEPDOG, SMOOTH COLLIES and WHIPPETS.

Canine Multifocal Retinopathy

A condition affecting parts of the retina and is inherited in some breeds including COTON DE TULÉAR DOGS, DOGUE DE BORDEAUX, MASTIFF and PYRENEAN MOUNTAIN DOG for which there are DNA tests.

Canine Myasthenia Gravis

(See MYASTHENIA GRAVIS.)

Canine Nasal Mites

A white mite, *Pneumonyssoides caninum*, is an uncommon inhabitant of the nose and nasal sinuses of dogs; and has also been found in the bronchi, and in the fat near the pelvis of the kidney.

Rubbing the nose on the ground and shaking the head are signs of this infestation, which has been reported from Scandinavia, America, Australia and South Africa. Avermectins are an effective treatment.

Canine Parvovirus (CPV)

This infection appeared as a new disease entity in 1978–9 in Europe, Australia, and America. Dogs proved highly susceptible, and serious outbreaks of the illness occurred with numerous deaths. By 1981 many dogs had acquired a useful degree of immunity against the virus, following either recovery from a naturally occurring attack or vaccination; with puppies protected for up to 16 weeks by the antibodies received in the colostrum of their dams, assuming that the latter were themselves resistant.

Cause A parvovirus, possibly a mutation of the feline enteritis or the mink enteritis virus.

Canine parvovirus (CPV-2), feline panleucopenia virus (FPV), and mink enteritis virus share common antigens; however, CPV-2 has at least one specific antigen which is not present in the other viruses.

Signs The illness takes the form of a severe gastroenteritis, and diarrhoea is the main sign. In the early outbreaks many dogs died within 48 hours. Puppies may die suddenly, within minutes of eating or playing, as a result of the virus having infected the heart muscle and caused myocarditis.

Treatment Symptomatic treatment must include measures to overcome the severe DEHYDRATION resulting from the diarrhoea. Treatment of the myocarditis is seldom effective.

Prevention Vaccination is widely practised and has greatly reduced the incidence of the disease. Live vaccines, often combined with vaccines against distemper and other viral diseases, are available. It is essential to follow the manufacturers' directions if protection is to be effective. Annual booster doses are recommended to maintain immunity. It should be noted that apart from the effect of persisting MATERNAL ANTIBODIES, vaccination may fail in some individuals which have a defective immune system and cannot

produce adequate antibodies. This occurs with all vaccines.

Canine Pasteurellosis

(See under BITES, STINGS AND POISONED WOUNDS.)

Canine Respiratory Disease

(See DISTEMPER; KENNEL COUGH; KLEBSIELLA.)

Canine Rickettsiosis

(See ROCKY MOUNTAIN FEVER.)

Canine Seasonal Illness

A problem first described in 2010 with dogs suffering illness, diarrhoea, and lethargy within three days of walking in woodland. It occurs between August and November and is thought to be associated with THROMBICULOSIS.

Canine Staphylococcal Dermatitis

This may be seen in Irish setters, collies and shelties. The lesions appear on the fine skin with few hairs on the abdomen or between the thighs. The condition is itchy, and causes the dog to scratch or lick the part. The lesions consist of roughly circular areas of reddened skin, some with a ring of blackish or greyish crust, having papules or pustules at the edge. The appearance may suggest ringworm at first glance.

The *Staphylococcus aureus* involved is resistant to penicillin, so other antibiotics must be used. An autogenous vaccine may be needed if antibiotics are not effective.

Canine Teeth

Canine teeth are the so-called 'eye-teeth', which are such prominent features of the mouths of carnivorous animals. In different animals they are known by different names, e.g. 'tusks' in the pig, and 'tushes' in the horse and ass. (See DENTITION; TEETH.)

Canine Transmissible Venereal Tumours

Canine transmissible venereal tumours affect mainly the mucous membrane of the vagina or that of the prepuce; occasionally the lips of both sexes. The lesions resemble warts, and can result in infertility.

Canine Tumours

These are common. It has been suggested that the incidence of neoplasia in the dog is higher than in any other animal species including man. In fact, the age-adjusted incidence rate for mammary neoplasia is three times larger in the bitch than in women. Tumours arising in the mammary glands of the bitch and the perianal glands of the dog together may account for almost 30 per cent of all canine neoplasms. (See also TUMOUR; CANCER.)

Canine Viral Hepatitis (CVH)

Canine viral hepatitis (CVH) is also known as Rubarth's disease, *Hepatitis contagiosa canis*, or infectious canine hepatitis (ICH).

Dogs of all ages may be affected – even puppies a few days old – but perhaps the disease occurs most frequently in young dogs of three to nine months. CVH may occur simultaneously with DISTEMPER.

Cause A canine adenovirus (CAV). CAV-1 is associated with liver, eye, kidney and respiratory disease. (CAV-2 is implicated only in respiratory disease.)

Signs Infection may exist without signs, and in such cases it can be recognised only by laboratory tests. In the very acute form of the disease a dog, apparently well the night before, may be found dead in the morning. In less acute cases the dog may behave strangely and have convulsions. A high temperature, wasting, anaemia, lethargy and coma are other signs observed in some cases. A thin, thready pulse is characteristic.

Vomiting, diarrhoea and dullness may persist for five or six days, and be followed by jaundice. Such cases may be thought to be leptospiral jaundice.

Puppies may show signs of severe internal haemorrhage, and have blood or blood-stained fluid in the peritoneal cavity, with petechial haemorrhages from several organs. Haemorrhages, including subcutaneous ones, may also occur in older dogs. More commonly, there is fever, dullness, some vomiting, tenderness of the abdomen. Of those that survive five days or so, many recover. Keratitis ('blue-eye') occurs a week or two after the beginning of the illness in some cases. In older dogs, restlessness, convulsions, and coma are common.

Glucose and vitamin K are also recommended.

Dogs which have recovered may continue to harbour the virus and act as carriers, spreading the disease to other dogs via the urine.

Diagnosis A gel diffusion test is useful at post-mortem examination, especially where decomposition of the animal's body has involved cell disintegration.

Prevention Vaccines are available, both live and inactivated. Hepatitis vaccine is usually presented as a multiple vaccine in combination with distemper and parvovirus; some preparations also include protection against leptospirosis and parainfluenza. Dosage instructions vary with different brands of vaccine; normally, puppies are given two doses at

VetBooks.ir

an interval of two to six weeks followed by annual booster inoculations. (See under DISTEMPER.)

Canine Wobbler Syndrome

It is also called CERVICAL VERTEBRAL MALFORMATION-MALARTICULATION, CERVICAL SPONDYLOPATHY or CERVICAL SPONDYLOLISTHESIS and is mainly seen in large breeds of dogs. (See also under SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Cannabis Poisoning

(See MARIJUANA POISONING.)

Cannibalism

Poultry Cannibalism may follow feather-picking – especially if blood is drawn – or a case of prolapse. The crowding together of housed birds is a common cause; and boredom (no scratching for insects as out-of-doors) is a factor, too. Occasionally a nutritional deficiency may be involved. In broiler plants, beak-trimming or subdued red lighting, making everything appear pink, has been resorted to. (See also SPECTACLES.)

In free range hens, cannibalism can be stimulated by the appearance of the pink of the inside of the cloaca at egg-laying. The wall of the cloaca may be penetrated, the intestine grasped and ripped out.

Pigs TAIL-BITING is a complex problem, and tail sores can lead to death. In some cases, the runt of the litter starts the vice, possibly because it is prevented by litter mates from access to the teats or trough and has nothing but tails presented to it. Cannibalism, where sows eat piglets mainly at birth or shortly afterwards, has been seen increasingly among farrowing sows kept on free range, chiefly on arable farms. The cannibal sow does not eat her own litter but guards it fiercely against other predatory sows. Thus this vice is entirely different from the occasional savaging of a litter by a hysterical sow or (more commonly) gilt in intensively kept pig herds.

Wild boar Wild boar sows must be allowed to leave the herd to give birth, returning to it later. If piglets are born near other sows they are at risk of being eaten while still in the membrane. The risk lessens when the piglets are running about.

Cannon Bone

(See METACARPAL.)

Cannula

This is a surgical tube used to establish an access route to the lumen of a viscus (internal organ) or vessel. They are usually described according to the organ in which they are normally used: arterial cannulas, venous cannulas, ruminal cannulas, etc.

Canola

A selectively-bred rapeseed strain originating from Canada with a very low eruric acid content compared with normal rapeseed strains. (See RAPESEED OIL - RAPESEED MEAL).

Cantharides

Cantharides is a powder made from the dried bodies and wings of the Spanish fly *Cantharis vesicatoria*, or *Lytta vesicatoria*. It contains cantharidin, an irritant poison, which has been used in rubefacient and blistering applications. It can be fatal if taken internally: a young woman died after being given a drink spiked with cantharides by a would-be suitor.

Cantharidin poisoning has been reported in a horse and a mule, which died after eating hay contaminated by beetles (*Epicanta vittata*) which contain cantharidin.

Actions Cantharadin has an irritant action on the genital and urinary organs by which it is eliminated from the body. This action is responsible for its reputation as an aphrodisiac.

Canthus

Canthus is the angle at either end of the aperture between the eyelids.

CAP

(See COMMON AGRICULTURAL POLICY.)

Capillaria spp.

A genus of ROUNDWORMS which occurs in mammals and birds. The disease is called CAPILLARIASIS.

Capillaries

Capillaries are the very minute vessels that join the ultimate arteries (or arterioles) to the commencement of the veins. Their walls consist of a single layer of fine, flat, transparent cells, joined together at their edges, and the vessels form an intricate mesh-work throughout the tissues of the body, bathing them in blood, with only the thin walls interposed, and allowing free exchange of gases and fluids. These vessels are less than 0.25 mm (1/1000th of an inch) in diameter.

Capillariasis

Infestation with *Capillaria* worms; it causes loss of condition and gastroenteritis in birds including poultry, raptors and pigeons. In mammals, diarrhoea, cystitis, hepatitis or bronchial disease may be seen. *C. obsignata* has been recognised as of

economic importance in intensely reared poultry in Britain.

Treatment is with flubendazole in poultry and game birds and with cambendazole and levamisole in pigeons, and thiabendazole, LEVAMISOLE and AVERMECTINS in raptors. (See also URINARY BLADDER, DISEASES OF.)

C. hepaticum is a parasite of rodents but can produce a potentially fatal infestation in primates through contact with rodents or with faeces from carnivores that have eaten infected rodents.

(See also URINARY BLADDER, DISEASES OF.)

Capillary Refill Time

A means of obtaining a rough assessment of the state of the peripheral circulation. It is the time taken for mucosa (e.g. in the mouth) to return to its normal colour after application of pressure. The time should normally be less than two seconds.

Caponisation

The castration of cockerels, carried out in order to provide a more tender carcase, and also to obviate crowing and fighting. The castrated bird is called a capon. Stilboestrol or hexoestrol, used as pellets implanted under the skin high up the neck, were used to achieve a similar effect but such hormonal treatments are now banned.

Capped Elbow

(See under BURSITIS.)

Capped Hock

Capped hock is a term loosely applied to any swelling over the point of the hock. At this point there are two bursae: the first – a false bursa, distension of which constitutes true 'capped hock' – lies between the skin and the tendon which plays over the bone; and the second, the true bursa, separates the tendon from the bone.

The lesion is virtually identical with that of capped elbow (see under BURSITIS), and treatment is practically the same.

Since the condition may be brought about in the mare by continual kicking at the heel posts of the stall (e.g. in cases of nymphomania), it is necessary to pad the heel posts or to house the horse in a loose-box.

'Cappie'

'Cappie' is a disease of sheep. (See also 'DOUBLE SCALP'.)

Caprine Arthritis-Encephalitis

A disease of goats caused by a lentivirus. It is present in Britain, Switzerland, France, Norway, the USA and Canada. It was following the importation of goats from Switzerland and the USA into Kenya that the disease reached Africa in 1983. In Australia a retrovirus was isolated from goats which caused a clinical disease similar to caprine arthritis-encephalitis, and produced antibodies in goats similar to those caused by maedi/visna virus, which has never been recorded in that continent. Transmission is by milk and colostrum or, occasionally, from other body fluids.

Signs A lowered milk yield, due to mastitis, is sometimes the first sign noticed; and transmission of the virus is thought to be mainly via colostrum and milk.

The main sign, however, is arthritis. Lameness does not always accompany swelling of the joints.

Encephalitis, caused by the virus affecting the brain, affects mainly kids two to four months old. Lesions may occur in the spinal cord also. Head-tilting and trembling may be seen, together with an unsteady gait. Opisthotonus may occur. Partial paralysis may lead to recumbency and often death. A chronic interstitial pneumonia occurs in some goats and subclinical infections may occur.

Control Blood testing goats over one year old and culling positive animals controls and can eradicate the disease in a herd. Alternatively, goats can be bred from and kids taken at birth before they suck and then fed colostrum from a doe known to be unaffected, preferably from the same herd. A CAE monitoring scheme is run by the Scottish Agricultural Colleges as part of the Premium Sheep and Goat Health Scheme, which involves routine blood testing.

Capripox Viruses

(See 'LUMPY SKIN DISEASE'; POX.)

Capsaicin

A chemical giving chillies their 'hot' taste. It may be a potential 'natural' coccidiostat for poultry; it can raise serum levels of some antibiotics in poultry.

Capsule

Capsule is a term used in several senses. The term is applied to a soluble case, either of gelatine which dissolves in the stomach, or of keratin which only dissolves in the small intestine, for enclosing small doses of medicine. The term is also applied to the fibrous or membranous envelope of various organs, as of the spleen, liver, or kidney. It is also applied to a 'joint capsule'.

Captive Bolt Pistol

This is a hand gun firing a solid bolt which penetrates the skull and stuns or kills the animal. They are not suitable for euthanasia for lambs, kids and piglets and other similar animals under eight weeks old.

VetBooks.ir

Car, Parked in the Sun

The temperature inside a car parked in the sun, even with two windows opened to the extent of 2.5 cm (1 in), can within three hours reach 33° C (92° F), when the shade temperature outside the car is only 18° C (65° F). With only one window opened 2.5 cm (1 in), or all windows closed, a dangerously high temperature would obviously be reached much sooner. A dog left in a car parked not in the shade is in danger of HEAT-STROKE; a cat similarly. (See also HYPERTHERMIA.) Owners causing suffering to their pets by leaving them in cars may face prosecution under the Protection of Animals Act 1911. This has been mainly superseded by the Animal Welfare Act 2006 for England and Wales, Part 2 of Animal Health and Welfare (Scotland) Act 2006, and The Welfare of Animals (Northern Ireland) 2011.

Carapace

The shell of tortoises, other chelonians, and crustaceans. When assessing the health of a chelonian, it is important to relate the length of the carapace in relation to the body weight, especially as to ability to withstand a period of hibernation. The landing of crabs and lobsters in Britain is subject to the carapace being of a specified minimum length.

Carapace Ulceration

In its mild form, ulceration of the carapace causes discoloration and pitting of the scutes ('scales') as a result of erosion. Affected areas should be debrided and treated with a local antiseptic and or antibiotic cream. Affected aquatic chelonians should have access to water for only 30 minutes per day. More severe cases involve secondary infection with fungi or bacteria, in aquatic species usually *Enterbacteria*. Treatment is as for the mild form but cleaning and debridement is under anaesthesia. Repair can only begin once all infection has been removed.

Carassus auratus

(See GOLDFISH.)

Carbachol

Carbachol is a potent parasympathomimetic agent which is used in the treatment of glaucoma in dogs.

Carbamates

These compounds are used as agricultural insecticides and sometimes cause accidental poisoning in animals. Carbamates inhibit cholinesterase. Signs of poisoning include profuse salivation, muscular tremors. Atropine is used in treatment. (See ORGANOPHOSPHORUS POISONING.)

Carbamide

(See UREA.)

Carbimazole

A drug used to treat hyperthyroidism in cats. It is metabolised to methimazole in the body and inhibits thyroid hormone production. Hormone levels return to pre-treatment values within 48 hours of ending treatment.

Carbohydrate

Carbohydrate is a term used to include organic compounds containing carbon, hydrogen, and oxygen, the two latter being in the same proportions as they are present in water, viz. two parts of hydrogen to every one part of oxygen. The simplest carbohydrates are the monosaccharide sugars (e.g. glucose), then come disaccharides (e.g. cane sugar, lactose) and polysaccharides. These are complex carbohydrates, such as the starches, celluloses, and lignified compounds in hay, which must be broken down into simpler sugars by both bacterial and protozoal action and by the processes of digestion before they can be absorbed and used in the body.

Carbolic Acid

(See PHENOL.)

Carbolic Acid Poisoning

Carbolic acid poisoning may occur from the application to the skin of dressings medicated with PHENOL; from the internal administration of the drug by mistake; and cases have been recorded from the use of strong carbolic disinfecting powders sprinkled on to the floors of animal buildings.

Carbonate of Zinc

(See CALAMINE.)

Carbon Dioxide (CO_2)

Carbon dioxide (CO_2) is a colourless gas. It is formed in the tissues during the metabolic process, taken up by the blood, exchanged for oxygen in the lungs, and expired from them with each breath. In a building, the VENTILATION must be such as will get rid of it rapidly so that it does not accumulate in the atmosphere. In the air it is present to the extent of about 0.03 per cent by volume, although this amount varies. CO_2 is used as a respiratory stimulant by anaesthetists.

Carbon Dioxide Anaesthesia

CO_2 has been widely used for anaesthetising pigs and poultry prior to slaughter. For pigs, it is necessary to have a concentration of 70 per cent CO_2 by volume. An alarm must be fitted which goes off if the level in the gassing tunnel drops below this. The pigs are driven in single file through a tunnel and inhale the CO_2 for less than a minute, after which a very brief period of unconsciousness follows – long enough, however, for hackling and 'sticking' to be accomplished

without causing pain. There is no adverse effect upon the carcase. CO_2 has also been used, instead of chloroform, in lethal chambers or cabinets for the euthanasia of cats, but if it is to be humane the technique must be correct. A mixture of argon with carbon dioxide has been shown to be preferable on humane grounds to CO_2 alone.

Carbon Dioxide Snow

Carbon dioxide snow is formed when CO_2 is first compressed in a cylinder to a liquid and then released through a small nozzle. The temperature falls to about –70° C (94° F) and the CO_2 solidifies as a snow. This is then compressed into solid blocks, which are used for a variety of purposes where a low temperature is required for a considerable time, such as to cool meat, milk, or fish in transit by rail, to preserve tissues, bacteria, or foods, so that normal enzyme action is arrested, and sometimes to produce local anaesthesia by freezing or to cauterise a surface growth on the skin.

A piece of 'dry ice' or carbon dioxide 'snow' placed on the floor of an infested building will act as a bait for ticks which will gather round it and can then be collected and destroyed.

Carbon Fibre Implants

These have been used in the surgical repair of tendons in racehorses, and dogs, and have generally given good results.

Carbon Monoxide

Carbon monoxide poisoning may result from gas and solid-fuel heating systems in the home when there is an inadequate supply of air. Many dogs and cats have been found dead in the kitchen in the morning.

In Britain, until the late 1960s, town gas (derived from coal) contained 10 to 20 per cent of carbon monoxide. Natural and oil-based gas contain less than 1 per cent. However, where there is inadequate VENTILATION, incomplete combustion may occur leaving not carbon dioxide and water but carbon monoxide.

Stillbirths in sows have been 'associated with incomplete combustion in propane gas heaters and inadequate ventilation. In one herd when poor ventilation and faulty heaters were corrected, the stillbirth rate dropped from 28 per cent to 6.7 per cent. The pig fetus is very susceptible to carbon monoxide poisoning, and may die in the uterus or at farrowing, without clinical signs of ill health being shown by the sow.

Exhaust fumes from an ordinary motor car have been used as a source of carbon monoxide for the destruction of mink and turkeys, but this is no longer legal. (See CAR EXHAUST FUMES.)

Diagnosis Cherry-red tissues and body fluids are suggestive of poisoning. Analysis of blood samples for carboxy-haemaglobin can be used for confirmation.

Abortion may be caused by carbon monoxide even at levels too low to cause signs in adult pigs.

Carbotocin

A synthetic analogue of oxytocin, carbotocin is used in obstetrical conditions in the cow and sow, often to correct uterine atony, as an aid to removal of retained fetal membranes or to initiate milk let-down. It can shorten parturition time but should only be used if the cervix is open. In sows it can be used as supportive therapy in the MASTITIS METRITIS AGALACTIA SYNDROME.

Carcases, Disposal of

(See under DISPOSAL OF CARCASES.)

Carcinogens

Carcinogens are oncogenic viruses or substances which give rise to CANCER. (See NITROSAMINES; BRACKEN POISONING; AFLATOXINS; HORMONES IN MEAT PRODUCTION; and substances mentioned under CANCER.)

Carcinoma

(See CANCER.)

Cardia

Cardia is the upper opening of the stomach at which the oesophagus terminates. It lies close behind the heart.

Cardiac Disease

(See HEART DISEASES.)

Cardiac Pacemakers

(See PACEMAKER.)

Cardianastrophe

An enlargement of the heart with massive hypertrophy. Also called MEGALOCARDIA.

Cardiganshire Corgis

One of the two breeds of corgi that originate from Wales (the other is Pembrokeshire). They are a long low dog with erect ears and usually red, brindle and sable in colour. Problems include PROGRESSIVE RETINAL ATROPHY.

Cardiography

Cardiography is the process by which graphic records can be made of the heart's action. Auricular and ventricular pressures can be recorded, the sounds of the heartbeat can be converted into

VetBooks.ir

waves of movement and recorded on paper, and the changes in electric potential that occur can be similarly recorded. (See also under ELECTROCARDIOGRAM.)

Cardiology
Study of the heart and heart diseases.

Cardiomegaly
An enlargement of the heart with massive hypertrophy. Also called MEGALOCARDIA.

Cardiomyopathy
A general term used to describe diseased heart muscle (MYOCARDIUM). Two distinct syndromes occur. Hypertrophic cardiomyopathy, in which the heart muscle is grossly enlarged and the chambers of the heart correspondingly diminished; and dilated cardiomyopathy in which the chambers are enlarged because the heart muscle appears to be stretched. (See HEART DISEASES.)

Car Exhaust Fumes
Car exhaust fumes from a specially adapted car engine were used for the humane destruction of mink. The Welfare of Animals (Slaughter or Killing) Regulations 1995 state that the exhaust gas must be cooled and filtered free of any irritant material. The carbon monoxide level must reach at least 1 per cent of the volume of the chamber used before mink are placed in it and the animals must remain there until dead. However, car exhaust fumes are no longer recognised as a legal means of killing birds in the UK. (See under BIRDS, HUMANE DESTRUCTION OF.)

Caries
(See TEETH, DISEASES OF.)

Carminatives
Carminatives are substances which help to relieve TYMPANY or flatulence. Almost all the aromatic oils are carminatives.

Carnassial Tooth
(See under SKULL.)

Carnidazole
A medicine used in tablet form to treat or control canker (TRITRICHOMONIASIS) in pigeons.

Carnitine
A vitamin of the B complex found in meat extracts. It is an amino acid thought to promote fat store catabolism instead of using carbohydrates as a source of energy. It is usually produced in the body from lysine and methionine and used as an adjunct to the treatment of human obesity. L-carnitine has a beneficial effect on dogs and cats suffering heart disease; lack of carnitine (or taurine) can cause cardiomyopathy. Addition of acetyl-L-carnitine with α-lipoic acid to dog diets stops the course of CANINE COGNITIVE DYSFUNCTION SYNDROME.

Carnivores
Any animals, particularly mammals, that are flesh-eating. It refers to any animals that eat other animals. It includes all members of the mammalian Order *Carnivora* including dogs, cats and bears.

Carnivorous
Flesh-eating.

Carob Pod Powder
May be used at 1 per cent in chicken diets to improve litter quality, the litter remaining dry resulting in less 'hock burn'. It also appears to have beneficial effects on intestinal health.

Carotene
A yellow pigment found in many feeds, carrots, egg yolks, etc. which can be converted into vitamin A (see VITAMINS).

Carotenoids
Precursors of vitamin A. The concentration of the carotenoid, canthaxanthin, in egg yolks affects their yellow colour.

Carpitis
Arthritis affecting the carpus.

Carpometacarpus Bone
A bone in the bird to which the flight feathers are attached. It is formed from the fusion of the metacarpal and carpal bones.

Carprofen
A non-steroidal anti-inflammatory drug (NSAID) used in companion animals, farm animals and horses.

Carpus
Carpus is the wrist in man, or the 'knee' of the fore-limbs of animals.

'Carrier'
'Carrier' is an animal recovered from an infectious disease, or not showing signs, but capable of passing on the infection to another animal. For example, cattle may carry infectious bovine rhinotracheitis; dogs may be carriers of *leptospirae*.

Carrying Injured Dogs and Cats
(See illustration under ACCIDENTS.)

Car Sickness
(See TRAVEL SICKNESS.)

Cartilage
Cartilage is a hard but pliant tissue forming parts of the skeleton, e.g. the rib cartilages, the cartilages of the larynx and ears, and the lateral cartilages of the foot, as well as the cartilages of the trachea. Microscopically it consists of cells arranged in pairs or in rows, embedded in a clear homogeneous tissue devoid of blood-vessels and nerves. The surfaces of the bones that form a joint are covered with articular cartilages, which provide smooth surfaces of contact and minimise shock and friction. In some parts of the body there are discs of cartilage interposed between bones forming a joint, e.g. between the femur and tibia and fibula there are the cartilages of the stifle joint, and between most of the adjacent vertebrae there are similar discs. When a bone is still growing, there are layers of cartilage interposed between the shaft and its extremities; these are called epiphyseal cartilages.

Diseases of cartilage Two chief diseases affect cartilages in animals. Necrosis, or death of the cells of the cartilage, results from accident, injury, or in some cases from pressure. The treatment is wholly surgical, and consists in the removal of the dead piece or pieces and the provision of drainage for discharges. Ossification: many of the cartilaginous structures of the body become ossified into bone in the normal course, especially in old age; but as the result of a single mild or many slight injuries to a cartilage, the formation of bone may take place prematurely, and interference with function results.

Caruncle
A small fleshy protuberance, which may be a normal anatomical part. In the uterus of ruminants, for example, mushroom-shaped caruncles project from the inner surface to give attachment to the cotyledons of the fetal membranes.

'Cascade'
Generally, medicines for use in animals must have a MARKETING AUTHORISATION (MA). The MA, which sets out the conditions for which a product may be used, is granted by a licensing authority (in the UK, the VETERINARY MEDICINES DIRECTORATE) for use in specific species; if no authorised product is available to treat a particular animal, a veterinary surgeon may prescribe an alternative under the 'cascade' system, which gives guidance for such unauthorised use. As the product is unauthorised (and therefore unproven in that species), the client must accept any risk attached to such use.

Cascara
A purgative occasionally used for the relief of constipation in dogs and cats, and for the treatment of furballs in cats.

Caseation
Caseation is the drying up and necrosis of a tissue. For example, a tuberculous abscess changes into a firm, cheese-like mass, which may later calcify. (See CALCIFICATION.)

Casein
A protein of milk and an important constituent of 'solids-not-fat'.

Caseous Lymphadenitis (CLA)
Caseous lymphadenitis is a chronic disease of the sheep and goat, characterised by the formation of nodules containing a cheesy pus occurring most commonly in superficial lymph nodes but also in other lymph nodes, lungs, skin, or other organs; it tends to produce a chronic pneumonia or pleurisy.

The disease is believed to have been introduced to the UK in a consignment of 20 goats imported from Germany in 1987. It leads to production losses and condemnation of carcases at slaughter.

Cause *Corynebacterium pseudotuberculosis*. Introduction of infected animals to a herd is the most important means of spreading infection. Wound infection is a common source. The organism can survive outside the animal on straw, etc. for months and in sheep dips for 24 hours. Contaminated shearing or ear-tagging tools have also been implicated.

Treatment This is difficult as the lesions become encapsulated and so inaccessible to antibiotics. The disease is likely to persist on farm and affected animals should wherever possible be destroyed. Vaccines are available overseas and one from Canada can be imported under permit.

Diagnosis Culture of *C. pseudotuberculosis* from pus from lesions confirms the diagnosis. An ELISA test identifies established infection.

Cashmere Goats
The fine soft wool known as cashmere was originally produced from the Kashmir goat; it is now produced by several types of goat. It is the hair produced by the secondary hair follicles, which forms a 'down' and grows in response to decreased day-length and has better insulating properties than the guard hairs produced by the primary hair follicles. The hair should be as fine as possible but must not exceed 18.5 microns in diameter and must be a suitable length 4.5 cm (1.8 in), construction, crimp and colour (white is most

VetBooks.ir

valuable). When the coat is shed in the spring the guard hairs have to be removed mechanically from the fine hairs. In Scotland importation of goats and crossing with native feral goats has produced fibre of a suitable standard.

Cassava

(*Manihot esculenta*) A widely-grown crop for human and animal food in the tropics, and the source of tapioca. The potato-like tubers, however, if eaten raw can cause cyanide poisoning and livestock in the tropics have died from this. It should not be fed to turkeys.

Castor Seed Poisoning

Castor seed poisoning has occurred overseas through animals being accidentally fed either with the seeds themselves or with some residue from them. The seeds of the castor plant (*Ricinus communis*) contain an oil which is used not only as a medicinal agent, but also for lubricating. Oil processing leaves the toxins behind in the press-cakes, and renders these 'castor-cakes' unsuitable as a food-stuff for all livestock.

Signs These consist of dullness, loss of appetite, elevation of the temperature, severe abdominal pain, and usually constipation but sometimes diarrhoea. The heart's action is tumultuous, the surface of the body is cold; there may be a watery cold sweat, and the respiration is distressed. Where large amounts have been eaten the faeces are usually hard, dry and brown in colour. Upon post-mortem examination there is an intense inflammation of the stomach and intestines, with 'false membrane' formation in the small bowel particularly.

First-Aid Give milk or oatmeal gruel pending veterinary advice.

Castration

In Britain, it is illegal to castrate a horse, ass, mule, dog or cat without the use of an anaesthetic. For other animals, an age limit is in force. (See ANAESTHETICS, LEGAL REQUIREMENTS.)

Reasons for castration To the humanitarian who has not an extensive acquaintance with animals the necessity for this operation may not be obvious, and it is advisable at the outset that the reasons for castration should be given.

Bullocks are able to be housed along with heifers without the disturbance which would otherwise occur during the oestral periods of the female, and they live together without fighting, and without becoming a risk to man. The uncertainty of the temper of an entire male animal, especially of the larger species, and the risk of injury to attendants, are well known. The same remarks apply to horses, asses and mules.

Another reason for castration of domesticated animals living under artificial conditions is that breeds and strains can be more easily kept 'pure', desirable types can be encouraged and retained, and undesirable types eliminated.

It used to be held that meat from uncastrated animals was greatly inferior to that from castrated ones. In fact, apart from such considerations as obtaining docility and avoiding promiscuous breeding, meat-quality was the main reason advanced for doing the operation. Nowadays the phrase 'greatly inferior' has tended to become 'slightly inferior'; feed conversion efficiency is better in the entire animal.

Some disadvantages of castration The growing practice of early slaughter of meat-producing animals, so that the majority never fully mature, has posed the question: is castration still necessary or, for efficient meat production, even advisable?

In all species, the entire male grows more quickly and produces a leaner carcase than that of the castrate. Since rapid and economic production of lean flesh is essential in modern meat production, the principle of male castration may seem to be becoming out of date.

The problem differs from one species of farm animal to another. Veal calves are not castrated. They have a better food conversion ratio than castrated calves.

With pigs, boars are not castrated if going for pork and, often, for bacon. In trials, the average boar took only 151 days to reach bacon weight (90 kg; 200 lb), and had a food conversion ratio of 2.87 between 32 and 90 kg (70 and 200 lb) liveweight. If the animals in the test had been castrated they would each have required about 50 kg (1 cwt) more food to reach 90 kg (200 lb) liveweight. There is an anti-boar taint vaccine available in the UK. In Germany all male pigmeat consumed (home produced or imported) is from castrated animals. (See also under STRESS; BULL BEEF.)

Methods These vary according to the species. In large animals, the operation consists of opening the scrotum and coverings of the testicle by a linear incision, separating the organ itself from these structures, and dividing the spermatic cord well above the epididymis which lies on the testicle, in such a way that haemorrhage from the spermatic artery does not occur.

In the interests of animal welfare, various methods of immunocastration have been tried. The aim is to 'immunise' the animal against the

Vetbooks

hormones involved in testosterone production. A series of injections is needed but the duration of effect is limited and re-injection is necessary at ever-shorter intervals. Techniques applied in other animals are described in the appropriate section.

Horses Entire colts are usually castrated when one year old, i.e. in early spring of the year following their birth, but they may preferably be castrated as foals, at an age of five months or younger. The colt is usually sedated and/or anaesthetised using detomidine, xylazine or romifidine in combination with ketamine. When the foal can no longer stand as a result of the anaesthetic, a hind-leg is pulled forwards to expose the operation site, and castration performed with the foal lying on its side. This method has been recommended as quick, requiring less assistance, less likely to traumatise the gelding, and more humane.

After castration the colt is either turned out into a well-strawed yard or put into a roomy loose-box and given a feed; or, if climatic conditions are favourable, it may be turned out to grass again. It is always advisable to see the colt at intervals during the 24 hours after castration, to ensure that there is no bleeding, that hernia has not developed, or that no other untoward accident has happened. Cryptorchid castration is briefly mentioned under RIG.

Cattle Various methods are used, including surgical castration by removal of the testes. In the United Kingdom, the law requires that calves over two months old must be anaesthetised and the operation performed by a veterinary surgeon. In very young calves – i.e. those between a month and six weeks old – castration may be carried out by merely opening the scrotum and scraping the spermatic cord through with the edge of the knife. However, complete removal of the testicle is preferable. In larger animals the spermatic artery should be ligated to prevent haemorrhage. Alternatively, a type of emasculator may be used which has two parts to the cutting arm so that the spermatic artery is cut and crushed at the same time to prevent haemorrhage.

Another method which does not involve removal of the testes is the Burdizzo or bloodless castration method. The instrument is placed with the jaws over the neck of the scrotum in such a way that when closed they will crush the spermatic cord through the skin of the scrotum, thus preventing maturation of the testes. Ideally, an assistant presses the handles together while the operator holds the cord to prevent it moving away from the closing jaws. The method has attracted objections on welfare grounds.

Sheep The most convenient age at which lambs are castrated is when they are between a week and a month old, the operation usually being carried out at the same time as tail docking. The point of the scrotum is cut off transversely and each testicle exposed by the one incision. They are then held alternately by a pair of rubber-jawed forceps, turned round and round so as to twist the cord, and then pulled off, or the cord may be scraped through with a knife. Special small emasculators are also used.

The rubber-ring method (see ELASTRATOR) is also used, and the Department of Agriculture, New Zealand, has stated that there was no significant difference in the fat quality of lambs castrated at three weeks of age by (a) rubber ring, (b) knife, and (c) emasculator. Lambs castrated at birth by the rubber-ring method were, however, lighter and smaller.

This method is not ideal. Pain immediately following application may be severe, and subsequent ulceration of the skin may also be painful and conducive to tetanus infection.

For the castration of adult rams the Burdizzo emasculator has been used (see above). Any method of castration of adult rams which involves opening the scrotum is usually attended by a percentage of deaths, no matter with how much care and asepsis the operation is performed.

Pigs Young male pigs are usually castrated at the time they are weaned, usually three to four weeks, and in any case before they are two months old. The tissues must not be torn and an anaesthetic is required for animals over seven days old, with additional prolonged analgesia. Currently it is not undertaken in UK commercial pig units.

Castration before weaning entails placing the newly-castrated pigs back with the sow; with a fractious gilt, or with an irritable old sow, the small amount of bleeding which may occur is apt to induce the mother to attack and perhaps kill her unfortunate offspring. Some owners prefer to have the pigs castrated before they are weaned, so that the check to their growth which always follows weaning does not coincide with the check they receive from the operation. In the United States it is often the practice for piglets to be castrated when they are between four and seven days old. Instead of the conventional incising of the scrotum, small incisions are made at different sites and, by means of a surgical hook, the spermatic cords are withdrawn and severed. The testicles may be left in position. It is claimed that this method reduces the danger of subsequent wound infection.

Dogs and cats A study of male cats following castration showed that there was 'a post-operative decline in fighting, roaming and urine-spraying in 88 per cent, 94 per cent and 88 per cent, respectively'. Improvement – especially as regards

VetBooks.ir

urine-spraying – was obtained in most cases within a fortnight.

Castration of dogs seems to produce no reliable effect on either aggressive or scent-marking behaviour.

There are significant species differences between cats and dogs as regards the effects of castration, but it has been said that 'the major effect of castration in either species is reflected by an overall reduction in the frequency of intromissions sometimes followed by a decrease in mounting behaviour. Nevertheless, some individuals retain the ability to copulate for a substantial period of time. Castration is likely to have a more pronounced effect on the mating behaviour of male cats than on that of male dogs.' Obesity is often a sequel to castration in pet dogs and cats. (See also SPAYING and VASECTOMY.)

Castration accidents or complications following the operation. Haemorrhage may occur either immediately following the operation or at any time afterwards up to the sixth or seventh day (usually within the first 24 hours). As a rule the small amount of haemorrhage which nearly always occurs immediately after the operation can be disregarded, since it comes from the vessels in the skin of the scrotum. When bleeding is alarming it is necessary to pack the scrotum with sterilised cotton wool or gauze or to search for the cut end of the cord, and apply a ligature. This is a task for a veterinary surgeon. (See under BLEEDING.)

Hernia of bowel or of omentum may occur where there is a very wide inguinal ring. This is a particular problem in rabbits. The replacement or amputation of any tissue that has been protruded from the abdomen requires the services of a veterinary surgeon. With all large animals, all that the owner should do until s/he arrives is to secure the animal, pass underneath its abdomen a clean sheet that has been soaked in a weak solution of an antiseptic, and fix this sheet over the loins in such a way that it will support the protruded portions and prevent further prolapse.

Peritonitis, which is almost always fatal in the horse, may follow the use of unclean instruments, or may be contracted through contamination from the bedding, or by attack by flies subsequent to the operation.

TETANUS may arise as a complication following castration in horses and lambs particularly. Sometimes there is a considerable loss among lambs from this cause. In districts where tetanus is common, colts should be given a dose of tetanus anti-toxin before castration, which will protect them until the wounds have healed.

Severance of a calf's urethra by a farm worker using a Burdizzo castrator has been reported rarely.

Casualty Animals

Slaughter of an animal which is injured or sick. On a farm, slaughter is permissible with appropriate veterinary certification (see under TRANSPORT STRESS).

'Cat, Angry' Posture

This is assumed by a cat partially crippled as a result of exostoses of neck bones due to an excess of vitamin A. The sign may appear within one to five years of being on a virtually all-liver diet.

Catadromy

A catadromous fish is one that spends most of its adult life in fresh water but returns to the sea to spawn. Eels are catadromous.

Cataphoresis

Cataphoresis is a method of treatment by introduction of medicine through the unbroken skin by means of electric current. (See also IONIC MEDICATION.)

Cataplasm

Cataplasm is another name for a poultice.

Cataplexy

Sudden onset of paralysis or collapse of short duration. Human patients suffering from NARCOLEPSY may also have attacks of cataplexy; this is true also of the dog and horse. A case in a bull was reported in which the animal would periodically, for no apparent reason, collapse on to its knees; getting to its feet again very soon afterwards. Apart from a 'sleepy demeanour', the bull seemed otherwise normal. There was a sudden snatch of a foreleg before attacks, which could be provoked by loud noise.

Cataract

Cataract is a cloudy white opacity of the crystalline lens of the eye. Several dog breeds (AFFENPINSCHERS, AFGHAN HOUNDS, AIREDALE TERRIERS, AMERICAN COCKER SPANIELS, BELGIAN SHEPHERD DOGS, BICHON FRISES, BORDER TERRIERS, BOSTON TERRIERS, CAVALIER KING CHARLES SPANIELS, CHESAPEAKE BAY RETRIEVERS, FLAT-COATED RETRIEVERS, FRENCH BULLDOGS, GERMAN SHEPHERD DOGS, GIANT SCHNAUZERS, HUSKIES, IRISH SETTERS, LARGE MUNSTERLANDERS, LEONBERGERS, MINIATURE SCHNAUZERS, OLD ENGLISH SHEEPDOGS, STAFFORDSHIRE BULL TERRIERS) have inherited cataracts, while others have possibly inherited forms including DANDIE DINMONT TERRIERS, ELKHOUNDS, ENGLISH SPRINGER SPANIELS, GREAT DANES, GOLDEN RETRIEVERS, HUNGARIAN VISLAS, NORWEGIAN BUHUNDS.

Diabetic patients develop mature blinding cataracts because of the high glucose levels within the lens. Age-related cataracts occur in all older animals with every dog over 14 years of age having some degree of lens opacification. Phacoemulsification is the treatment of choice. (See under EYE, DISEASES AND INJURIES OF; PHACOEMULSIFICATION).

Catarrh
An inflammation of a mucous membrane producing a copious flow of mucus. The term is often used to refer to the condition in the head, throat and neck.

Catarrhal
Having the characteristic of CATARRH.

Cat Bites/Scratches
These may sometimes give rise in man to CAT-SCRATCH FEVER and also yersiniosis, rabies, etc., should the cat be infected with organisms causing these diseases.

Catecholamines
These are SYMPATHOMIMETIC AGENTS derived from the amino acid TYROSINE and are highly potent. They include ADRENALIN, NORADRENALIN (from the ADRENAL GLAND) and MELATONIN.

Catechu
An extract from several species of Acacia plants, especially *Acacia catechu*, where the wood is boiled and the brew evaporated. It is a concentrated mixture of natural vegetable TANNINS and used as an ASTRINGENT.

Caterpillars
Several species of caterpillar have setae (hairs) which can cause an urticarial rash. Caterpillars of the brown-tailed moth (*Euproctis chrysorrhoea*) were extremely numerous in the Portsmouth area in two successive years, and 30 cats and a dog had lesions attributed to the caterpillars' setae which are barbed and also contain an enzyme. Loss of appetite, excessive salivation, wet patches on their flanks (probably the result of persistent licking) and redness of the underlying skin were observed. The dog developed a red rash under one eye, and later an excoriated area there, which took 3 weeks to heal.

'Cat Flu'
An inaccurate but convenient term widely used by owners for illness caused by FELINE VIRAL RHINOTRACHEITIS and FELINE CALICIVIRUS infection.

Cat Foods
Cats are, by nature, carnivorous and need a higher proportion of protein in their diet than dogs. They have specific requirements for vitamin A, and for certain other substances, such as taurine and arachidonic acid, that they cannot make for themselves. Thus a diet based too heavily on a particular meat deficient in those substances, such as heart or liver, can cause health problems. They are also fussy eaters, which means that they may acquire a taste for a diet that is not suitable.

Reputable pet food manufacturers have studied the cat's dietary needs in great detail; they produce a range of prepared prepacked foods that are formulated to provide a palatable and nutritious diet. Such prepared foods, fed according to the manufacturer's directions, provide the necessary elements for a complete diet. However, it is often thought wise to alternate them with fresh food, especially bones and hard food to maintain dental health.

Cats with certain medical conditions, or which are obese, may require special diets; a wide range is available, which are prescribed on veterinary advice. (See also DIET AND DIETETICS; FELINE JUVENILE OSTEODYSTROPHY; 'CHASTEK PARALYSIS'; STEATITIS; TAURINE.)

Cathartics
Another name for LAXATIVES.

Cathelitidin
An antimicrobial PEPTIDE in the family of PEPTIDES - POLYPEPTIDES. It was first found in the LYSOZYMES of NEUTROPHILS and occurs in several cells including epithelial cells and macrophages. Cathelitidins are activated by bacteria, viruses, fungi and the active form of VITAMINS - VITAMIN D. They have been isolated and found to be effective in controlling certain infections, including urinary ones in dogs.

Catheterisation
The insertion of a catheter.

Catheters
Long, slender, flexible tubes for insertion into veins, the heart, the bladder and other body cavities. They are used to remove fluids from, or introduce them into, those cavities. The range of catheters includes cardiac, endotracheal, eustachian, and urethral instruments.

Catheter Embolus Inserted intravenous catheters can occasionally result in embolus formation due to part of the catheter becoming separated or damage to the blood vessel or a clot developing in the catheter and not being correctly removed. Signs will depend on where the embolus lodges. Air embolism is of less risk than in human patients.

VetBooks.ir

Cationic Proteins
(See ORIFICES, IMMUNITY AT.)

Cations
A positively charged ion which is attracted to the negative electrode (cathode) of the battery. They include CALCIUM, POTASSIUM, SODIUM and they can combine with ANIONS to make compounds such as acids, alkalis and salts.

Cat Leprosy
An uncommon nodular disease of cats' skin in which granuloma formation occurs and ulcers may appear on the head and legs. There is lymph node enlargement, but without systemic illness. The condition is a skin disease associated with acid-fast bacilli. Surgical excision may be appropriate for localised lesions but natural resolution occurs in some cases.

Cause *Mycobacteria* species including *Mycobacterium lepraemurium*, which is believed to be transmitted by mice and rats.

Differential Diagnosis Cat leprosy needs to be distinguished from tuberculosis, neoplasia, foreign body granuloma, mycotic infection, nodular panniculitis, pansteatitis (see STEATITIS) and chronic abscesses secondary to feline leukaemia virus infection.

Cat Lungworm
Aleurostrongylus abstrusus can give rise to signs such as coughing, sneezing, and a discharge from the nostrils. Research has disclosed a relationship between infestation with this lungworm and abnormality of the pulmonary arteries. Often it is only when the cat is subjected to stress or to some other infection that lungworms cause serious illness.

Cat Pox
(See POX.)

Cats
Most cats, *Felis catus*, are non-pedigree and there are DOMESTIC LONG-HAIRED CATS and DOMESTIC SHORT-HAIRED CATS to cover many types although they are not of specific breeds. They include a wide genetic pool and so genetic defects are uncommon. There are DNA tests for AB blood group, COAT LENGTH, COAT COLOUR, MUCOLIPIDOSIS II, MUCOPOLYSACCHARIDOSIS II, VI, VII, POLYCYSTIC DISEASE IN CATS.

Population The UK cat population was highest in 2007 with an estimated 9,887,000 and in 2013 24 per cent of households owned a cat.

Signs of Illness There will be alterations in some part of behaviour and activities. These may include alterations in appetite, in attitude, in grooming behaviour, in locomotion, in routine behaviour and in sleeping patterns, as well as possible diarrhoea, constipation, coughing, sneezing, more/less vocalisation, listlessness, nervousness, muscular tremors, increase or loss in weight, swellings, skin changes, loss of hair, etc.

Cats, Breeding Difficulties of
For the novice breeder and others, the following facts and figures may be of interest.

Dystocia In a survey of 4007 cats, dystocia occurred in only 134, i.e. 3.3 per cent. An oversize kitten is seldom a cause, unless the queen has had a fracture of the pelvis. Occasionally a malpresentation such as a turning of the fetal head may render normal birth impossible and necessitate a Caesarean operation.

Prolapse of the uterus is rare.

Ectopic pregnancy This occurs when a fertilised egg, instead of passing down one of the Fallopian tubes towards the uterus, is released from the hind end of the tube, and develops outside the uterus. Another cause is violence of some sort leading to rupture of the uterus. Mummified fetuses have been found alongside the stomach, for example.

Uterine inertia is rare. So is torsion of the uterus. In a case of the former, veterinary advice was sought concerning a nine-month-old queen in her 70th day of gestation. Following veterinary intervention, a dead kitten was born. Ninety minutes later, three live ones followed.

Pyometra In 183 queens the signs were distension of the abdomen, feverishness, and – in some cases – a vaginal discharge. A complete recovery followed surgery in 168 cats. Any post-operative complications in 20 per cent of the patients cleared up within a fortnight after being returned home. Euthanasia or natural death accounted for 15.

Cats, Diseases of
(See diseases beginning with the words CAT and FELINE. For other diseases, see ALOPECIA; ASPERGILLOSIS; AUJESZKY'S DISEASE; BUBONIC PLAGUE; CANCER; CHLAMYDOPHILA infection; POX; CRYPTOCOCCOSIS; DIABETES MELLITUS; DIARRHOEA; ECLAMPSIA; EOSINOPHILIC GRANULOMA; GINGIVITIS; NOCARDIOSIS; PYOTHORAX; RABIES; SALMONELLOSIS; STEATITIS; toxocariasis under *Toxocara*; TUBERCULOSIS; TYZZER'S DISEASE; YERSINIOSIS; SPOROTRICHOSIS; POTOMAC HORSE FEVER; THROMBOSIS of

femoral arteries. See also FOREIGN BODY in the trachea; NEOSPORA CANINUM; PEMPHIGUS.)

Cats, Worm Parasites in

In a survey of 110 cats autopsied in the University of Sheffield, *Toxocara cati* were found in 35.4 per cent, the tapeworm *Dipylidium caninum* in 44.5 per cent and *Taenia taeniaeformis* in 4.5 per cent. In another survey made in the London area, and based on the microscopic examination of faecal samples over an 18-month period, it was found that of the 947 cats, 11.5 per cent were infected with *Toxocara cati*, 1.9 per cent with *Isospora felis*, 1.2 per cent with *D. caninum*, 1.2 per cent with *Taenia taeniaeformis*, 0.8 per cent with *I. rivolta*, and 0.2 per cent with *Toxascaris leonina*. (See also 'LIZARD POISONING' IN CATS; WORMS.)

CAT Scan

An abbreviation for COMPUTED TOMOGRAPHY using a CT scanner. (See CT SCANNING; X-RAYS - COMPUTED TOMOGRAPHY; DIAGNOSTIC IMAGING.)

Cat-Scratch Fever

Cat-scratch fever is a disease of man. The main sign is a swelling of the lymph nodes nearest the scratch, sometimes fever, and a rash; occasionally encephalitis. The cause is thought to be *Bartonella*, a bacillus, for the identification of which the Warthin-Starry stain has been used.

Cattle, Breeds of

There are now in the world nearly 1,000 breeds of cattle, including 250 major breeds. In addition, there are very many crossbreeds.

European breeds stem from *Bos taurus*, thought to have originated in temperate or western Asia. *B. indicus* (literally, Indian cattle), or zebus, have spread to SE Asia, China, Africa, the USA, and Australia. In Africa there have been many crosses between *B. indicus* and *B. taurus* groups, e.g. Africander.

(See also COWS; BULL MANAGEMENT; BEEF BREEDS AND CROSSES; CALF-REARING; HOUSING OF ANIMALS; MILK YIELDS; CATTLE HUSBANDRY.)

Cattle, Dairy Herd Management

(See under DAIRY HERD MANAGEMENT.)

Cattle, Diseases of

Many cattle diseases are multifactorial in origin. Although they may be triggered by infection with a particular bacterium or virus, an animal's susceptibility to disease is affected by its environment, management, feeding, immune status or genetic predisposition.

Surgical conditions include left or right displacement of the abomasum, abomasal torsion, abomasal ulceration, caecal dilatation and torsion, intussusception, mesenteric torsion, traumatic reticulitis, traumatic pericarditis, bloat, lameness, including sole ulceration, white line disease, foot abscesses and septic arthritis.

Other diseases include: ACTINOBACILLOSIS; ACTINOMYCOSIS; ANTHRAX; BLACK-QUARTER; BLUETONGUE; BOVINE ENCEPHALOMYELITIS; BOVINE SPONGIFORM ENCEPHALOPATHY; BRUCELLOSIS; CAMPYLOBACTER INFECTIONS; CATTLE PLAGUE; CEREBROCORTICAL NECROSIS; CLOSTRIDIAL ENTERITIS; COCCIDIOSIS; DIGITAL DERMATITIS; CONTAGIOUS BOVINE PLEURO-PNEUMONIA; ENTEQUE SECO; FOOT-AND-MOUTH DISEASE; HUSK; HYPOCUPRAEMIA; HYPOMAGNESAEMIA; JOHNE'S DISEASE; LEPTOSPIROSIS; BOVINE MALIGNANT CATARRHAL FEVER; MASTITIS; MILK FEVER; BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE; MUCORMYCOSIS; PARASITIC GASTROENTERITIS OF CATTLE; PASTEURELLOSIS IN CATTLE; POST-PARTURIENT HAEMOGLOBINURIA; PYELONEPHRITIS; RABIES; RED-WATER FEVER; RHINOSPORIDIOSIS; RHINOTRACHEITIS, INFECTIOUS BOVINE; RINDERPEST; SALMONELLOSIS; 'SKIN TUBERCULOSIS'; TICK-BORNE FEVER OF CATTLE; trichomoniasis *under Trichomonas*; TUBERCULOSIS; SMOG; VIRAL INFECTIONS OF COWS' TEATS; VULVOVAGINITIS. (See also CALVES, DISEASES OF; BOVINE ENZOOTIC LEUKOSIS; 'SLEEPER' SYNDROME; EYE, DISEASES AND INJURIES OF.)

Cattle, Import Controls

Cattle may be imported into the UK through one of the following Border Inspection Posts: Bristol Port, Luton Airport, Heathrow Airport or Tilbury Docks. All animals must be accompanied by a health certificate which satisfies the 16 points laid down by the EU. Once cattle are examined and found clinically free from infectious or contagious disease at the port of entry, they may be moved around the 27 member states of the EU. Special requirements apply to cattle imported from British Columbia. The regulations and points of import keep changing and so any importer, before making any arrangements, should contact the local AHVLA, who will direct them to the appropriate export department.

Cattle, Names Given According to Age, Sex, Etc.

Different localities have their own names for particular cattle at particular ages, periods of life, etc., and these names vary somewhat. The following is a list of the most usual names:

VetBooks.ir

Bobby or slink calves Immature or unborn calves used for human food, and often removed from the uteri of cows when the latter are killed. The flesh of slink calves is often called slink veal.

Freemartin (See FREEMARTIN.)

Calf A young ox from birth to 6 or 9 months old; if a male, a bull calf; if a female, a cow or heifer calf.

Stag A male castrated late in life.

Steer or stot A young male ox, usually castrated, and between the ages of 6 and 24 months.

Stirk A young female of 6 to 12 months old, sometimes a male of the same age, especially in Scotland.

Bullock A two-year-old (or more) castrated ox.

Heifer or quey A year-old female up to the first calving.

Malden heifer An adult female that has not been allowed to breed.

Cow-heifer A female that has calved once only.

Bull An uncastrated male.

Cow A female having had more than one calf.

Cattle, Reasons for Emergency Slaughter

A Swiss survey covered 44,704 cattle slaughtered. Major causes were dystocia (8.84 per cent, 3950 cattle), BLOAT (8.44 per cent; 62 per cent of this group were aged two months to three years), respiratory diseases (6.49 per cent; 72 per cent were two months to three years old), joint disease (5.78 per cent), reticular foreign bodies (5.16 per cent), circulatory disease (5.14 per cent), enteritis (4.65 per cent), fractures unrelated to parturition (4.43 per cent; 60 per cent were two months to three years old), recumbency (4.10 per cent), claw disease (3.46 per cent; 35 per cent were aged six to nine years, 27 per cent nine years old or more) and abortion (3.39 per cent); poisoning (1.07 per cent) and spastic paresis (1.02 per cent).

Cattle Crush

(See CRUSH.)

Cattle Handling

(See COWS; CRUSH; VETERINARY FACILITIES ON THE FARM.)

Cattle Husbandry

The management of cattle. It has a fundamental impact on the profitability of a dairy or beef farm and on the welfare and health of the animals.

For information on this and related health and disease problems which can cause economic loss to farmers, and for preventive measures, see under the following headings: ABORTION; ARTIFICIAL INSEMINATION; BARLEY POISONING; BEDDING AND BEDDING MATERIALS; BEEF CATTLE HUSBANDRY IN BRITAIN; BEEF BREEDS AND CROSSES; BRACKEN POISONING; BULL BEEF; BULL HOUSING; BULL MANAGEMENT; BUNT ORDER; CALF HOUSING; CALF-REARING; CALVING, DIFFICULT; CASTRATION; CLOTHING OF ANIMALS; COBALT; COLOSTRUM; COW KENNELS; COWS – Gentle treatment of; CONTROLLED BREEDING; CREEP-FEEDING; DAIRY HERD MANAGEMENT; DIARRHOEA; DIET AND DIETETICS; DISINFECTANTS; DRIED GRASS; ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION; EXPOSURE; FLIES – Fly control; FOOT-BATHS FOR CATTLE; GENETICS, HEREDITY AND BREEDING; GRAZING BEHAVIOUR; HORMONES IN MEAT PRODUCTION; HOUSING OF ANIMALS; INFECTION; INFERTILITY; INTENSIVE LIVESTOCK PRODUCTION; ISOLATION; LAMENESS; 'LICKING SYNDROME'; LIGHTING OF ANIMAL HOUSING; MILK YIELD; MILKING; MILKING MACHINES; NOTIFIABLE DISEASES; OESTRUS; OESTRUS, DETECTION OF, IN COWS; PARASITES; PREGNANCY AND GESTATION; PARTURITION; PARTURITION, DRUG-INDUCED; PASTURE, CONTAMINATION OF; PASTURE MANAGEMENT; POISONING; PROGENY TESTING; RATIONS FOR LIVESTOCK; SEAWEED; SILAGE; SLATTED FLOORS; SLURRY; 'STEAMING UP'; STOCKING RATES; STRAW; STRIP-GRAZING; TRACE ELEMENTS; TROPICS, LIVESTOCK PRODUCTION IN THE; UREA; VENTILATION; VETERINARY FACILITIES ON THE FARM; VITAMINS; WATER AND WATERING OF ANIMALS; WEANING; WORMS, FARM TREATMENT AGAINST; YARDED CATTLE.

Cattle Passports

These documents are provided to each bovine animal, giving its identity number, the identity of its dam, breed, sex, date of birth and where born. They became used following the establishment of the CATTLE TRACING SCHEME (CTS) on 28 September 1998. The passport accompanies the animal throughout its life. Each change of location has changed has to be notified to the BRITISH CATTLE MOVEMENT SERVICE (BCMS).

Cattle Plague

(See RINDERPEST.)

Cattle Tracing Scheme
A scheme operated by the BRITISH CATTLE MOVEMENT SERVICE by which cattle are identified and all their movements recorded on a 'passport'. (See CATTLE PASSPORTS.)

Cauda Equina
Cauda equina, meaning 'tail of a horse', is the termination of the spinal cord in the sacral and coccygeal regions where it splits up into a large number of nerve fibres giving the appearance of a 'horse's tail', whence the name.

Cauda Equina Syndrome
This syndrome, seen in the horse, is the result of damage to the sacral and coccygeal nerves, normally as the result of trauma or EQUINE HERPESVIRUS (EHV1) infection. There is a deficit of both motor and sensory function around the tail and the anus. In very serious cases there is ataxia and lack of bladder control.

Caudal
Relating to the tail. The caudal end of any part of the body means the posterior end.

Caudal Cervical Spondylomyopathy
Also known as CERVICAL VERTEBRAL MALFORMATION-MALARTICULATION, CANINE WOBBLER SYNDROME, CERVICAL SPONDYLOLISTHESIS. These abnormalities result in a state of dynamic compression of the spinal cord. It is particularly common in DOBERMANN PINSCHERS and GREAT DANES.

Causal Medicine, Causal Treatment
Treatment designed specifically to treat the cause of a disease or illness.

Cavalier King Charles Spaniel
The smallest of the spaniels, the breed is said to have originated in the reign of Charles II. The breed is larger and more popular than the KING CHARLES SPANIEL, the Cavalier has a less domed head, less prominent eyes and less flat face. It is prone to heart conditions such as chronic vascular disease and shows three other inherited conditions: CATARACT, MRD (MULTIFOCAL RETINAL DYSPLASIA) CORNEAL LIPIDOSIS and FLY CATCHING SYNDROME. In the latter, a form of epilepsy, the dog behaves as if it were trying to catch flies when none is present. Up to 95 per cent of the breed suffer from CHIARI-LIKE MALFORMATION and also this is often associated with SYRINGOMYELIA. A possible recessive condition involves both KERATOCONJUNCTIVITIS SICCA and fish-scale dermatitis (ICHTHYOSIS) with abnormally long rough curly coat, scale along the flanks and spine with a fizzy and alopecic coat (see ALOPECIA).

Cavitation
The formation of cavities; also a cavity.

CCN
(See CEREBROCORTICAL NECROSIS.)

CDVHD
(See CHRONIC DEGENERATIVE VALVULAR HEART DISEASE.)

Cefovecin
A cephalosporin which is used for treating bacterial skin and urinary conditions in dogs and cats requiring a long duration of antibacterial activity. Following reconstitution, a single subcutaneous injection can provide up to 14 days of activity.

Ceftiofur
A beta-lactamase (penicillinase) resistant cephalosporin antibiotic used in cattle and pigs against infections caused by pathogenic species of *Pasteurella Haemophilus*, *Mannheimia*, *Fusobacterium (Fusiformis)*, *Bacteroides* and *Actinobacillus*. It is also used in cases of bacterial meningitis in pigs.

Celery
The seeds contain 3-n-butylphthalide which acts as a sedative and lowers blood pressure and blood cholesterol levels. There are anti-inflammatory agents present whose chemical structure has not yet been determined. They are used as a herbal remedy for dogs and cats with arthritis and skin and kidney disorders.

Celiotomy
American spelling of coeliotomy.

Cell Count Service
A routine monitoring of the number of somatic cells in the milk (see under MASTITIS).

Cell-Mediated Immunity
(See under IMMUNE RESPONSE.)

Cells
Cells are the microscopic units of which all the tissues of the animal and plant kingdoms are composed. Every cell consists essentially of a nucleus, a cell wall or membrane, and the jelly-like cytoplasm (protoplasm) contained within the cell membrane. The cytoplasm consists of water, protein, lipids, inorganic salts, etc. and microscopic structures called organelles, which include the nucleus that controls the activities of the cell and its genetic material (chromatin in the non-dividing cell; chromosomes in the dividing cell), Golgi

VetBooks.ir

apparatus, mitochondria (containing enzymes); ribosomes (granules containing RNA), etc.

(The circulating red blood corpuscles although commonly referred to as red cells are not typical cells; in mammals they have no nucleus.)

The nucleus is bounded by the nuclear membrane and contains a nucleolus or two or more nucleoli. DNA and RNA are both present in the nucleus.

Cells vary very much in size, the smallest being about 0.002 mm in diameter, and the largest being the egg of a bird, which is still a simple cell although much distended with food.

It is estimated that mammalian cells contain about 10,000 genes, but only a small proportion of these will be active at any one time. Each cell of an animal contains a complete set of its genes. The function of the individual cell is determined by which genes are 'expressed' and which 'repressed'.

(See also CANCER; TISSUES OF THE BODY; BLASTOCYST; GIANT CELLS; BLOOD; LYMPHOCYTE; GENETIC ENGINEERING; B CELLS; T CELLS.)

Cellulitis

Usually refers to a diffuse area of inflammation, often with suppuration causing swelling in the subcutaneous tissues. Cellulitis, unlike an acute abscess does not tend to come to a head, or 'point', and then burst. However, cellulitis, if untreated, is liable to spread beneath the skin.

Cause Bacterial infection of the tissue, usually by streptococcus or pasteurella.

Treatment Antibiotics are used, usually in association with hot fomentations. If, however, treatment has been delayed, it may be necessary to lance the lowest part of the area.

Cattle The term 'necrotic cellulitis' has been applied to cases of diffuse swelling beginning under the jaw and then, if untreated, extending down the neck to the brisket.

Horses Cellulitis occurs in a form referred to also as ULCERATIVE LYMPHANGITIS.

Cats Cellulitis is more common than an abscess, which is localised and comes to a head. A frequent sequel of bites sustained from other cats.

Animals in the tropics For a form of cellulitis occurring in many species, see under HAEMORRHAGIC SEPTICAEMIA.

Celom

American spelling of COELOM.

Celoschisis

A congenital fissure of the abdominal wall.

CEM

(See CONTAGIOUS EQUINE METRITIS.)

Central Nervous System (CNS)

(See also BRAIN).

This comprises the brain and spinal cord, each with its grey and white matter. The 12 pairs of cranial nerves from the brain and the 42 pairs of spinal nerves carry between them all the messages to and from the brain.

For descriptive purposes the CNS is divided into two further systems: (1) somatic, and (2) autonomic.

Somatic This system is concerned with the control of voluntary muscles, and with nerve impulses from the skin, eyes, ears, and other sense organs. Accordingly, this system includes both motor and sensory nerves.

Autonomic This system of the CNS maintains the correct internal environment of the body (e.g. see HOMEOSTASIS), and its functions lie outside voluntary control. This system regulates breathing and heart rates, for example, and likewise the activity of the liver, digestive tract, kidneys, bladder, etc. This autonomic system comprises sympathetic and parasympathetic nerves. Most organs receive nerve impulses from both these, and they have opposite effects. For example, sympathetic nerves increase heart rate, while parasympathetic nerves slow heart rate.

The sympathetic nervous system prepares the body for 'flight or fright', i.e. for emergency action. Accordingly, under its influence breathing becomes more rapid, the heart's action faster, and blood is diverted from the digestive organs to heart, CNS and voluntary muscles; while the liver releases glucose for extra muscular activity.

The parasympathetic system restores the situation after the emergency, slows the heart, and relaxes the body generally, as it also does during sleep. (See also BRAIN; SPINAL CORD; NERVES.)

Central Progressive Retinal Atrophy (CPRA)

This is also called PROGRESSIVE RETINAL EPITHELIAL DYSTROPHY; it is not the same as PROGRESSIVE RETINAL ATROPHY and involves the retinal pigment epithelium. There is attenuation of retinal vasculature and atrophy of the optic disc. Signs begin with effects on day vision followed by further visual impairment, but blindness does not always result. The condition is usually seen in middle-aged dogs, including BORDER COLLIES, GOLDEN RETRIEVERS, IRISH

SETTERS, LABRADOR RETRIEVERS and SMOOTH COLLIES.

Central Veterinary Laboratory
The headquarters of the Veterinary Investigation Service, now part of the ANIMAL HEALTH AND VETERINARY LABORATORIES AGENCY (AHVLA) and formerly the Veterinary Laboratories Agency, New Haw, Addlestone, Surrey KT15 3NB.

Cephalocele
Protrusion of part of the brain from cranial cavity.

Cephalopods
These include clams, cuttlefish, mussels and octopuses. It is now accepted that some octopus species can experience pain and have a considerable memory. As a result, *Octopus vulgaris* is protected under the Animals (Scientific Procedures) Act 1976. It is quite likely that squid, nautilus, cuttlefish and other species of octopus can also feel pain but it has not been shown that they can remember the experience.

Cephalosporin Antibiotics
A range of bactericidal antibiotics related to penicillin. Earlier cephalosporins are active against both Gram-positive and Gram-negative organisms. Later ones are active against some Gram-negative organisms resistant to the earlier 'first generation' products. Examples of cephalosporins used for animal treatment include Cefalexin, Cefapirin, Cefoperazone, Cefovecin, Cefquinome, Ceftiofur, Cephalexin and Cephalonium.

Ceratomyxa
Myxosporidian parasites of fish which damage any soft tissue that they invade.

Cercaria
(plural, Cercariae)
Cercaria is an intermediate stage in the life-history of the liver-fluke, viz. the tadpole-like form, which is produced in the body of the freshwater snail *Limnoea truncatula*, bores its way out of the snail, and attaches itself to a suitable blade of grass to wait for the arrival of a sheep or bovine which will eat it. In the sheep's stomach and intestines further development takes place. (See LIVER-FLUKES.)

Cere
The area above the beak containing the nostrils in PSITTACINE birds. In the budgerigar, the cere is usually a means of sexing with a blue colour in males and pink in females. Overgrowth in budgerigars is usually a sign of mange infestation with Cnemidocoptes pilae. (See MANGE - MANGE IN CAGE BIRDS.)

Cereals
Cereals, such as wheat, barley, oats, rye, maize, millets, and rice, are all rich in starch and comparatively poor in proteins and minerals, and mostly poor in calcium but richer in phosphorus. Some dangers of cereal feeding for cattle are referred to under BARLEY POISONING. (See also MOIST GRAIN STORAGE; DIET AND DIETETICS; HORSES, FEEDING OF

Cerebellar Abiotrophy
A premature loss of vitality involving the cerebellum (see BRAIN). It is seen in cattle, pigs and dogs and may have an inherited origin. Animals are born normal but at a young age signs of cerebellar dysfunction occur, and they may become completely immobilised. In dog breeds it is common in KERRY BLUE TERRIERS.

Cerebellar Ataxia
This is seen as an uncoordinated gait with exaggerated movements. There is exaggerated strength and steps (hypermetria). No paresis occurs. It occurs as a result of damage to the CEREBELLUM and it may be congenital or acquired. It is seen more often in certain breeds such as ITALIAN SPINONES, SMOOTH-HAIRED FOX TERRIERS. (See also BRAIN.)

Cerebellar Hypoplasia
A congenital malformation resulting from infection of the pregnant female. It is a form of degeneration of the cerebellum characterised by ataxia, head tilting and nystagmus. It is seen in infection caused by FELINE PANLEUKOPENIA virus, herpes virus in dogs and BOVINE VIRAL DIARRHOEA virus. It is an inherited defect in some Airedale terriers.

Cerebellitis
Inflammation of the cerebellum; it occurs in several diseases including CANINE DISTEMPER, CANINE HERPESVIRUS, FELINE PANLEUKOPENIA, FELINE INFECTIOUS PERITONITIS, mycotic infections especially *Cryptococcus* and/or *Blastomyces* spp., parasite migration *Toxoplasma* and *Neospora*; and very rarely algal infection by *Prototheca* spp. usually in immunocompromised animals.

Cerebellum and Cerebrum
(See BRAIN.)

Cerebral Aqueduct
(See AQUEDUCT OF SYLVIUS.)

Cerebral Haemorrhage
Cerebral haemorrhage is, in human medicine, referred to as a stroke. An older name was apoplexy.

VetBooks.ir

It is characterised by loss of consciousness, and may arise from bleeding from an artery in the brain or following embolism or thrombosis. It has been recorded in dogs, rabbits and birds.

Cerebrocortical Necrosis (CCN)

A condition found mainly in ewes and calves. It is also called POLIOENCEPHALOMALACIA. The cause is a thiamin deficiency due to endogenous thiaminase production in the rumen by, for example, *Clostridium sporogenes* and *Bacillus thiaminolyticus*. Signs include: apparent blindness, circling movements, a staggering gait, excitement, opisthotonos and convulsions. Only a few animals in a flock or group become affected, but nearly all of those die unless treated early.

A differential diagnosis has to be made between CCN and bacterial meningitis, GID, BSE, listeriosis, and lead poisoning – each can give rise to similar signs.

At post-mortem examination, autofluorescence is seen when the CCN-affected brain is examined under ultra-violet light.

The lesions consist of multiple foci of necrosis of the cerebral neurones.

Treatment High doses of thiamin (vitamin B_1) daily for a minimum of three days can produce recovery.

Cerebrospinal Fluid Sampling

A diagnostic technique.

Indications for cerebrospinal fluid sampling in the dog include the following:

Encephalitis	Intracerebral haemorrhage
Meningitis	Subarachnoid haemorrhage
Myelitis	Toxoplasmosis
Brain neoplasia	Spinal cord compression caused by epidural abscess
Spinal cord neoplasia	

Ceroid Lipofuscinosis

An atrophy of the brain in which there is accumulation of lipopigments (ceroid bodies), first in nervous tissues and then the viscera. Blindness, dullness and abnormal behaviour follow. It has been found in cats, cattle, dogs and sheep. In dogs it is seen in BORDER COLLIES, DACHSHUNDS, ENGLISH SETTERS and TIBETAN TERRIERS, and there are DNA tests for it.

Ceroidosis

A form of liver degeneration characterised by deposition of a pink/golden, fat-insoluble material within cells. It is associated with the use of rancid or vitamin-E deficient feeds. (See FISH, DISEASES OF; also LYSOSOMES.)

Cervical

Cervical means anything pertaining to the neck or to the cervix (the neck of the uterus).

Cervical Lymphadenitis

A guinea pig infection of the cervical lymph glands caused by *Streptococcus zooepidemicus* which may lead to abscessation. Affected lymph nodes may be lanced or removed and antibiotics may be used.

Cervical Spondylolisthesis

This is the canine 'wobbler syndrome' or CERVICAL SPONDYLOPATHY. (See also under SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Cervical Spondylopathy

It is known as CANINE WOBBLER SYNDROME and is most commonly seen in the GREAT DANE; it also occurs in other breeds, especially the DOBERMANN PINSCHER, IRISH SETTERS, OLD ENGLISH SHEEPDOGS and RHODESIAN RIDGEBACKS. The problem is also called CERVICAL SPONDYLOLISTHESIS. It is usually first seen between 8 and 12 months, and the clinical signs include hind-limb incoordination, abduction of the limbs, a prancing gait, and dragging of the feet causing wearing of the toe nails.

(See under SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Cervical Spondylosis

Also called cervical ankylosis. It is fusion of the intervertebral joints in the neck. It can occur with hypervitaminosis A and certain breeds of dog are prone to the condition, including BASSET HOUNDS.

Cervical Vertebral Malformation-Malarticulation

Also known as CANINE WOBBLER SYNDROME, caudal CERVICAL SPONDYLOPATHY, CERVICAL SPONDYLOLISTHESIS. The abnormalities result in a state of dynamic compression of the spinal cord. It is particularly common in DOBERMANN PINSCHERS and GREAT DANES.

Cervicitis

Cervicitis is inflammation of the *cervix uteri*. (See UTERUS.)

Cervid

A member of the Cervidae, the deer family. The red deer is *Cervus elaphus*.

Cervix

A muscular area found at the caudal extremity of the body of the uterus; it is responsible for the retention of the fetus in pregnancy. In some mammals a plug of mucus (the cervical plug) is

formed in its lumen during pregnancy. In the doe rabbit the cervix is duplicated, each one opening into one horn of the uterus.

Cervus elaphus
(See RED DEER.)

Cestode
A tapeworm.

Cetavlon
Proprietary name for CETRIMIDE.

Cetrimide
An antiseptic of value in wound treatment and for cleaning cows' udders and teats; a 0.1 per cent solution being effective against *Streptococcus agalactiae*, a cause of mastitis. A 1 per cent solution acts as a detergent. (See QUATERNARY AMMONIUM COMPOUNDS.)

CFT
(See COMPLEMENT FIXATION TEST.)

CFU, cfu
(See COLONY-FORMING UNIT.)

Chabertiasis
Infection of the colon with chabertia worms (*Chabertia ovina*); found in sheep and occasionally in goats and cattle.

Signs Usually mild: soft faeces, with mucus and sometimes blood-flecked. In severe cases, anaemia may occur.

Chagas Disease
An infection with *Trypanosoma cruzi*, mainly occurring in wild mammals (such as opossums, armadillos, and wood rats) of Central and South America, but also infecting man, dogs, cats, and pigs. (See TRYPANOSOMES – American trypanosomiasis.)

Chalazion
Chalazion is a small swelling of the eyelid caused by a distended Meibomian gland. It is commonly seen in dogs; usually referred to as a 'stye'.

Chancre
In human medicine this term is reserved for the ulcer or hard 'sore' which is the primary lesion of syphilis. In a veterinary context it means the local skin reaction at the sites of bites by tsetse flies carrying trypanosomes. The chancre – the first sign of trypanosome infection – begins as a small nodule, developing into a hard, hot, painful swelling measuring up to 3 in or 4 in (7.5 cm or 10 cm) across.

Charlock Poisoning
The common charlock *Brassica sinapis* (wild mustard) is dangerous to livestock after its seeds have formed in the pods, although only when eaten in large amounts. The seeds contain the volatile oil of mustard and also a glycoside.

Signs are those of abdominal pain, loss of appetite, a yellowish frothy liquid at mouth and nostrils, diarrhoea. There is nephritis, and the urine may be blood-stained.

First-Aid Give milk and strong tea.

Charolais Cattle
This is numerically the second-largest breed of cattle in France, and they have been exported throughout Europe and the USA. The Charolais, white, is an excellent beef animal, a most efficient grazer, with a rapid growth-rate and a quiet disposition. The loin and thigh muscles are exceptionally well developed. The bulls are colour-marking and highly prized for crossing purposes. UK trials of this breed for crossing purposes were approved in 1961, and the British Charolais is now the third most important beef breed.

Charollais Sheep
This breed was developed in the 19th century by crossing Dishley Leicester with the local sheep of Central France, and has been recognised as a breed since 1974. They have fine fleece, grey faces, both sexes are naturally polled and are used for meat production. Mature ewes weigh up to 90 kg and rams up to 135 kg.

'Chastek Paralysis'
A condition of secondary vitamin B_1 (THIAMIN) deficiency, seen in foxes and mink on fur farms as a result of feeding raw fish. This contains the enzyme thiaminase, which destroys thiamin. Thiaminase is destroyed by heat and so cooking removes the problem. The condition is seen also in cats.

Check Ligament
This is joined to the Perforans tendon, and acts as a check on the movement of the pastern joint. There are two of these ligaments in the foreleg of the horse. The radial check ligament of the superficial digital flexor lies proximal to the carpus. The carpal check ligament of the deep digital flexor lies distal to the carpus. The check ligaments are often strained in the racehorse.

Cheese
When cheese is made from raw milk, *Brucella*, *Listeria* and other organisms may infect the cheese. In the UK, pasteurised milk is used, although it is argued that the flavour may be less good. The

VetBooks.ir

unpasteurised form is widely produced in Europe; sheep and goat cheese is popular as well as cow's milk cheeses. (See BRUCELLOSIS.)

Cheilitis

Inflammation of the lips. It is often found in guinea pigs following eating abrasive or acidic feeds; the wounds should be debrided and the offending feeds removed.

Cheiloschisis

A hare lip; central, unilateral or bilateral.

Cheilosis

Cracked and scaly lips, often also affecting the corners of the mouth. Caused by deficiency of vitamins of the B group (especially FOLIC ACID). Such deficiency is rare in animals, given the availability of modern well-formulated diets. However, some chemotherapeutic agents (e.g. methotrexate) can lead to a drug-induced deficiency.

Chelating Agents

Chelating agents are substances which have the property of binding divalent metal ions to form stable, soluble complexes which are non-ionised and so virtually lacking in the toxicity of the metal concerned. Derivatives of ethylene-diamine-tetra-acetic acid (EDTA) afford examples. EDTA itself is poisonous, as it removes calcium; but the calcium-EDTA complex has been recommended in the treatment of acute lead poisoning, being given repeatedly for several days. It is also useful in the event of zinc poisoning in aviary birds (See 'NEW WIRE DISEASE') and may possibly be of service in mercury, copper and iron poisoning.

Chelonian

The suborder of reptiles with a carapace (shell), including tortoises, turtles and terrapins. It is no longer legal to import some of these into the United Kingdom but some can be bred in the UK and then sold.

Clinical examination is restricted to those parts that protrude from the carapace or plastron (shell covering the abdomen). Blood samples can be obtained from the dorsal caudal vein after training. Abscesses should be treated surgically after general anaesthetic wherever possible and an antibiotic paste applied after the wound has been cleaned. Vitamin A deficiency is seen as caseous debris in the conjunctival sac. It seldom occurs on its own and other factors involved in the problem should be sought. *Balantidium coli* may be seen in faecal smears, and high levels can be fatal to hatchlings. Other flagellates such as *Hexamita* spp. can cause the animal to drink excessively. Nematode worms may be a cause of failure to survive hibernation and so worming before hibernation is advisable. However, ivermectin and related drugs are contraindicated in tortoises. It may be difficult to get a tortoise to eat after hibernation and advice should be sought (See CHELONIAN POST-HIBERNATION ANOREXIA). The eyes should always be examined routinely, cataracts are quite common. Egg binding is quite common and can have various causes, including the female not finding a suitable egg-laying site. Eggs can be surgically removed. Oedema of the legs gives rise to a suspicion of a urolith.

PHIMOSIS may be the result of a nutritional problem. Respiratory disease is not uncommon and animals with such disease must be prevented from hibernating. Diphtheritic stomatitis ('mouth rot') may have various causes including a virus; the diphtheritic material should be removed under general anaesthesia and the wound debrided thereafter. Daily cleaning of the lesions will be required and the animal fed by stomach tube, which must be done with great care. (See TORTOISES.)

Chelonian Post-Hibernation Anorexia

Successful revival of tortoises in the spring following hibernation can be difficult. They may show only a partial response, and be lethargic with some showing rhinitis (unable to smell) and apparent blindness so that they are unable to find feed. Supportive therapy is necessary with glucose-saline by stomach tube and the animal may require assisted feeding for a long time.

Chemosis

Chemosis means swelling of the conjunctival membrane that covers the white of the eye, leaving the cornea depressed.

Chemotherapy

Chemotherapy means the treatment of disease by chemical substances. The use of antibiotics, sulfonamides, and the diamidines, useful in the trypanosome diseases, are examples. In the treatment of cancers, chemotherapy has come to mean the use of cytotoxic drugs, which are usually associated with severe side-effects.

Chesapeake Bay Retriever

A dog breed that is less popular than in the past. It has two important inherited conditions, cataract inherited by a dominant trait, while progressive retinal atrophy is a recessive trait. DEGENERATIVE MYELOPATHY and EXERCISE-INDUCED COLLAPSE also occur.

Chest, Thorax

The chest, or thorax, is the part of the body lying between the neck and the abdomen. It is a conical cavity, with the apex directed forwards. The base is

formed by the diaphragm, while the sides are formed by the ribs, sternum, and vertebrae. Lying between adjacent ribs on the same side there are 2 layers of intercostal muscles, those on the outside running almost at right angles to those on the inside. The intercostal muscles fill up the spaces between the ribs and their cartilages, and are active agents in moving the ribs during respiration. The outsides of the chest walls are covered with the masses of the shoulder muscles, and the shoulder-blades or scapula lie one on either side, anteriorly over the rib-cage, but not attached to it by bony connections.

Within the thorax are the termination of the trachea, the bronchial tubes, and the lungs. Between the lungs, but projecting towards the left more than to the right, lie the heart and its associated vessels. The oesophagus, or gullet, runs through the chest, passing for the greater distance between the upper parts of the lungs, and enters the abdomen through an opening in the diaphragm. The thoracic duct, which carries lymph from the abdomen, runs forwards immediately below the bodies of the vertebrae and ends by opening into one of the large veins in the apex of the cavity. Various important nerves, such as the two vagi which control the abdominal organs, the phrenics, which supply the muscles of the diaphragm, and sympathetics, pass through the chest in particular situations. The thymus gland lies in the anterior portion of the chest. Lining each of the 2 divisions of the chest cavity is the pleura, a fold of which also covers the surface of the lung, and the heart is enclosed in a special sac or pericardium. (See HEART; LUNGS; PLEURA; PERICARDIUM.)

Chest Injuries/Diseases

Injuries to the chest wall are often the result of dogs or cats being struck by a car; or of falls leading to fractured ribs and closed PNEUMOTHORAX. Puncture-type wounds from animal bites are less common, except in pet rabbits; these can sometimes lead to pneumothorax. Some subcutaneous emphysema may occur. Infection may lead to PLEURISY.

(See THORACOTOMY; DIAPHRAGMATOCELE; HYDROTHORAX; 'FLAIL CHEST'; PYOTHORAX; also BRONCHITIS; PNEUMONIA; HEART DISEASES; PARASITIC BRONCHITIS; 'BROKEN WIND'; LUNGS, DISEASES OF.)

Chestnut

This a popular colour of horses; the whole animal including mane, tail and legs are the same one colour. It ranges from a deep red to a light chestnut to a heavier brown colour.

Chestnuts

Flat oval areas of the horn on the inside of the fore- and hind-limb of the horse.

Cheviot Sheep

This breed originated in the borders of Scotland and England. It has a wide face and is used for meat and wool. The rams weigh 80 kg to 90 kg, (175 lb to 200 lb) ewes 50 kg to 70 kg (110 lb to 155 lb) and the fleece 2 kg to 5 kg (4.5 lb to 11 lb). They may show DWARFISM.

'Chewing Disease'

The colloquial name in the USA for a type of encephalomalacia in the horse caused by yellow star thistle (*Centaurea solstitialis*).

Cheyletiellosis

A dermatitis caused by mites of the genus *Cheyletiella*. These are non-burrowing mites which can infest dogs, cats, birds, rabbits, squirrels, etc. It gives rise to itching and scurfiness of the skin. In man *Cheyletiella* species (including *C. yusguri*) may cause urticarial weals of trunk and arms, together with intense itching.

C. blakei infests cats; *C. parasitivorax*, rabbits; *C. yasguri*, dogs.

Cheyne-Stokes' Respiration

Cheyne-Stokes' respiration is an abnormal form of breathing in which the respirations become gradually less and less until they almost die away; after remaining almost imperceptible for a short time they gradually increase in depth and volume until they are exaggerated; after attaining a maximum they again decrease until nearly imperceptible. This alternation proceeds with considerable regularity.

Cheyne-Stokes' breathing is always a very serious condition, which is generally associated with severe nervous disturbance, shock, and collapse, or with heart or kidney disease. It is most obvious in the dog and horse after they have sustained very severe injury but without internal haemorrhage (which induces what is generally known as 'sobbing respiration').

Chianina

These Italian cattle are named after their place of origin, the Valdichiana and middle Tiber valley. Probably the largest cattle in the world, the cow weighs 800 kg to 900 kg (1,800 lb to 2,000 lb). They are white with a black switch to the tail and have a black-pigmented skin which means that they are heat tolerant. They are a very old breed, recorded from 55 AD. Formerly used as draught animals, they are an excellent beef breed, now present in the UK.

Chiari-Like Malformation (CM)

A problem of the brain in which there is reduction in caudal fossa volume with descent or herniation of the cerebellum, and often the brain-stem, into

VetBooks.ir

or through the foramen magnum. This can also be associated with SYRINGOMYELIA. It is particularly seen in the CAVALIER KING CHARLES SPANIEL, in which breed up to 95 per cent are believed to be affected to some extent, and also the GRIFFON BRUXELLOIS. It is also suspected to be inherited in other small (toy) breeds including KING CHARLES SPANIELS, CHIHUAHUAS, POMERANIANS, AFFENPINSCHERS and MALTESE DOGS. It is diagnosed by MAGNETIC RESONANCE IMAGING. A BVA/Kennel Club Canine Health Scheme for this and SYRINGOMYELIA began in January 2012.

Chicken Anaemia Virus

Transmitted by breeder flocks to their progeny, chicken anaemia virus causes increased mortality with anaemia, lymphoid depletion, liver changes and haemorrhages throughout the body. Signs develop at two to three weeks old.

Chick Oedema

(See 'TOXIC FAT SYNDROME'.)

Chicks

Ambient temperature for rearing chicks should be 32° C (90° F). Chilling is one of the commonest causes of pullet chick mortality. Chicks require artificial heat for 3 to 8 weeks, depending upon the type of house, weather, etc. (See also POULTRY AND POULTRY KEEPING - CHICK FEEDING).

Chicory

A woody perennial herbaceous plant (*Cichorium intybus*) which has bright blue flowers, occasionally white or pink. It has been fed to ruminants, especially sheep and horses and can be used to finish lambs. It contains volatile oils effective at eliminating intestinal worms. In cattle, excessive eating of the roots can lead to anorexia, salivation and diarrhoea.

Chihuahua Dogs

One of the smallest breeds of dog, named after a Mexican province. Caesarean operations are not unusual at parturition, HYDROCEPHALUS can occur but its inheritance is not known. It is suspected that CHIARI-LIKE MALFORMATION and SYRINGOMYELIA may be inherited in the breed. CLEFT PALATES and PYRUVATE KINASE DEFICIENCY of an unknown inheritance mechanism is seen, as well as PATELLAR LUXATION is possibly a recessive trait and HAEMOPHILIA B (Factor VII Deficiency) is sex-linked. PULMONARY STENOSIS appears to be due to many factors. MANGE in this breed must never be treated with AMITRAZ.

Chikungunya Disease

A viral infection of humans transmitted by mosquitoes and causing headaches, muscle pain, joint swellings and rash. The painful joints may persists for longer than a year. Currently there is no treatment or preventative vaccine. Cases have occurred in Africa, Asia and the Americas including USA. Birds, cattle, monkeys and rodents are reservoir hosts.

Chilblain Syndrome in Dogs

This was first described as affecting Service dogs in Northern Ireland. These dogs had previously thrived in unheated, outdoor kennels, but were affected during a very cold winter. The first sign was biting of the tip of the tail – found to be red, swollen, warm and intensely itchy. Ulceration, infection, and necrosis of the tail tip occurred in a few cases, necessitating amputation of the tip. It is not unknown for a dog to eat the affected part of its tail. Elizabethan collars, protective tail covering, and anti-inflammatory drugs were used in treatment.

Chilling

(See under CHICKS and HYPOTHERMIA.)

Chimera

An animal having in its body, cell populations arising from different species; that is, cells with different KARYOTYPES which have originated from 2 or more zygotes with different karyotypes. A freemartin is, technically, an example of XX:XY chimerism. This is secondary chimerism. Primary chimerism occurs if 2 sperms fertilise the same ovum. (See CYTOGENETICS.)

Other examples which have been reported include a fertile female mule that had apparently inherited a mixture of both horse and donkey chromosomes, and was phenotypically a chimera rather than a hybrid. And a sheep-goat chimera found at the School of Veterinary Medicine, University of California, USA, was capable of oestrus cycles, producing fertile ova, and carrying pregnancy to full term.

Chimera is also a term used to describe an organism that has had foreign DNA inserted into its genome.

China Clay

(See KAOLIN.)

Chinchilla

A long-haired cat breed with pale colours, white, silver and golden. It resembles the Persian except for a longer nose which results in easier respiration and better lacrimal drainage. The mature eyes are blue-green or blue in colour.

Chinchilla, Diseases of

The commonest condition encountered in the pet chinchilla is dental overgrowth. This prevents a

proper bite and in many cases 'spurs' grow from the edge of the tooth injuring the tongue or the cheeks. The condition is due to soft food and lack of hard materials to gnaw on. It is usually incurable but the animal's quality of life may be improved by constant veterinary attention. Due to the species' intolerance of ambient temperatures in excess of 21°C respiratory diseases are common in pets kept in domestic situations – secondary infections like *Streptococcus pneumoniae*, *Strep. Zooepidemicus*, *Bordetella bronchiseptica*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*.

Conditions of the PELAGE are next most common and include FUR SLIP, FUR RING, RINGWORM, BARBERING and FUR CHEWING. Reproductive disorders are more common than digestive problems. Dystocia is particularly common, often due to an oversized fetus; and SCHISTOSOMUS REFLEXUS has been reported.

Chinchillas

Chinchilla laniger is a small rabbit-like rodent, prized for its fur. It originates from the South American Andes; those living at higher altitudes have better coats. Originally brought to the UK for fur farming, the project had to be abandoned because of the poor quality of the imported animals. Adults weigh about 400 g to 500 g (0.88 lb to 1.1 lb); the female is larger than the male. Pregnancy lasts 111 days; there are usually two in a litter but up to five may be born. Weaning is at 6 to 8 weeks. They are sexually mature at 8 months and can live for 10 years although the record is 18. Body temperature is 38° C to 39° C (100° F to 102° F). They can be active during the day but are mainly nocturnal in habit.

Chinchillas require ample room (about 4 m^3) with a nest box about 30 x 25 x 20 cm (12 x 10 x 12 in) within that. An ambient temperature of 10° C to 20° C (50° F to 68° F) is adequate; as low as 0° C (32° F) can be tolerated provided there are no draughts. Fine sand must be provided for sand-bathing to keep their coat in good condition.

If treated with sulfonamides, the coat colour may fade; it will eventually return to normal. FUR SLIP may occur if the animals are handled improperly.

To handle a chinchilla it is best to lift it up by the tail, placing the other hand over the chest, to grasp the torso. (See RESTRAINT.)

Chinese Crested Dogs

This is a small (3 kg to 5 kg; 7 lb to 11 lb) hairless dog with long hair on the head (crest) legs and tail. It is susceptible to PROGRESSIVE RETINAL ATROPHY and primary LENS LUXATION.

Chinese Lanterns

These are now often released at celebrations such as weddings. They can cause problems for domestic animals and wildlife. Although the lights have occasionally been said to cause disturbance or excitement to animals in fields, the main risk is from the lanterns after return to earth. They can start fires. They usually contain bamboo which can break and splinter and some also contain wire. As the lanterns disintegrate parts may be eaten particularly by cattle or are more likely to be ingested when present in silage leading to damage of the OESOPHAGUS, TRAUMATIC RETICULITIS, TRAUMATIC PERITONITIS or TRAUMATIC PERICARDITIS. In Britain some retail outlets have made the decision to no longer stock them.

Chipmunks

A rodent (*Tamias striatus*), not dissimilar to the squirrel, with longitudinal stripes across its back. Adults weigh 72 g to 120 g. When kept as pets they should be in pairs or a trio of one male and two females, one of the females becoming the dominant animal. A large, escape-proof enclosure should be provided. They become hyperactive if stressed and must never be kept near a television set. If outside, protection from adverse weather conditions must be given.

Body temperature is 38° C when awake, falling to a few degrees above ambient temperature when hibernating. Chipmunks are comparatively healthy animals provided they are well kept, but wounds from fighting are common. Ectoparasites may be present, as mange, fleas and harvest mites. Cataracts occur in older animals; emphysema has been recorded and is difficult to treat. If hypoglycaemia (milk fever) is seen after parturition, it can be treated with 0.5 ml calcium borogluconate given subcutaneously. Swellings due to collection of fluid (lymphoedema) may be seen. These usually regress during hibernation but can be treated with a daily dose of 0.5 mg frusemide.

Chiropractic

A technique which aims to relieve disease problems by manipulation of body structures, particularly the spinal vertebrae.

Chitin

The horn-like substance forming the main constituent of the body-covering of insects, ticks, mites, spiders, etc. A polysaccharide, it is also found in some fungi.

Chitosan

A product derived from chitin in the exoskeleton of marine invertebrates. When impregnated into wound dressings it acts as a haemostatic. It has a positive electrical charge which attracts the negatively-charged red blood cells to the injury site thereby speeding up clotting and healing.

VetBooks.ir

Chlamydiales

A bacterial Order containing obligate intracellular bacteria which have a chlamydia-like developmental cycle of replication. Most families in the Order have Gram-negative staining extracellular infectious bodies. They live in animals, insects and protozoa.

Chlamydophila, Chlamydia

Widespread Gram-negative bacteria containing species of veterinary and medical significance. They include *Chlamydophila psittaci*, responsible for psittacosis (see below) in birds (and man); *Chlamydophila abortus*, a major cause of abortion in sheep and some other ruminants; *Chlamydophila felis*, which causes pneumonia, conjunctivitis and respiratory problems in cats. *Chlamydophila suis* causes conjunctivitis, pneumonia and enteritis in pigs.

Psittacosis Sometimes called parrot disease, psittacosis affects virtually all avian species. There are several strains (serovars) of *Chlamydophila psittaci*, some of which affect other species. Affected birds may show no signs initially but active infection is often triggered by stress. Parrots and other cage birds become listless, have diarrhoea, coryza, conjunctivitis and sinusitis. Pigeons develop respiratory signs and bronchitis. In poultry, egg production falls off; up to a third of a flock may die.

There is a considerable risk that people in contact with infected birds pick up the disease, sometimes with serious results.

In one Edinburgh outbreak, 100 out of about 300 budgerigars in an aviary died. Human cases followed and a dog was found to be excreting *Chlamydophila* organisms and to have a lung infection.

Treatment Tetracycline or doxycycline, given to birds over a period of seven weeks in the feed or on medicated seed. Enrofloxacin is used for shorter periods.

Prevention Quarantine of imported birds; disinfection of infected premises.

Ornithosis is the name formerly given to the same infection in birds other than those of the parrot family.

Post-Mortem findings include enlargement of liver and spleen, together with pneumonia. Confirmation of diagnosis is by ELISA, immunofluorescent test or bacterial culture.

Measures to protect the UK's poultry against psittacosis infection from abroad are specified under the Importation of Birds, Poultry and Hatching Eggs Order 1979, much of which has been revoked. EU import controls on third country imports were set out in Commission decision 2010/734EU, which is the basis for pet bird import licences from third countries. No licences are required for birds from within the EU. All diagnoses of the disease in imported birds are notified by the Animal Health and Veterinary Laboratories Agency to medical officers of environmental health. The DEFRA website may be helpful: http://defraweb/foodfarm/farmanimal/diseases/atoz/index.htm#psittacosis.

Public health Human psittacosis in its milder forms resembles influenza. In children the signs are slight or absent altogether, but in older people the illness is more likely to be severe. Signs include shivering, headache, backache. Death from pneumonia may follow. Acute kidney failure has been recorded; also heart disease. Human infection comes through handling infected birds.

Abortion *Chlamydophila abortus* (and some strains of *Chlamydophila psittaci*) are responsible for abortion in ruminants.

Sheep infected with *Chlamydophila abortus* usually show no signs of disease until they become depressed shortly before abortion occurs. Afterwards, most ewes recover uneventfully. When disease is established in a flock, 5 to 10 per cent of ewes will abort; immunity develops following infection. The infection is usually transmitted at lambing, through placenta, uterine discharges and faeces.

Vaccines are available against certain strains of chlamydophilial infection.

Cattle Animals show no sign of disease but sporadic abortions occur, usually in the seventh to ninth month of gestation. Sometimes, dead or short-lived weakly calves are born at full term.

Public health The infection is transmissible to humans. Cases in pregnant women who have assisted at lambing have been recorded. Difficulties during pregnancy, and in one case death, followed.

A farmer's wife who aborted in the 28th week of pregnancy, had helped with difficult lambings. Five of 200 ewes had aborted and a serum sample had shown high antibody titres to chlamydia. *Chlamydophila* spp. were detected in smears of liver, lung and placenta from the human fetus.

Chloral Hydrate

Chloral hydrate is a clear, crystalline substance with a sweetish taste; it dissolves rapidly in water. It was formerly used widely as a hypnotic, and occasionally for euthanasia.

Chloral Hydrate Poisoning
In the dog, poisoning has occurred after eating meat from horses humanely euthanased by means of chloral hydrate. It results in sedation, narcosis and, in severe cases, death.

Chlorambucil
A chemical that can be used to treat certain types of NEOPLASIA and is used in dogs with secondary PROTEIN-LOSING ENTEROPATHY.

Chloramines
Chloramines are widely used as a disinfectant. Their activity depends upon the amount of available chlorine.

Chloramphenicol
An antibiotic which has a similar range of activity to the tetracyclines. It can be given orally (except to ruminants), by intravenous injection, and by local application, especially as an eye ointment. Because of its importance in the treatment of human typhoid and the avoidance of resistant strains, its use in veterinary medicine has been severely restricted, particularly in food-producing animals.

In human medicine, poisoning by chloramphenicol has led to aplastic anaemia, skin eruptions, and moniliasis. There are three main side-effects: allergy or hypersensitivity to the drug; damage to the blood or bone-marrow; and gastrointestinal upsets.

Intramuscular injections of chloramphenicol are painful.

Chlorate
Sodium or potassium chlorate has been added to feed in order to reduce the numbers of *Salmonella* spp. in poultry. In Texas incidence of *Salmonella* spp. in turkeys fell from 35 per cent to zero and in broilers from 37 per cent to 2 per cent. High doses are toxic (see below).

Chlorate Poisoning
In acute cases cattle may die after showing signs suggestive of anthrax. In subacute cases, a staggering gait, purgation, signs of abdominal pain, and red-coloured urine may be seen. Cyanosis and respiratory distress are also signs.

Treatment Gastric lavage. If cyanosis is present, methylene blue should be given intravenously.

Chlordane
A highly toxic insecticide of the chlorinated hydrocarbon group. It is volatile and poisoning through inhalation may occur.

Chlorfenvinphos
An organophosphorus acaricide and insecticide. It has been used in sheep dips, etc. and against fly strike, keds, lice and ticks. Less toxic compounds are now preferred.

Chlorhexidene
Chlorhexidene gluconate is widely used as an antiseptic and surgical scrub; and in teat dips, sprays and udder washes. It is used as a shampoo to treat MALASSEZIA skin infect ions in dogs.

Chloride (Cl)
A negatively charged ANION. It can be found in many chemicals such as hydrochloric acid, and common salt (sodium chloride). It is important in acid-base, fluid balance within and outside cells and in the transmission of nerve impulses. It is calculated when determining the DIETARY CATION-ANION BALANCE for the TRANSITION COW.

Chloride Cells
Cells on the gills of marine fish responsible for the extra-renal excretion of chloride in hypo-osmotic fish, which swallow sea water. Damage or disease of these gills in such fish can have more significant implications than interference with oxygen supply.

Chlorinated Hydrocarbons
These insecticides include: chlordane, DDT, DDD, methoxychlor, BENZENE HEXACHLORIDE, toxaphene, aldrin, dieldrin, isodrin, and endrin plus a range of others less well known. Ingested at toxic levels, or absorbed through the skin, they act primarily on the central nervous system causing excitement/frenzy at the outset followed by muscular tremors leading to convulsions in acute cases. Species capable of vomiting do so. Loss of appetite with marked loss of body weight is usual in subacute poisoning. Cats are especially susceptible. Wash off any residues from the skin and keep the animal warm, comfortable and sedated.

Most compounds – methoxychlor is an exception – can be stored in the body fat and excreted in the milk and so may constitute a public health problem. Their use in animals is now minimal because of the residue levels caused by this persistence.

Chlorine
Chlorine has been used to treat washing water in slaughterhouses to reduce the presence of pathogens.

Chloroform
Chloroform is a colourless, mobile, non-inflammable liquid, half as heavy again as water. It is much less used now than formerly as a general anaesthetic. (See ANAESTHESIA, GENERAL; EUTHANASIA.)

Four stages of chloroform anaesthesia are recognised:

VetBooks.ir

1. The stage of excitement begins immediately the drug is administered. Vigorous animals struggle violently, and when in the standing position may rear or strike out with their forefeet and shake their heads in an endeavour to dislodge the mask. Deep breaths are taken often in a gasping manner, and in from 3 to 6 or 7 minutes the second stage follows.
2. The stage of depression follows the stimulation stage, and is marked by a quieting of the movements of the voluntary muscles, by a lessening of the force and volume of the pulse, and by slower and deeper breathing. Pain is still felt and, if inflicted, induces reflex movement.
3. The stage of anaesthesia produces complete muscular relaxation and unconsciousness. This is the safe or operating stage; all the centres of the brain are subdued except those that govern respiration and heart action.
4. The stage of paralysis occurs when the anaesthetic is pushed beyond the safe stage. The centres of respiration and heart action, in common with all the other nervous centres, become paralysed. The heart stops beating about 2 minutes after respiration ceases, and any attempts at ARTIFICIAL RESPIRATION must be prompt.

Chlorophyll, Chlorophyl

A group of green pigments found in most plants, algae and CYANOBACTERIA. The pigments are magnesium-PORPHYRIN complexes used in photosynthesis. They are concerned with plant respiration absorbing energy from light and producing oxygen from carbon dioxide. Water-soluble chlorophyll derivatives have been used in oral preparations to deodorise alimentary ulcerative lesions, faeces, urine, and others have been applied topically to deodorise skin lesions. Chlorophyll in herbivores' alimentary tracts produces a degradation product PHYLLOERYTHRIN which is mainly excreted in the bile, but can enter the circulation and cause PHOTOSENSITISATION.

Chlortetracycline

A TETRACYCLINE antibiotic mainly used topically as an ophthalmic ointment powder or spray. An oral powder form was licensed for adding to calf milk feeds until supplies ended in 2009. An alternative product was allowed to be used under special dispensation of the VMD. However it began to be prescribed for routine treatment of calves and so the dispensation was withdrawn 1 January 2013. Chlortetracycline could then only be used under the 'CASCADE', ideally imported from other Member States where authorised for use and under a SPECIAL IMPORT CERTIFICATE. It was not to incorporated in milk replacer but added when the feed was being prepared.

Chlosoma anatis

A protozoan parasite primarily of ducks but also turkeys. Treatments include a plant-derived product called Natustat, which is given to reduce intestinal lesions and improve performance in infested flocks.

Chocolate Poisoning

The feeding of waste chocolate bars to cattle has led to fatal poisoning in calves in the UK. The animals showed excitement, stared about in all directions, walked with exaggerated strides, and had convulsions.

It was suggested that the caffeine content would account for the excitement; the theobromine content may have caused heart failure. In dogs, poisoning follows feeding particularly of 'real dark chocolate' and also over-engorging on stolen sweets or Christmas decorations.

In dogs, the signs include panting, vomiting, thirst, diarrhoea, excitement, fits, coma.

Treatment Use of an emetic or gastric lavage. (Activated charcoal is used in human medicine.) For control of the convulsions, diazepam is among the suitable drugs.

Autopsy findings include cyanotic mucous membranes, swollen and reddened gastric mucosa.

(See also COCOA POISONING; THEOBROMINE.)

'Choking', Obstruction of Pharynx or Oesophagus

'Choking' is, by dictionary definition, an obstruction to respiration, but in a farming context the word has been misused to denote an obstruction to the passage of food through the pharynx and oesophagus, either partial or complete.

The domesticated animals, especially cattle and dogs, are very prone to attempt to swallow either foreign bodies or masses of food material too large to pass down the oesophagus (gullet), with the result that they often become jammed. Such substances hinder the free passage of solid or fluid food, give rise to pain and discomfort, and are very often attended by serious and even fatal consequences. Choking in cattle, dogs, and cats is usually due to a hard, large, sharp-pointed, or irregularly shaped object; while in the horse it is most often due to a mass of dry impacted food material, or to a portion of a mangold or turnip.

Cattle Choking is of comparatively common occurrence, particularly in districts where roots are fed whole to the animals, and where there is a quantity of rubbish scattered about the pastures.

Signs The animal immediately stops feeding, and becomes uneasy. A feature of nearly all cases of

choking in cattle is the rapidity with which gas formation occurs in the rumen. (See BLOAT.)

In a number of cases of choking, relief occurs quite spontaneously after the lapse of from 30 minutes to two or three hours from the origin of the signs. This is because the muscles of the gullet, which have been tightly gripping the obstruction, gradually become fatigued and relax, thereby allowing the object to pass down into the stomach. Naturally, such a satisfactory termination cannot occur wherever there is a sharp projecting point on the object causing the obstruction, but it frequently happens with eggs, apples, potatoes, and other smooth bodies.

First-Aid In all cases of choking, no matter how simple they appear to be, the owner should seek veterinary assistance as soon as possible.

Professional treatment depends on the site of the obstruction. This may be palpable in the oesophagus and manipulation up to the mouth may be possible after giving hyoscine hydrobromide or hyoscine butyl bromide (Buscopan; Boehringer) as a muscle relaxant. If in the intestine, passage of a probang or stomach-tube down the oesophagus may dislodge the obstruction; if not, it can be removed by rumenotomy or a trocar can be inserted into the rumen; in many cases, the blockage will reduce by maceration over three to four days.

Horses The horse is less often choked than the cow, but owing to the long and narrow equine oesophagus, the accident is more serious.

Treatment Avoid raising the head or giving drenches, lubricating or otherwise. It is imperative to secure professional assistance at once.

Dogs and cats The most commonly recorded objects causing choke in dogs are pieces of bone. Other materials found include gristle (pieces of cartilage), fish hooks and balls.

Signs At first there is usually a sudden pain, which causes the animal to cry out. If it has been feeding it immediately ceases, and becomes very restless. It may paw at its mouth. Salivation is often profuse.

When a threaded needle has become fixed in the throat or below it, the end of the thread may often be seen.

Treatment Swallowed objects which become jammed in a dog's oesophagus can be treated in one of two ways: surgically or conservatively. The latter includes the use of an endoscope, passed into the oesophagus and enabling the foreign body to be grasped with forceps and drawn out or, alternatively, pushed down into the stomach, whence it can, if necessary, be removed. Pieces of grass have been implicated in choke in rabbits following anaesthesia when the oropharynx has not been inspected following induction of general anaesthesia – a difficult procedure.

A young African elephant died from obstruction of its oesophagus by an apple.

Cholagogues
Cholagogues are substances reputed to act on the liver, increasing the secretion of the bile.

Cholangiocarcinoma
Cancer of the bile ducts; it is associated with liver-fluke infestation of animals in Thailand.

Cholangiohepatitis
Inflammation of bile ducts and associated liver parenchyma.

Cholangioma
A benign tumour originating from the bile ducts, and occurring in cats, dogs, sheep, and poultry. It can be caused by AFLATOXINS.

Cholangitis
Inflammation of the intra-hepatic bile ducts.

Cholecalciferol
This is the form in which vitamin D is used in pharmaceutical preparations.

Cholecystitis
Inflammation of the gall-bladder.

Cholecystography
Cholecystography is the term used for X-ray examination of the gall-bladder after its contents have been rendered opaque by administration of lipiodol or pheniodol compounds.

Cholecystokinin
A hormone produced in the small intestine and causing emptying of the gall-bladder.

Cholecystomy
A surgical incision into the gall-bladder.

Cholera, Fowl
(See FOWL CHOLERA.)

Cholesteatoma
An epidermoid cyst within the middle ear cavity, complicating simple otitis. It can be the result of chronic otitis or intermittent otitis. The tympanic membrane ruptures resulting in epithelial cells entering the middle ear and forming a mass, which

VetBooks.ir

can be removed surgically. It is rarely seen in dogs, although it has been reported in gerbils where there is a head tilt and ALOPECIA between the ears.

Cholesterol
A sterol present in blood, brain and other tissues, bile, and many foods. It is produced in the liver and adrenal glands; it decreases in cows with fatty liver.

A high cholesterol level can be a precursor to high blood pressure, ATHEROMA and THROMBOSIS.

Cholesthiasis
(See GALLSTONES.)

Choline
Choline is an amine compound with important functions in the metabolic process. It is found in egg-yolk, liver, and muscle, and is associated with the vitamin B complex. It is also a key component of cell membrane phospholipids, a lipotrophic agent in fat utilisation and a methyl group donor in reactions involving METHIONINE, FOLIC ACID, CYANOCOBALAMIN, glycine and serine. Acetyl choline is essential for the transmission of an impulse from nerve to muscle.

Cholinesterase
Cholinesterase is an enzyme which inactivates acetylcholine. Some poisons, such as carbamates and organophosphates, cause cholinesterase inhibition, and it is inactivated by a substance occurring in white clover.

Chondritis
Inflammation of cartilage.

Chondrocytes
Cartilage-forming cells.

Chondrodystrophy, Chondrodystrophia
This is a disorder in cartilage formation.

Chondrogenesis
(See BONE, DISEASES OF - GROWTH-PLATE DISORDERS.)

Chondroitin Sulphate
A substance found in body tissues in combination with protein which is important in cartilage formation and in healing fractures and wounds. Deficiencies of VITAMINS A, C, growth hormone (see SOMATOTROPIN) and THYROXINE impair the formation of chondroitin sulphate.

Chondroma
A rare tumour, composed of cartilage-like cells, which has been seen in dogs, rats, and mink.

Chorea
Twitching or trembling caused by a succession of involuntary spasmodic contractions (clonic spasms) affecting one or more of the voluntary muscles. The spasm is of a rhythmic nature, occurring at fairly regular intervals, and between the individual contractions relaxation of the affected muscle takes place.

The condition affects dogs almost exclusively, although muscular spasms of a similar nature have been seen in horses, cattle, and pigs. In lambs, congenital chorea is described under 'BORDER DISEASE' OF SHEEP. (See also 'SHIVERING'.)

Causes In dogs, chorea generally follows a mild attack of distemper. It may appear within a few days after apparent recovery, or its appearance may be delayed. All dog owners would be well advised to regard cases of distemper as not cured until the lapse of at least 10 days after apparent recovery, and during this period to continue to treat the animal as though it were still sick, so far as exercise is concerned.

Signs Twitchings usually begin about the lips and face, or in the extremities of one or more limbs. Later, perhaps the whole head is seen continually nodding or jerking backwards and forwards, quite irrespective of the pose or position of the animal. As the condition progresses, there comes a time when it is unable to rest, loss of condition and weakness result, and the dog becomes exhausted. Ulceration of the affected limb, as the result of continual friction with surrounding objects, the ground, etc., is not uncommon. Chorea is always a serious condition.

Treatment is with ANTISPASMODICS.

Chorion
Chorion is the outermost of the three fetal membranes, the others being the amnion and the allantois. The chorion is a strong fibrous membrane, whose outer surface is closely moulded to the inner surface of the uterus. Chorionic villi are the vascular projections from the chorion which are inserted into the crypts of the uterine mucous membrane. (See also PARTURITION.)

Chorionic Gonadotrophin
(See HORMONE THERAPY.)

Choroid, Chorioid
Choroid, or chorioid, is the middle of the 3 coats of the EYE, and consists chiefly of the blood vessels which effect nourishment of the organ.

Choroiditis
Inflammation of the choroid.

Chow Chow
A stocky, medium-sized dog with a thick coat; the tongue is blue-black in colour. Originally bred in China for meat, the breed specification still reads as if that were its main purpose. They tend to be a 'one person' dog. Entropion and muscle spasm (myotonia) may be inherited.

Christmas Rose
(See HELLEBORES.)

Chromium (Cr)
A trace element in animal nutrition; as the organic form, chromium tripolinate, it has a beneficial effect on growth reproductive performance and stress control. Chromium is necessary for a proper functioning of insulin; it is a catalyst in some enzyme reactions and enhances the glucose utilisation rate of the liver.

Chromobacter Violaceum
An organism, often regarded as non-pathogenic, which has caused a fatal pneumonia in pigs in the USA.

Chromodactyorrhoea
A condition in rats and mice in which a reddish-brown oversecretion from the Harderian gland can be seen running from the eyes. The condition is caused by stress, and removal of the stress is the only treatment.

Chromomycosis
A fungal disease of amphibians characterised by nodules and/or grey papules on the skin. Ulceration may occur later. The disease can become systemic with granulomata in internal organs; treatment should begin as soon as infection is seen. Antifungal medicines are used in treatment.

Chromosomes
Minute bodies, within the nucleus of cells, which carry the genes, and are composed largely of DNA. The number of chromosomes is constant for any given species. (See under GENETICS, HEREDITY AND BREEDING.) The haploid number (n) represents the basic set found in the gametes, i.e. egg and sperm. The diploid number (2n) represents paired basic sets, one set from the sire, the others from the dam, and this number is found in all somatic cells.

(See also under CYTOGENETICS for chromosome abnormalities; and PLASMIDS.)

Chronic
A condition that persists for a long time. There is no definition of the period: it is usually implies a period of over a week but it may indicate a long lasting condition. The antithesis is ACUTE.

Chronic Degenerative Valvular Heart Disease (CDVHD)
The most common heart disease in dogs. Usually with suitable therapy dogs remain alive for many years, although those that develop CONGESTIVE HEART FAILURE may die within a year. (See also HEART DISEASES.)

Chronic Nephritis
(See KIDNEYS, DISEASES OF.)

Chronic Obstructive Pulmonary Disease (COPD)
A name for an allergic non-infective disease of horses affecting principally the lower airways of the respiratory system; it is now called RECURRENT AIRWAY OBSTRUCTION (RAO). It seems that *Micropolysporum faeni*, hay dust, and food mites are all potentially involved in causing COPD, which – in one survey – was found to have a higher incidence in stables with much ammonia and dust particles in the air. Dyspnoea is worse at night, as is the case with human asthma. The disease is also seen in goats, when it is called 'winter cough'.

Chronic Respiratory Disease (CRD)

Poultry Chronic respiratory disease is a complex problem in poultry. The signs include noisy breathing (rales), coughing and nasal discharge. It is usually set off by infectious bronchitis virus and if the birds also carry *Mycoplasma gallisepticum* the condition can be severe. Strains isolated from chickens and turkeys can be resistant to macrolides antibiotics. Further infection by strains of *E. coli* usually follows and air sacculitis may develop.

Treatment is by administering an antibiotic by injection in severe cases, or by addition to the drinking water.

Rats Chronic respiratory disease in pet rats is very difficult to treat as often the animals are kept in an insufficiently ventilated environment. There are many bacteria and viruses involved, all of variable virulence, so all that can be hoped is to achieve alleviation of clinical signs by appropriate antibiotic treatment, often without total resolution.

Chyle
The milky fluid which is absorbed by the lymphatic vessels of the intestine. The fluid mixes with the lymph and is discharged into the thoracic duct. (See LYMPH; DIGESTION, ABSORPTION AND ASSIMILATION.)

VetBooks.ir

Analysis of chyle can be helpful in the diagnosis of several diseases of the abdomen.

Chyloperitoneum
The presence of chyle in the peritoneal cavity.

Chylothorax
The presence of pleural fluid identifiable as chyle, following injury to, or a tumour of, the thoracic duct. Treatment consists of repeated drainage. The condition has been recorded in cats and dogs.

Chyme
Chyme is the partly digested food passed from the stomach into the first part of the small intestine. It is very acid in nature, contains salts and sugars in solution, and the food constituents in a homogenised semi-liquid state.

Chytridiomycosis
A condition caused by the fungus *Batrachochytrium dendrobatidis* which affects frogs and toads. Most cases are found dead, but occasionally there is ERYTHEMA and brown shedding of skin. It causes defects in the oral disc in tadpoles. Chytridiomycocis is a serious disease which can destroy a population. Pollution may be important in causing immunosuppression. The fungus can be carried in water to captive collections.

Cicatrix
Cicatrix is a scar.

CID
Abbreviation of COMBINED IMMUNODEFICIENCY (CID). (See SEVERE COMBINED IMMUNODEFICIENCY.)

Cilia
This term covers both the eyelashes, and the microscopic hair-like projections from the cells of the mucous membranes lining the larynx and trachea. The rhythmic beating of cilia moves fluid over the cell surface.

Ciliary Apparatus
This is part of the UVEA and involves the ciliary muscles used in ACCOMMODATION of the eye. The ciliary processes radiate from the ciliary muscle and provide attachments for the ligaments that support the LENS OF THE EYE. It is also often referred to as the CILIARY BODY. (See EYE.)

Ciliary Body
A thickened vascular part of the CHOROID of the eye which connects the IRIS and the CHOROID. It contains the ciliary muscle and the ciliary processes. It is also called the CILIARY APPARATUS. (See EYE.)

Ciliata
Ciliated protozoa are found in the alimentary canal of animals. (See BALANTIDIUM.)

Cimetidine
A drug used to control the vomiting associated with canine chronic gastritis. It provides only symptomatic relief, and it inhibits CYTOCHROME activity; the excretion of some drugs and other chemicals may be reduced. Absorption of drugs which require an acid environment may be impaired as cimetidine raises the gastric pH.

Cincophen
An anti-inflammatory medicine used in the treatment of osteoarthritis in dogs. It is used in conjunction with steroids and is prescribed with care since adverse reactions can occur if certain pathological conditions are present.

Circling Movements
Repetitive circling behaviour in an animal may be a sign of meningitis or encephalitis. (See BRAIN DISEASES.)

Circoviruses
These are the cause of, or are linked with, CHICKEN ANAEMIA VIRUS, COLUMBIFORM BEAK AND FEATHER DISEASE, POST-WEANING MULTISYSTEMIC WASTING SYNDROME, PORCINE DERMATITIS AND NEPHROPATHY SYNDROME and PSITTACINE BEAK AND FEATHER DISEASE.

Circulation of Blood
The veins of the whole body – head, trunk, limbs, and organs in the abdomen – with the exception of those in the thorax, convey their blood into one of the three great terminal radicles which open into the right atrium of the heart. This contracts and drives the blood into the right ventricle, which then forces the blood into the lungs by way of the pulmonary artery. In the lungs it is contained in very thin-walled capillaries, over which the inspired air plays freely, and through which the exchange of gases can easily take place. The blood is consequently oxygenated (see RESPIRATION), and passes on by the pulmonary veins to the left atrium of the heart. This left atrium expels it into the left ventricle, which forces it on into the aorta, by which it is distributed all over the body. Passing through the capillaries in the various organs and tissues it eventually again enters the lesser veins, and is collected into the cranial and caudal vena cava and the azygos vein (see VEINS), from where it passes to the right atrium once more.

In one part of the body there is, however, a further complication. The veins coming from the

stomach, intestines, spleen and pancreas, charged with food materials and other products, unite into the large 'portal vein' which enters the porta of the liver and splits up into a second capillary system in the liver tissue. Here it is relieved of some of its food content, and passes to the caudal vena cava by a second series of veins, joining with the rest of the blood coming from the hind parts of the body, and so goes on to the right atrium. This is known as the 'portal circulation'.

The circuit is maintained always in one direction by four valves, situated one at the outlet from each cavity of the HEART, and by the presence of valves situated along the course of the larger veins.

The blood in the arteries going to the body generally (i.e. to the systemic circulation) is a bright red in colour while that in the veins is a dull red; this is owing to the oxygen content of arterial blood being much greater than that of venous blood, which latter is charged with carbon dioxide. For the same reason the blood in the pulmonary artery going to the lungs is dark, while in the pulmonary veins it is bright red.

There is normally no connection between the blood in the right side of the heart and that in the left; the blood from the right ventricle must pass through the lungs before it can reach the left atrium. In the fetus, two large arteries pass out from the umbilicus (navel), and convey blood which is to circulate in close proximity to the maternal blood in the placenta, and to receive from it both the oxygen and the nourishment necessary for the needs of the fetus, while one large vein brings back this blood into the fetal body through the umbilicus again. There are also communications between the right and the left atria (the foramen ovale) and between the aorta and the pulmonary artery (the ductus arteriosus), which serve to 'short-circuit' the blood from passing through the lungs in any quantity. At birth these extra communications rapidly close and shrivel up, leaving mere vestiges of their presence in adult life. There are rare instances, however, in which one or more of the passages may persist throughout life.

In reptiles there is a different anatomical arrangement: there is only one ventricle (except for crocodiles in which there are two) and the oxygenated and deoxygenated are kept apart by pressure differentials.

Circulation of Lymph

(See LYMPH.)

Circumanal Glands

(See ANUS - ANAL GLANDS.) They are also called CIRCUMFERENTIAL GLANDS or PERIANAL GLANDS. Tumours are common and may be treated with PROGESTAGENS such as DELMADINONE ACETATE.

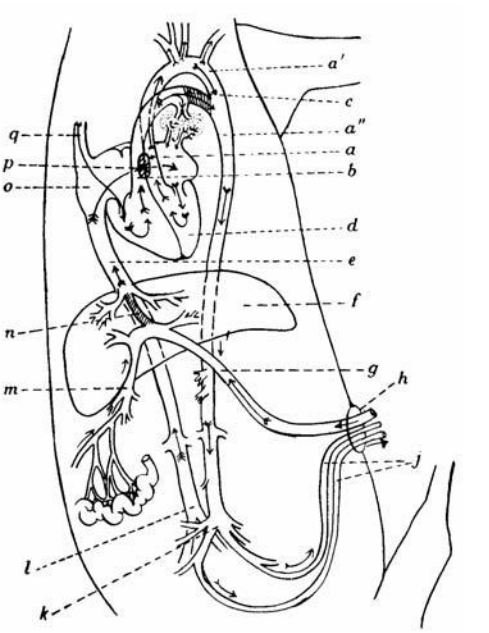


Diagram of fetal circulation. *a*, Origin of aorta; *a'*, arch of aorta; *a"*, posterior aorta; *b*, origin of pulmonary artery; *c*, the ductus arteriosus (shaded); *d*, left ventricle; *e*, caudal vena cava; *f*, liver; *g*, umbilical vein; *h*, the umbilicus; *j*, umbilical arteries; *k*, bifurcation of aorta; *l*, origin of caudal vena cava; *m*, portal vien; *n*, ductus venosus, which short-circuits blood from umbilical vien to vena cava without passing through liver; *o*, right atrium; *p*, foramen ovale (shaded); *q*, crania vena cava. (After Bradley, *Thorax and Abdomen of the Horse*.)

Circumferential Glands

(See ANUS - ANAL GLANDS; CIRCUMANAL GLANDS.)

Cirneco dell'Etna Dogs
(plural, Cirneci)

A small hound originating from Sicily to hunt rabbits; often called 'Sicilian greyhounds'. They weigh 10 kg to 12 kg (22 lb to 27 lb) and they are 43 cm to 51 cm (17 in to 20 in) in height. The dog has a tan or chestnut colour and large erect ears. It looks like a miniature PHARAOH DOG.

Cirrhosis, Fibrosis

Cirrhosis, or fibrosis, is a condition of various internal organs, in which some of the non-parenchymatous cells of the organ are replaced by fibrous tissue. The name 'cirrhosis' was first used for the disease as it occurs in the liver, because of the yellow colour, but it has been applied to fibrosis in the lung, kidney, etc. Classic instances of cirrhosis are seen in the liver in chronic ragwort poisoning in cattle, in chronic alcoholism in man, and in old dogs.

VetBooks.ir

CITES
Convention on Trade in Endangered Species of Wild Flora and Fauna. (See COUNCIL OF MINISTERS.)

Citric Acid Cycle
Also called KREB'S CYCLE and TRICARBOXYLIC ACID CYCLE.

Citrinin
A nephrotoxic mycotoxin, which also causes fissures in the gizzard.

Citrobacter Murliniae
A bacterium causing heavy losses (up to 45.5 per cent) in quail in the tropics with ducks less susceptible (9.4 per cent mortality) and low deaths in chickens (2.8 per cent). Affected birds show nasal discharges, diarrhoea, and a severe drop in egg production. Post-mortem examinations in chickens and quails show haemorrhagic enteritis and egg peritonitis; in ducks there is hepatomegaly, lung congestion and haemorrhages of the flanks.

Citronellol
An oil extracted from the citronella plant, which is incorporated into some topical fly repellants.

Citrullinaemia
This disease occurs in some Australian Friesian cattle; also in dogs. It is hereditary in origin, and due to a deficiency of the amino acid Citrulline. In calves depression, recumbency, and convulsions result.

Citrulline
An amino acid involved in stimulating the immune system. It detoxifies ammonia and metabolises arginine.

Citrus Pomice
An absorbent used in treating diarrhoea.

CJD
(See CREUTZFELDT-JAKOB DISEASE.)

CK
Creatine kinase.

CLA
An abbreviation for two very different entities: CASEOUS LYMPHADENITIS and CONJUGATED LINOLEIC ACID.

Classical Swine Fever
(See SWINE FEVER.)

Claviceps
A fungus (see ERGOT, FUNGAL).

Clavicle
Clavicle is another name for the 'collar-bone' in man. This bone is not present in the domesticated mammals (except sometimes in a very rudimentary form in the cat), but is present in birds. (See FURCULA.)

Clavulanic Acid
An inactivator of β-lactamase used in conjunction with PENICILLIN (including semi-synthetic penicillins – usually AMOXYCILLIN) to protect the antibiotic from inactivation.

Claws
(See NAILS.)

Clay Pigeons
Ruminants and outdoor pigs may eat these if found lying on pasture. The outcome can be fatal in pigs but in ruminants, chronic unthriftiness results as the material is digested only slowly. (See PITCH POISONING; LEAD POISONING.)

Clazuril
In racing pigeons, clazuril is given for the prevention and treatment of coccidiosis.

'Clean' Pasture
(See PASTURE, 'CLEAN'.)

'Cleansing'
(See PLACENTA.)

Cleft Cheek
A transverse facial cleft.

Cleft Palate
Cleft palate is a hereditary defect of the roof of the mouth, generally seen in puppies of the toy breeds that have been in-bred. It consists of a gap in the structures forming the hard and/or soft palates, often so extensive as to allow of communication between the mouth and the nasal passages. Puppies so affected are usually unable to suck, and die soon after birth unless given artificial feeding; others are able to obtain some small amount of nourishment, but never thrive as the rest of the litter. It is seen in certain breeds including AMERICAN COCKER SPANIELS, BEAGLES, BERNESE MOUNTAIN DOGS, BOSTON TERRIERS, BOXERS, BULLDOGS, BULL MASTIFFS, BULL TERRIERS, CHIHUAHUAS, DACHSHUNDS, ELKHOUNDS, GERMAN SHEPHERD DOGS, PEKINGESE and STAFFORDSHIRE BULL TERRIERS. Congenital cleft palate in rats and possibly puppies and kittens has been associated with excessive vitamin A intake by the dam in the first third of pregnancy.

The condition of 'HARE-LIP', or 'split-lip', is often associated with cleft palate. It also called

secondary cleft palate and paltoschisis. The palate may also be cleft as the result of violence; for example, it is commonly seen in the cat which has fallen from a considerable height.

Cleft palate in cattle is referred to under GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.

Clenbuterol Hydrochloride

A specific β_2 agonist, used as a bronchodilator in coughing horses; and to suppress contractions of the uterus in cows to aid obstetrics.

Clenbuterol has also a metabolic effect, and is an effective growth-promoter in beef cattle, increasing the volume of skeletal muscle (as well as heart muscle) and decreasing fat. The size of other organs is not increased, as is the case with anabolic steroids such as trenbolone acetate. However, their use as growth promoters is prohibited in food animals in the UK and some other countries.

Cleveland Bay Horses

Originally bred as carriage horses, and originating from Yorkshire, they stand between 16 to 17 HANDS high, are bay coloured and have clean (non-feathered) legs.

Climate Change

Animal involvement in climate change has begun to be appreciated. It will mean efforts will be made to ensure animals are productively using areas and not over-contributing to carbon outputs and greenhouse gas production. (See METHANE.)

Climate in Relation to Disease

(See entries under ENVIRONMENT; also TROPICS, LIVESTOCK PRODUCTION IN THE.)

Clindamycin

An antibiotic used in dogs and cats for the treatment of infected wounds, pyoderma, osteomyelitis and as supportive therapy during dental procedures. It is usually given by mouth; injections may also be used.

Clinical Sign

An abnormal appearance in an animal indicating illness. The synonym in man is 'symptom'.

Sometimes animals show subclinical signs (not detectable) but effects of disease may be seen as reduced production or an abnormal laboratory test, e.g. increased milk cell counts in dairy cows.

Clinodactyly

A congenital deformity with a permanent deflection, either LATERAL or MEDIAL, of one or more fingers or phalanges.

Clinoptilolite

A form of zeolite that can be added to animal feed at a level of about 5 per cent. It is an absorbent for water, carbon dioxide, ammonia and mercury.

Clipping of Dogs

These animals are usually clipped for medical reasons, such as to allow better dressing of the skin during treatment of mange. Some owners however, particularly of long-haired breeds, have their dogs regularly clipped at the beginning of the summer to rid them of long matted, or thick winter, coats. In addition to this, certain breeds are clipped for show purposes, such as the French poodle and the Bedlington terrier.

Clipping of Horses

The covering of hair over the body of certain of the domesticated animals is liable at times to interfere with health if allowed to grow unchecked, and accordingly it is customary to remove it at certain periods of the year; in horses the long winter coat, if left to grow, hinders efficient grooming and drying, prevents the skin from excreting waste products, and causes the horse to perspire more. (See also SHEARING.)

Methods Clippers work best when used against the flow of the hair, and should be thoroughly and frequently lubricated. It is of course essential that the blades should be sharp. For racehorses, carriage-horses, ponies, etc., it is usual to clip 'down to the ground', as it is called, i.e. all the hair is clipped from the body, legs, and face, the mane is 'hogged' (clipped short), and the tail is thinned. For saddle-horses a 'hunter's clip' is preferred; in this the hair is taken from the body, except for a patch on the back which corresponds with the outline of the saddle ('saddle-patch'), and the legs, which are left covered with hair below the level of an oblique line running across the middles of the fore-arms and gaskins. The mane is hogged, and the tail is thinned and cut straight across about a hand's-breadth above the level of the points of the hocks.

Times for Clipping The time for clipping horses varies according to the weather, but should take place as soon as the winter coat has 'set', i.e. as soon as the summer coat has been fully cast off and the winter coat is well grown. It usually happens that in an ordinary autumn this condition is fulfilled about the end of October and the beginning of November, but in some years it is earlier and in some later. Sometimes horses are clipped twice during the winter, once before Christmas and once some time after; but this is only necessary in animals which have a luxuriant growth of hair.

VetBooks.ir

Precautions Never clip a horse suffering from a cold or other respiratory trouble. Never clip during excessively severe weather. Always provide a rug when standing outside for the first week or 10 days to allow the heat-regulating mechanism to become accustomed to the more rapid radiation of heat from the body surface. Thoroughly dry a newly clipped horse after coming into the stable in wet or snowy weather, by means of straw or hay wisps. Do not allow newly clipped horses to stand in draughty places in a stable without protection. Give extra bedding for a few days after clipping. Give an extra ration of hay and oats to recently clipped horses to make good the loss of heat occasioned.

Clipping of Sheep

(See SHEARING; CLOTHING OF ANIMALS.)

Clitoris

Clitoris is the small organ composed of erectile tissue, situated just within the lower commissure of the vulva. It is the homologue of the penis.

Clitoral sinusectomy The RCVS has ruled that veterinary surgeons who are asked to carry out clitoral sinusectomies on mares which are destined for export to the United States can be clear that they will not be held to be acting unethically, even if, at the time of the performance of the operation, there is no evidence that the mare is infected with the CEM organism (see EQUINE VIRAL ARTERITIS).

It is contended by the United States Department of Agriculture that clitoral sinusectomy:

(a) could show up, on the subsequent culturing of the excised material, that CEM was present when swabbing proved negative;
(b) when accompanied by the prescribed follow-up treatments would eliminate the CEM organism if it was present; and
(c) was the method by which CEM outbreaks in Kentucky had been eliminated.

Enlargement of the clitoris may occur in bitches treated with androgens for the suppression of oestrus.

Cloaca

In birds and lower vertebrates the alimentary, urinary and genital systems have a common outlet; this is the cloaca. When an egg is laid, however, the alimentary outlet is closed, reducing the risk of shell contamination with enteric bacteria. (See VENT GLEET.)

Cloacal Atresia

The absence of an opening in the cloaca which may be seen in neonatal cage birds. It usually corrected surgically.

Cloacal Prolapse

The external protrusion of the cloaca. The prolapse may involve the intestinal, genital or urinary tracts – even all three. It is usually due to dystokia in birds and chelonians and to parasitism in lizards. It can be idiopathic in cockatoos. The condition often requires surgical correction.

Clomipramine

A drug used in conjunction with behaviour therapy in dogs (separation anxiety). It is used with caution as some pathological conditions (including EPILEPSY, cardiovascular dysfunction (see HEART DISEASES), CONSTIPATION, urine retention, narrow angle GLAUCOMA) can result in adverse effects.

Clones

A group of cells derived from a single cell by mitosis. (See CLONING.)

Clonic

Clonic is a word applied to spasmodic movements of muscles lasting for a short time only.

Cloning

A technique whereby genetically identical animals can be produced. The first sheep produced by transfer of the nucleus from cells from the mammary tissue of adult sheep was produced at Roslin Institute in 1997. The cell nucleus was transferred to an ovum from which the nucleus had been removed and which was then implanted into a surrogate mother. After a normal pregnancy the ewe produced a lamb genetically identical to the sheep from which the mammary cells were taken. The 'age' of a cloned sheep has been questioned. The original cloned sheep had aged centromeres in her cells from birth and developed arthritis at a younger age than normal.

A similar technique has been developed by the same workers to produce transgenic lambs containing therapeutic proteins which can be collected from the sheep's milk, a technique which it is believed will have important implications for the production of human medicines.

Rats, calves, cats and rabbits have all been successfully cloned.

Clopidal

A drug used to prevent or control coccidiosis in chickens, guinea fowl and rabbits.

Cloprostenol

A prostaglandin analogue, used for induction of oestrus or pregnancy termination in horses and in cattle. In the latter it is also used for endometritis, pyometra and removal of a mummified fetus. In pigs, it is used for induction of parturition. (See CONTROLLED BREEDING.)

Closantel
An antiparasitic drug. Among its applications are the treatment and control of fascioliasis, nasal bots (*Oestrus ovis*) and the barber pole worm (*Haemonchus contortus*) in sheep.

Closed-circuit Anaesthesia
(See ANAESTHESIA, GENERAL - ENDOTRACHEAL ANAESTHESIA.)

Clostridial Enteritis, Enterotoxaemia
Clostridial enteritis, or enterotoxaemia, is a cause of sudden death in cattle. The deaths usually, though not invariably, occur shortly after calving. The animal, usually one, is found dead. Where death is not immediate, 'milk fever' may be suspected, but the elevated temperature at once rules this out. The cow may be in considerable pain before succumbing. On post-mortem examination, acute inflammation of the intestine is found – such as might be expected with some types of poisoning. This enteritis is associated with the presence of a toxin, difficult to demonstrate in the laboratory, produced by the organism *Clostridium welchii* type A. The same condition may account for the sudden death of pigs. *Cl. oedematiens* may likewise be a cause of sudden death in sheep, pigs, cattle, goats and camelids.

Clostridial Myositis
(See BLACK-QUARTER; GAS GANGRENE.)

Clostridium spp.
A genus of anaerobe spore-bearing bacteria of ovoid, spindle, or club shape. They include *Cl. tetani*, *Cl. perfringens* (formerly *welchii*), *Cl. haemolyticum* (also called *Cl. novyi* type D); *Cl. oedematiens*, *Cl. septicum*, *Cl. botulinum* and *Cl. difficile* (a possible pathogen of piglets, especially if receiving antibiotics, and associated with enteritis). *Cl. chauvoei* may cause pericarditis and meningitis, as well as BLACK-QUARTER in cattle (and sheep). (See CLOSTRIDIAL ENTERITIS; TETANUS; LAMB DYSENTERY; BRAXY; BOTULISM.) Vaccination is an effective control and is often a prerequisite for survival of sheep. In cattle, goats and camelids vaccination for some specific diseases may be necessary.

Cl. perfringens caused the sudden death from enterotoxaemia of 18 cats, aged 2 months to 3 years, in Saudi Arabia. They died within a few hours of scavenging on chicken remains, which caused vomiting and diarrhoea. *Cl. perfringens* also causes NECROTIC ENTERITIS IN CHICKENS, which has become a problem since the withdrawal of antibiotic growth promoters. It also causes downgrading of carcases at processing plants. *Cl. perfringens* type A has been isolated from JEJUNAL HAEMORRHAGIC SYNDROME in adult cattle as have fungi.

Clothing of Animals
As a general rule, only cows, horses and dogs, of the domesticated animals, are supplied with clothing. Sheep already possess protection in the form of wool sufficient except in severe weather on the uplands, although plastic and fabric coats may be used to prevent hypothermia in lambs; while pigs carry a deep layer of subcutaneous fat.

Horses Horses require clothing for the following reasons: (1) to provide protection against cold, chills, draughts, and sudden lowering of the temperature; (2) to protect parts of the body from bruises and abrasions, such as might occur while travelling by road, rail or on board ship; (3) to afford protection from sudden showers of rain or snow when at work in the open. For the latter purposes, waterproof sheets lined with woollen fabric on the inside are usually used.

Cattle Formerly, it was only for sick cattle, and for use at agricultural shows and upon similar occasions, that clothing was provided for cattle, but some cows may wear coats. A large quarter-sheet, kept in position by a surcingle (girth band) is commonly employed. An ordinary horse-rug serves the purpose, but the buckle at the neck should never be fastened for cattle.

Sheep Jute coats for ewes were designed and introduced by William Wilson, a Carlisle farmer, who found them economic in his flock in severe weather on the Pennines. The idea is for the coats to be worn from mating to lambing. Five stitches secure the coat. Rugs or coats of man-made fibre have been used in Australia to protect the fleeces of sheep, and have proved economic, since buyers have paid more for the wool. Plastic coats have been used for lambs in the UK.

In Australia an estimated 800,000 sheep die each year during the first fortnight after shearing. Many of the deaths are associated with cold, wet, windy weather. The use of plastic coats during this period has saved many lives.

Head caps have been found to give good and sometimes complete protection against the headfly in the UK.

Dogs For the dog a coat made of woollen fabrics which wraps round the body and buttons or straps together is often used. Dog-coats or rugs are made according to various patterns, but whatever variety is selected should provide protection for the front and under part of the chest, as well as for the sides of the body. The elaborate garments which are used for coursing greyhounds and whippets are excellent articles of clothing, and may be copied with advantage for other breeds of dog.

VetBooks.ir

Clotting of Blood

This is a very complex process, and an obviously important one since on it depends the natural arrest of haemorrhage.

The jelly-like clot consists of minute threads (filaments or fibrin), in which are enmeshed red blood corpuscles, white blood cells, and platelets.

When the injury giving rise to the bleeding occurs, thromboplastin is released from the damaged tissue and from the platelets, and reacts with circulating PROTHROMBIN and calcium to form thrombin. This reacts in turn with circulating fibrinogen to produce the fibrin.

The above, however, is only a part of the story, for several other factors are involved. For clotting to take place, adequate vitamin K is necessary; prothrombin supply being dependent on this vitamin.

Clotting time varies in different species and under different degrees of health, but normally it takes between 2.5 and 11 minutes after the blood is shed. After some hours the fibrin contracts and blood serum is squeezed out from the clot.

Clotting may be inhibited by anticoagulants, such as heparin, dicoumarol and warfarin. In cases of haemophilia, a disease from which some dogs suffer, clotting is also inhibited. (See CANINE HAEMOPHILIA.)

'Cloudburst'

'Cloudburst' is a colloquial name for false pregnancy in the goat which, after an apparently normal gestation, suddenly voids from the vulva a large quantity of cloudy fluid – after which the size of the abdomen returns to normal. 'Cloudburst' is a fairly common condition.

Clover

A protein-rich pasture herb. (See INFERTILITY; BLOAT; LEYS, NEW; SILAGE; PASTURE MANAGEMENT.

Cloxacillin

A semi-synthetic penicillin resistant to penicillinase (beta-lactamase). It is mainly used in the treatment and prevention of mastitis.

Clubbed Down

An abnormality of the down of newly hatched chicks and poults in which the ends of the down are shaped like clubs. It is caused by a deficiency of riboflavin in the breeder flock.

Club Foot

(See TALIPES.)

Clumber Spaniel

A stockily-built spaniel in which euryblepharon (sagging eyelids) may be inherited. It also suffers from PYRUVATE DEHYDROGENASE PHOSPHATASE DEFICIENCY. A DNA test is available.

Clun Forest Sheep

An upland sheep breed developed in the Clun Forest, Shropshire, first mentioned in 1803. It is hardy and a good forager. It has a short- to medium-length coat with a dark brown face and lower limbs; the fleece (3 kg to 4 kg) does not contain any dark hairs. It is used for wool, meat and milk to make cheese.

Clydesdale Horses

A breed is a draught horse, classified as a HEAVY HORSE, and normally stand 16 to 18 HANDS high. They are normally bay in colour with extensive white markings and have feathered legs. They are renowned for their quiet, kind temperament.

Cnemidocoptiasis, Knemidocoptiasis

Infection of birds with *Cnemidocoptes* mites such as *Cn. mutans* which causes 'SCALY LEG' in poultry and *Cn. pilae* causing 'SCALY BEAK' or TASSEL FOOT. Some endectocides can be used successfully but in off-licence use. (See MANGE; MITES, PARASITIC.)

CNS

(See CENTRAL NERVOUS SYSTEM.)

Coagulation Necrosis, Coagulative Necrosis

Dead tissue which keeps its structure, remains firm but is more dense than the surrounding tissue. (See also LIQUEFACTION NECROSIS.)

Coat Colour

There are DNA tests for coat colour in many breeds of cats and dogs.

Coat Colour Change

(See CUSHING'S SYNDROME.)

Coat Length

There are DNA tests for coat length in many breeds of cats and dogs.

Cob

A cob is a short-legged horse, suitable for saddle work of a prolonged but not rapid nature; also used for light trade-carts. Cobs generally stand from 13.5 to 14.5 hands (1.35 m to 1.45 m) high.

The word 'cob' is also used for cubes made from unmilled dried grass.

Cobalamin

A complex containing COBALT, found in all members of the VITAMIN B12 group.

Cobalamin Malabsorption

Failure to absorb VITAMIN B12. It is seen as a genetic defect in the GIANT SCHNAUZERS. A DNA test is available.

Cobalt

Cobalt is one of the mineral elements known to be essential for health, but only required in minute amounts – a trace element. Its function is to act as a catalyst in the assimilation of iron into haemoglobin in the red blood corpuscles. Cobalt is essential to the synthesis of cyanocobalamin (vitamin B_{12}) and a lack of it leads to a deficiency of this vitamin. (See BUSH SICKNESS; 'PINING'; ANAEMIA; TRACE ELEMENTS; MOLYBDENUM.)

Cobalt deficiency occurs most frequently in parts of Scotland, Northumbria, Devon, and North Wales. Affected sheep may show signs such as progressive debility, anaemia, emaciation, stunted growth, a lustreless fleece, and sunken eyes from which there is often a discharge, with a mortality of up to 20 per cent.

However, signs are seldom as definite and clear-cut as the above description might suggest, and in many flocks a 'failure to thrive' is all that is observed or suspected. Sometimes poor performance comes to be accepted as normal, and yet could be remedied by preventive measures after soil analyses had indicated a cobalt deficiency.

Nowadays, 0.25 parts per million of cobalt in the soil is regarded as an acceptable level; and 0.17 ppm as constituting a deficiency.

In a comparison of two methods of treatment – the administration of a single cobalt 'bullet', and two doses of cobalt chloride – both appeared to have been equally effective in alleviating the deficiency as judged from the liveweight response of the lambs. Treatment by cobalt bullet was, however, more effective in increasing and, more importantly, in maintaining serum vitamin B_{12} (closely related to cobalt) than was the cobalt-dosing regime.

Poisoning Overdosage must be avoided. Twelve beef stores on cobalt-deficient land died when they were not only offered a cobalt supplement in boxes, but drenched as well with cobalt sulphate 'measured' by the handful. (See also under TRACE ELEMENTS.)

Cocaine or Coca

Coca leaves are obtained from two South American plants, *Erythroxylon coca* and *Erythroxylon bolivianum*, and contain the alkaloid cocaine. This acts as a local anaesthetic by paralysing the nerves of sensation in the region to which it is applied. It has now been displaced by synthetic local anaesthetic agents which are less toxic.

Coccidian Parasites/Diseases

(See COCCIDIOSIS; ENCEPHALITOZOON CUNICULI; *Hammondia hammondi*; SARCOCYSTIS; TOXOPLASMOSIS.)

Coccidian life-cycle The oocyst is passed in the faeces. It consists of the zygote, which results from the union of the male and female elements, enclosed within a protective membrane or cyst wall. On the ground and in the presence of moisture, oxygen and a suitable temperature, development proceeds. The zygote splits into two or four sporoblasts (depending upon the genus), each of which becomes enclosed in a capsule to form oval sporocysts. The contents of each sporocyst divide into four (or two) sporozoites. Once this process of sporulation is completed, the oocyst is 'ripe' and capable of infecting a host; unsporulated oocysts are not infective. When ripe oocysts are swallowed by a suitable host, the action of the digestive juices on the cyst walls allows the motile sporozoites to escape and each penetrates an epithelial cell. Here each parasite increases in size and finally becomes a large rounded schizont. This divides into a number of small elongated merozoites which, escaping from the epithelial cell into the gut, attack new cells, and the process is repeated. The massive feeding stage in the cell before it starts dividing is called a trophozoite, and is usually a young schizont. Under certain conditions, however, some trophozoites develop into large female forms or macrogametocytes which, when mature, become macrogametes. Meanwhile certain other trophozoites develop into male cells or microgametocytes, which divide into a number of small microgametes. One of these unites with each macrogamete, and the resulting cell is called the zygote. The fertilised macrogamete, or zygote, then secretes a thick capsule around itself, forming an oocyst which is discharged into the lumen of the organ intestine or bile-duct and thus escapes from the host in the faeces.

(a) *Levincia* (formerly *Isospora)* – the mature oocyst contains two sporocysts, each with four sporozoites.
(b) *Eimeria* – the mature oocyst contains four sporocysts, each with two sporozoites.

Coccidiomycosis, Coccidioidomycosis

Coccidiomycosis is a fungal disease, involving chiefly the lymph nodes, and giving rise to tumour-like (granulomatous) lesions. It occurs in cattle, sheep, dogs, cats and certain wild rodents, caused by infection with a fungus, called *Coccidioides immitis*. It has been recognised in many parts of the USA and Canada. It is seen in animals with immuno-suppression; especially young dogs.

VetBooks.ir

Signs Loss of appetite, fever, weight loss, cough, enlarged lymph nodes.

Chiefly recognised in abattoirs during the inspection of meat for human consumption, or in other animals at post-mortem examination. The lesions are sometimes confused with those of ACTINOMYCOSIS or ACTINOBACILLOSIS. In the dog, the disease may involve several internal organs and also bone.

An imported baboon diagnosed with the condition had skin lesions on muzzle and tail consisting of raised, plaque-like ulcers. The lesions may resemble those of *Mycobacterium tuberculosis* and *Yersinia pseudotuberculosis*. Coccidiomycosis is communicable to man.

Coccidiosis

A disease of major economic importance affecting many species of farm and domestic mammals, poultry; also people and birds. Each host has its specific coccidial species.

Cause *Eimeria*, a group of protozoan parasites. For the life-history of the parasites causing this disease, see under COCCIDIAN PARASITES/DISEASES.

Cattle (in which coccidiosis is sometimes called red dysentery).

Causal agent *Eimeria zürnii and E. bovis.* These are believed to be the most important species affecting cattle. Developmental forms occur wholly in the large intestine and caecum where considerable denudation of epithelium occurs, resulting in extensive haemorrhage. The oocysts are nearly spherical, and sporulation, under favourable conditions, takes place in from 48 to 72 hours. It is found in Europe, Africa and North America. It is prevalent during the warm season, and attacks especially animals of 2 months to 2 years.

Signs are first seen one to eight weeks after infection. There is persistent diarrhoea which becomes haemorrhagic. After about a week, emaciation is evident; the temperature rises, and there are digestive disturbances. Milk is diminished or stopped. Passage of faeces is attended by straining or even eversion of the rectum. Convalescence is slow. The lesions are mainly in the large intestine. Mortality varies between 2 per cent and 10 per cent of affected animals, and, generally speaking, the younger the animal, the more likely it is to succumb.

Treatment consists of isolation of all sick animals and careful nursing, with the use of sulfadimidine, decoquinate, diclazuril and taltrazuril.

Sheep and goats

Causal Agents Many species of *Eimeria* occur in these animals although they are exclusive to each ruminant type. Mixed infections with two or more species are the rule rather than the exception. The various species are widely distributed and as a rule the clinical disease is seen in lambs and kids, but seldom in the old animals which, however, may harbour coccidia. However, newborn lambs are relatively resistant. Decoquinate, sulfadimidine or diclazuril and toltrazuril are used to treat or prevent coccidiosis.

Signs are those of a pernicious anaemia accompanied by diarrhoea and emaciation.

Pigs Coccidiosis caused by *Isospora suis* is common but is seldom reported as a serious disease in the UK. It is a common cause of diarrhoea and poor performance of sucking piglets. Outbreaks have been treated with toltazuril.

Horses Diarrhoea, emaciation and death have occurred following infection. (See also GLOBIDIOSIS.)

Rabbits There are two forms of the disease: one attacking the intestines, the other the liver. Young rabbits may have acute enteritis, leading to death. The hepatic form often takes a chronic course, with diarrhoea developing later. Affected livers show whitish spots at autopsy. Robenidine or clopidol may be used for treatment.

Dogs and cats The following species have been found in cases of coccidial infection: *Isospora felis*; *I. rivolta; I. bigemina; E. canis*; and *E. felina.*

Most of these parasites have been isolated from healthy animals. The majority of coccidial infections of dogs and cats are light, and there is little evidence of serious damage to the hosts. In a few cases, however, there is diarrhoea and occasionally fatal dysentery.

Coccidiosis in carnivores is commoner than was once believed, especially in young cats, where the parasite is *I. felis*. The disease causes no signs except diarrhoea when a heavy infestation has occurred. Death is rare. The rabbit parasite may be found in faeces when diseased rabbits have been eaten. *I. canis* was isolated from 4 per cent of 481 faecal samples from dogs in North Island, New Zealand; *I. ohioensis* from 9 per cent.

Fowls At least seven species of *Eimeria* have been implicated. The disease commonly affects chicks 5 to 7 weeks old, as well as older growing birds. In the former the mortality may be high. Diarrhoea, often with blood in the faeces, is seen.

Control A vaccine derived from the species of *Eimeria* that affect chickens (Paracox) is administered in the drinking water. A single dose gives effective control of coccidiosis and, unlike earlier live vaccines, does not carry the risk of causing the disease in non-vaccinated birds.

Before the introduction of this vaccine, control was dependent upon antibiotics such as monensin and SALINOMYCIN. Monensin, salinomycin and toltrazuril are used. Mannan oligosaccharides have also been used in control.

Turkeys Six species of *Eimeria* cause disease. Usually seen as milky-white droppings. It rarely occurs in birds over 12 weeks old.

Ducks Coccidiosis occurs, but is of little economic importance.

Geese Three species of *Eimeria* occur in the intestine. Rather severe outbreaks have been ascribed to *E. anseris*. A fourth, important species is *E. truncata*, which causes a severe form of renal coccidiosis. The disease affects goslings from 3 weeks to 3 months of age, and in heavy infections goslings may die within 2 or 3 days after signs are first seen. The mortality is often very high.

Guinea Pigs They may be infected with *Eimeria caviae*.

Reptiles Coccidiosis is also seen in reptiles, especially those kept in indoor vivaria. The oocysts are detected in routine faecal analyses.

Coccidiostats

Medicines used to control the numbers of coccidial parasites in domestic animals. They are usually incorporated in the feed of farm animals but are delivered as individual medication in companion animals. Use of such compounds are not intended to eradicate the parasites but to reduce their numbers to allow the premune response of the host to develop. Some of these compounds also have improved production properties in farm animals and poultry. (See PREMUNITION.)

Coccygeal

Coccygeal vertebrae are the tail bones. One or more may fracture if a dog, cat, etc., becomes caught by a closing door or gate. The coccygeal vein is often used to obtain venous blood in cattle.

Cochin Chickens

These were originally bred in China and imported into Britain in the mid-19th century. They are a large breed with males weighing 5 kg (11 lb) and hens 3.9 kg (8.5 lb); there are also bantam varieties. Colours include buff, black, partridge, silver laced, splash, golden laced and white. The plumage covers the legs and feet and the skin is yellow. The eggs are medium sized and brown, but they do not lay well. They have good temperament and are quiet.

Cochlea

The essential organ of hearing; it forms the inner ear. It has a spiral shape and looks like a snail's shell. It contains fluid and the Organ of Corti, which contains highly specialised cells that convert vibrations into nerve impulses.

Cocker Rage Syndrome

A condition seen in cocker spaniels, especially those of a golden or dun colour with a domed head. For no apparent reason a quiet dog will suddenly become very aggressive. The dog then returns to its normal behaviour. (Also called 'JEKYLL AND HYDE' SYNDROME.)

Cocker Spaniel

The commonest and most popular of the spaniels. Originally used to retrieve game, the breed has blunt teeth which avoid damage when carrying birds, etc. They are liable to inherit brachury (short tail) and progressive retinal atrophy probably as recessive traits, DISTICHIASIS and ENTROPION as possible dominant traits, while ectropion, familial nephropathy, glaucoma and retinal pigment epithelial dystrophy are inherited by mechanisms not fully understood. A 'rage syndrome' is also associated with the breed (AMERICAN COCKER SPANIEL; COCKER RAGE SYNDROME). PUPILLARY MEMBRANE, PERSISTENT is recorded. Enterocolitis and CANINE DILATED CARDIOMYOPATHY, PHOSPHOFRUCTOKINASE DEFICIENCY are also seen in this breed..

Cockroaches

These insects may be responsible for the spread of salmonella, which they carry in their gut. A protein found in the faeces of European and North American cockroaches could induce an attack of ASTHMA.

Cocoa Poisoning

Poisoning of pigs and poultry, as a result of feeding cocoa residues or waste, was recorded in the UK during the 1939–45 war. (See also CHOCOLATE POISONING.)

Cocoa Shells

Ground cocoa shells are sometimes used in animal feeds. The material contains traces of caffeine and theobromine and was blamed as the source of those drugs found in the blood of a winning racehorse, which was subsequently disqualified.

VetBooks.ir

CODD
(See CONTAGIOUS OVINE DIGITAL DERMATITIS.)

Codeine
Codeine is one of the active principles of OPIUM, and is used as codeine phosphate, to check severe coughing in bronchitis, common cold, and in some cases of laryngitis. It is also used as an analgesic.

Cod-Liver Oil
A valuable source of vitamin A and D supplements for animal feeding. The best varieties contain about 1,000 to 1,200 International Units of vitamin A, and 80 to 100 Units of D, per gram. It should be stored in a dark-coloured container, preferably in a cool place, and if air can be excluded until it is to be used, this will enable it to be kept longer. Both strong sunlight and oxygen cause a destruction of vitamin A. Overdosage can be harmful. (See also VITAMINS). Feed to which cod liver oil has been added or to which it has not been correctly incorporated, or that has been allowed to stand beyond the usual storage time, can be subject to RANCIDITY. (See also GIZZEROSINE.)

Uses It prevents rickets developing in young animals

Swabs of cod-liver oil are also useful in eye injuries and in simple burns.

Cod-Liver Oil Poisoning
This may occur through the use of oil which has been allowed to oxidise or become rancid. One result may be muscular dystrophy in cattle (see under MUSCLES, DISEASES OF).

Codon
In messenger RNA it is a triplet in a chain of nucleic acids which specifies the sequence in which amino acids are added. The codon triplet pairs with a sequence of three complementary nucleotides, called the ANTICODON and these are present on the anticodon arm of transfer DNA.

Coeliotomy
The surgical entry into the body cavity of birds and reptiles.

Coelom
The body cavity of birds and reptiles not divided between thorax (pleural cavity) and abdomen (peritoneal cavity) as it is in mammals.

Coenuriosis
Infestation of the sheep's brain with cysts of the dog (and fox) tapeworm *Taenia multiceps.* Commonly called GID or STURDY. (See under TAPEWORMS.)

Coffin Bone
The bone enclosed in the hoof of the horse. Also known as the pedal bone.

Coggins Test
The agar-gel immunodiffusion test. Useful in the diagnosis of, e.g., equine infectious anaemia.

Coit, Mal Du
Another name for DOURINE.

Coital Exanthema
(See VULVOVAGINITIS; also RHINOTRACHEITIS, INFECTIOUS BOVINE.)

Coitus
(See REPRODUCTION.)

Colbred
A cross between the East Friesland and three British breeds of sheep (BORDER LEICESTER, CLUN FOREST and DORSET HORN). The aim of Mr Oscar Colburn, their breeder, was to produce ewes with a consistent 200 per cent lambing average and a corresponding sufficiency of milk.

Colchicine
The alkaloid obtained from meadow saffron (*Colchicum autumnale*). It is used in plant and experimental animal breeding as 'a multiplier of chromosomes'. It has been possible to produce TRIPLOID rabbits, pigs, etc., by exposing semen to a solution of colchicine prior to artificial insemination.

Colchicum Poisoning
(See MEADOW-SAFFRON POISONING.)

Cold
(See HYPOTHERMIA; EXPOSURE; FROST-BITE; SHEARING.)

Colic
Colic is a vague term applied to signs of abdominal pain, especially in horses.

Horses A large number of different conditions may produce abdominal pain in the horse, including:

1. Acute indigestion, resulting from the feeding of unsuitable food, the presence of gas (flatulent colic).
2. Disorders such as impaction of the colon, INTUSSUSCEPTION, volvulus, or strangulation of the bowel, rupture of the stomach, enteritis, and PERITONITIS.
3. The presence of large numbers of parasitic worms, horse bots, etc. (See under EQUINE VERMINOUS ARTERITIS.)

Vadbook

4. Calculi in the kidney, urinary bladder, or urethra in the male.
5. Anthrax.
6. Approaching parturition in the pregnant mare.
7. Grass sickness.
8. See HYMEN, IMPERFORATE.
9. Uterine rupture.
10. Nephritis.
11. Various poisons (see POISONING).
12. In countries where RABIES is endemic, this disease should be borne in mind when presented with a horse which appears to have colic.

The horse has a comparatively small stomach, but intestines of great bulk and capacity. The narrow entrance to the stomach inhibits reflux; the small exit leading to the S-shaped bend of the pylorus and first part of the small intestine is very liable to become occluded when there is any considerable pressure of gas within the stomach. It is thus difficult or impossible for gas produced in the stomach, by fermentation, either to escape by the mouth or to pass on into the intestines. Fermenting food may cause tympany of the stomach, while an excess of any food may lead to its impaction and occasionally to its rupture.

Inflammation or volvulus may affect the small intestine, but most cases of colic involve the large intestine. Impaction of the caecum or colon may occur; likewise tympany.

The ileum, supplied only by a single artery, appears to be particularly vulnerable to ischaemia, following thrombosis often caused by *Strongylus vulgaris* worms.

Anaerobic bacteria and their toxins may exacerbate the situation after circulation defects have occurred.

Signs 1. Spasmodic colic is typified by sudden and severe attacks of pain, usually of an intermittent character. Breathing is blowing and faster than usual; there is an anxious expression about the face; and the pulse is accelerated and hard. In a few minutes the attack may pass off and the horse becomes easier, or the pain may continue. In the latter case the horse lies down and rolls, after having first walked round about the box. In some cases rolling appears to afford some measures of relief, but in others the horse rises again almost at once. During an attack the horse may kick at its belly, or may turn and gaze at its flank.

In another form, ileus – often called flatulent colic – the pain begins suddenly, but there are not such distinct periods of ease. The horse walks round and round the box, kicks at the abdomen, gazes at its sides, breaks out into patchy sweating, and breathes heavily. It frequently crouches as if to lie down, but only actually lies in the less severe cases, and seldom or never remains lying for any length of time. Attempts at passing urine are noticed, but, as in the truly spasmodic colic, they are seldom successful. Faeces may be passed in small quantities, and are usually accompanied by flatus.

2. Obstructive colic may arise through impaction of the bowel with dry, fibrous, partly digested food material. Signs develop slowly, commencing with dullness and depression, irregularity in feeding, and abdominal discomfort. In 12 hours or so signs of abdominal pain appear. In some cases acute pain is shown, the horse rolling on the ground in agony. Small amounts of faeces are passed with considerable frequency at first, but when an attack is well established the passage of both urine and dung ceases. A sign strongly suggestive of impaction of the colon is one in which the horse backs against the manger or other projection, and appears to sit upon it, sometimes with the hind-feet off the ground. In other cases a horse with obstruction in the colon or caecum may sit with the hindquarters on the ground, but retains an upright position with the forelegs – somewhat similar to the position assumed by a dog. (See CALCULI for another cause of obstruction.)

3. In colic due to a twist (volvulus) there is great pain, during which the horse may become restless and violent. Sometimes the pain passes off, and sweating occurs, before a further period of pain. The temperature may be 41° C (105° F or 106° F), becoming subnormal in the last stages. Pulse-rate may rise to 120. Death is usually preceded by convulsions.

Many colic cases end fatally, and it is certain that many horses might have been saved if a veterinary surgeon had been summoned at the outset.

A survey of 134 cases of colic, seen at the veterinary clinic, University of Zurich, included 34 which were symptomless on arrival, required no treatment, and were regarded as cases of spasmodic colic. Thirty-three horses had impaction of the pelvic flexure of the colon and were treated conservatively; as were 14 with impaction of the ampulla, coli (4), and caecum (1). There were 7 cases of tympany of the stomach and two of impaction. Of 53 cases of ileus, the prognosis was hopeless in 7 which were destroyed, and owners refused surgery in another 6 cases. Forty underwent laparotomy, and 24 were discharged. Surgical success rate was 60 per cent; overall success of treatment was 68 per cent. Suggestions included maintenance of a nasal stomach tube to eliminate possibly lethal consequences of secondary gastric distension by fluid and gas during the journey to the clinic; and 1 litre of 5 per cent sodium

bicarbonate solution intravenously to help control the start of acidosis. (See also HORSES, COMMON CAUSES OF DEATH IN.)

Cattle Bovine colic occurs relatively infrequently. It is mainly caused by torsion of the caecum or abomasum, mesenteric torsion, intussusception, strangulation or phytobezoar (a fibrous mass causing obstruction).

Coliform

A term used to describe several species of lactose fermenting bacilli which inhabit the gut. The most common is *Escherichia coli* and approximately 80 per cent of coliform isolates tested at the National Institute for Research in Dairying are *E. coli*. Other coliform species implicated in bovine mastitis include *Klebsiella pneumoniae*, *K. oxytoca*, *Enterobacter cloacae*, *E. aerogenes* and *Citrobacter freundii*. All are 'gut associated' but some, notably *K. pneumoniae* and Enterobacters, may be free-living in forest environments or soil and be introduced into a dairy herd with sawdust or wood shavings used for cattle litter.

Coliform Infections

Coliform infections include mastitis, enteritis and septicaemia. Coliform organisms are frequently found in apparently healthy animals. An examination of cattle carcases at slaughterhouses showed that coliform organisms were isolated from surface swabbings from 208 out of 400 head of cattle (52 per cent); 81 of these being resistant to one or more antibiotics. Of 400 pig carcase swabs, 331 (83 per cent) were positive for coliforms; 246 being resistant to one or more antibiotics. Chloramphenicol resistance was present in 19 pig isolates and one cattle isolate. (See BEDDING AND BEDDING MATERIALS; *E. Coli*; MASTITIS IN COWS.)

Colistin

A polymyxin antibiotic active against Gram-negative bacteria such as *Salmonella* spp. and *E. coli*. Resistance is rare. It is mainly used in pigs.

Colitis

Inflammation of the colon, or first part of the large intestine (see INTESTINES).

Collagen

(See FIBROUS TISSUE; also CUTANEOUS ASTHENIA.)

Collapse

A state of extreme prostration. A state of extreme exhaustion and depression with circulatory failure. It can also mean the abnormal falling in of the walls of a tissue or organ.

Collateral Circulation

(See ANASTOMOSIS.)

Colliculus Seminalis

This protrudes into the lumen of the urethra, and at its centre is a minute opening into a tiny tube (the uterus masculinus) which runs into the prostate gland.

Collie Dogs

A large dog used for herding sheep or cattle. The breed originated from Scotland and Northern England and is about 20 kg to 30 kg (45 lb to 65 lb) in weight. They are also called the Scotch collie or ROUGH COLLIE. There are several other types including the BORDER COLLIES, SMOOTH COLLIES, WELSH COLLIES (WELSH SHEEPDOGS). They are prone to COLLIE EYE ANOMALY, PROGRESSIVE RETINAL ATROPHY and SUPERFICIAL PYODERMA.

Collie Eye Anomaly

A congenital disease occurring in some AUSTRALIAN SHEPHERD DOGS, LANCASHIRE HEELERS, NOVA SCOTIA DUCK TOLLING RETRIEVERS, SMOOTH COLLIES, ROUGH COLLIES, SHETLAND SHEEPDOGS and WHIPPETS (DNA tests available) in which there are missing parts of the CHOROID. In the worst cases, blindness may follow detachment of the retina or haemorrhage within the eye.

Collodion

Flexible collodion, a mixture of pyroxylin, alcohol and ether, is fairly elastic and does not crack with movement. It was used for application to lesions around joints. Medicated collodion contains substances such as salicylic acid and iodoform. A collodion preparation containing a caustic was used for destroying the horn-buds of calves. (See DEHORNING OF CATTLE.)

Colloid

Colloid is matter in which either the individual particles are single large molecules, such as proteins, or aggregates of smaller molecules are more or less uniformly distributed in a dispersion medium, e.g. water, oil. Examples: colloidal silver (used for eye infections), and colloidal manganese.

Coloboma

A congenital eye defect caused by an absence or fault in the tissue. It can be seen as a congenital cleft in the iris, ciliary body, choroid or eyelids. (See EYE, DISEASES AND INJURIES OF - COLOBOMA.)

Colon

The part of the large intestine extending from the caecum to the rectum or cloaca. In birds the organ

VetBooks.ir

is very short but very important because of caecal fermentation and also due to the influx of bacteria from the cloaca by reverse peristalsis. (See COLITIS; INTESTINES.)

Colony Collapse Syndrome

A serious condition of bees with a sudden loss, or complete death of bees, within a hive. The cause is not yet determined although a virus has been found in the USA but not Europe. Some keepers have observed an overproduction by the queens of drones (which do not produce honey) and possibly due to gender-changing chemicals affecting the queens.

Colony-Forming Unit (CFU; cfu)

These indicate the number of live viable bacteria or fungi that can multiply. They are expressed as cfu/ml or in solid materials cfu/g.

Colostrum

Colostrum is the milk secreted by the udder immediately after parturition and for the following three to four days. It contains 20 per cent or more protein, a little more fat than normal milk, and may be tinged pink due to blood corpuscles. It coagulates at about 80° C to 85° C (176° F to 185° F), and cannot therefore be boiled. It is rich in vitamins A and D provided the dam has not been deprived of these in her food. It acts as a natural purgative for the young animal, clearing from its intestines the accumulated faecal matter known as 'meconium', which is often of a dry, putty-like nature. Of much greater importance, it is from the colostrum that the young animal obtains its first supply of antibodies which protect it against various bacteria and viruses.

Before the cow calves, her udder selectively withdraws these immunoglobulins from her blood into the colostrum. In the sucking calf, the immunoglobulins become active in the blood serum after absorption, and they also have a local protective action within the small intestine. If the calf is to survive, both the serum and intestinal immunoglobulins must be present in adequate quantities; for the serum immunoglobulin will protect against septicaemia, but not against the enteritis which leads to scouring and dehydration.

The importance of the calf receiving colostrum early has long been emphasised. This is recognised in the Welfare of Livestock Regulations 1994, which specify that colostrum must be fed within six hours of the calf's birth.

The ideal amount of colostrum is about 3 litres (6 pints) fed within six hours of birth. The ability to absorb antibodies reduces after six hours and is complete at 24 to 36 hours old. Other species such as sheep, goats and horses all obtain much of their initial immunity via their colostrum.

Colour-Marking Bulls

Colour-marking bulls, e.g. Hereford, Aberdeen Angus, Charolais, and Galloway, for mating with cows in dairy herds which are of dual-purpose type and moderate to poor milkers, in order to increase the number of store cattle suitable for fattening for beef production. (See also BEEF BREEDS AND CROSSES.)

Colt

A young male horse.

Columbiform Beak and Feather Disease

It shows similar signs to those of PSITTACINE BEAK AND FEATHER DISEASE but it is caused by a circovirus.

Columnaris Disease

A disease in fish caused by *Chondrococcus columnaris*, an opportunist myxobacterium present in the water. Affected fish have greyish-white lesions on the skin. It is prevented by controlling water temperature to below 25° C (77° F) and reducing stress on the fish.

Coma

Coma is a state of profound unconsciousness in which the patient not only cannot be roused, but there are no reflex movements when the skin is pinched or pricked, or when the eyeballs are touched, etc. The cause is generally an excessively high temperature, brain injury, cerebral haemorrhage, some poisons, or too much or too little insulin in cases of diabetes, or the terminal stage of a fatal illness.

Comb

A projection of the skin, serrated at the top, running from front to back of the skull. In healthy poultry, it should be bright red and well developed. When birds go out of lay or are caponised, the comb becomes smaller and paler. Anaemia may also cause this. A pale comb of normal size suggests internal haemorrhage. Scurfiness is suggestive of favus; yellow scabs of fowl-pox.

Comedo

(plural, Comedones)

A hair follicle plugged with SEBUM and KERATIN; a blackhead. It is seen in cases of feline ACNE; HYPERADRENOCORTICISM and a specific syndrome in SCHNAUZERS.

Comeny's Infectious Paralysis of Horses

This condition, of unknown aetiology, was first described in French army horses by Comény. The reported signs are a sudden rise in temperature to 40° C (104° F or 105° F), persisting for five days,

VetBooks.ir

and followed in some cases by paralysis after a period of hind-limb incoordination and difficulty in turning. The disease is likely to be caused by an EQUINE HERPESVIRUS.

Commensalism
Commensalism is the association of two species in which one alone benefits, but the other does not suffer. The term is used to refer to a benign parasitism. Commensal micro-organisms are found on the skin surface, for example, and do not produce disease.

Comminuted Fracture
A fracture in which the bone is broken into more than two pieces. (See also COMPOUND FRACTURE; SIMPLE FRACTURE.)

Commissure
Commissure means a joining, and is a term applied to strands of nerve fibres that join 1 side of the brain to the other, to the band joining 1 optic nerve to the other, to the junction of the lips at the corners of the mouth, etc.

Common Agricultural Policy (CAP)
The European Union policy concerning agricultural subsidies. Initially, the CAP was to provide subsidies for food production and to control overproduction. The subsidy altered to a single farm payment based on the size of the farm. The payment is linked to environment schemes such as the Stewardship schemes and Entry Level Schemes providing payments for specific environmental enhancement.

Communicable Diseases
For diseases communicable to man, see under ZOONOSES. (For diseases communicable from man to farm livestock, etc. see ANTHROPONOSES)

Comorbidity
The presence of, or the effect of, one or more other diseases, conditions or disorders in addition to the primary disease or disorder. These other condition(s) may exist simultaneously but independently to the primary disease or condition, or they can have caused, be related to, or the result of the primary disease or condition. A condition concurrent with the main condition.

Companion Animal Welfare Council
An independent body established in 1999 to conduct and publish studies into the welfare, treatment and care of companion animals. It is funded by a charitable trust. Address: CAWC Secretariat, The Dene, Old North Road, Bourn, Cambridge CB22 2TZ. Telephone: 01954 718882; email: cawc@cawc.freeserve.co.uk.

Comparative Test
(See TUBERCULIN TEST.)

Compensation
Compensation is the term applied to the method by which the body makes good a defect of form or function in an organ which is abnormal in these respects.

Complement
A complex protein that is a constituent of serum and plays an essential part in the production of immunity. Bacteria are killed by the specific antibody developed in an animal's serum only in the presence of complement. Complement is also necessary for haemolysis.

An immune serum may contain antibodies which, together with the antigen, absorb or fix complement and are hence called complement-fixing antibodies. These form the basis for the Complement Fixation Test, which is used in the diagnosis of certain diseases, e.g. JOHNE'S DISEASE. As an indicator for the test, red blood corpuscles plus their specific antibody are used, i.e. the corpuscles plus the antiserum heated at 55° C (131° F) to inactivate or destroy the complement. In the test, on adding the indicator, haemolysis will not occur if the complement has been fixed.

Complementary Medicine, Complementary Treatment
Often also called ALTERNATIVE MEDICINE. The term includes any medicine or treatment that is proposed to treat end heal animals or man, other than CONVENTIONAL MEDICINE and that are not part of standard care. They are not based on EVIDENCE-BASED MEDICINE or a scientific base to support their use. This includes ACUPUNCTURE, HOMOEOPATHY, and HERBALISM.

Complement Fixation Test (CFT)
A test used on serum with COMPLEMENT to detect a specific antibody or antigen, usually from a micro-organism. It has been used in detection of antibodies to diseases such as JOHNE'S DISEASE. CFT has largely been superseded by PCR and ELISA tests.

Compliance
Defined as the animal owner's adherence to a given or recommended treatment plan.

Compost
Compost must not be used as bedding under the ANIMAL BY-PRODUCTS REGULATIONS 2003.

Compound Feeds
A number of different ingredients (including major minerals, trace elements, vitamins and other

additives) mixed and blended in appropriate proportions, to provide properly balanced diets for all types of stock at every stage of growth and development. (See DIET AND DIETETICS; FLUOROSIS.)

Compound Fracture

A fracture of a bone which is associated with a skin injury, usually over the fracture site; this may result in the bones becoming infected. (See also COMMINUTED FRACTURE; SIMPLE FRACTURE.)

Compulsive Polydipsia

The urge to drink excessive quantities of water, due to some psychological disturbance, is a recognised syndrome in human medicine, and it probably occurs in dogs as a result of stress; leading to urinary incontinence. The syndrome is also seen in horses ('bed wetter'). (See also DIABETES INSIPIDUS.)

Computed Tomography (CT)

A sophisticated and effective method of visualising the interior of the body, this has revolutionised radiography and DIAGNOSTIC IMAGING.

A focused electronic imaging scanner is used to build up, by a series of consecutive exposures, a picture of an organ or specific area. The resulting image is enhanced by computer analysis and viewed on a visual display unit (VDU) which shows a clear picture without the superimposition of other body tissues which surround the targeted area. In the apparatus, whose British development was by Godfrey Hounsfield FRS, crystal detectors are used in place of the film in a normal X-ray system.

(See ANGIOGRAPHY; CAT SCAN; DIAGNOSTIC IMAGING; TOMOGRAPHY; X-RAYS.)

Conalbumin

An important constituent of egg-white. It makes iron unavailable to certain bacteria (*Salmonella* and *Arizona* spp.) thus inhibiting their multiplication within the egg during incubation. (See also IRON-BINDING PROTEINS.)

Concentrates

Commercial concentrate feeds are expertly formulated by manufacturers, taking into consideration not only the current price of various ingredients but also the proper balancing of these ingredients. The inclusion of trace elements, minerals, and vitamins makes these compound feeding-stuffs foods complete in themselves. Suitable mixes are obtainable for every class of farm livestock.

Farm-mixed concentrates are commonly used on large arable farms, using home-grown barley, oats, beans, etc. The expertise required for formulation may also be lacking, so that on the smaller farm, proprietary concentrates are often to be preferred.

(See DIET AND DIETETICS; CUBES AND PELLETS; also ADDITIVES, COMPOUND FEEDS; SUPPLEMENTS.)

Conception Rates

Conception Rates following artificial insemination of cattle were stated to be in the region of 65 per cent in dairy breeds, but appear now to be about 45 per cent, and were over 70 per cent but possibly 55 per cent in beef breeds. The conception rate is usually based upon the number of animals which, in a three-month period, do not return to the first insemination.

Conception rates are influenced by many factors. The best time for insemination is between 2 and 20 hours after 'heat' is observed; after that, delay will mean a lower conception rate. Health of male and female, and the inseminator's skill also influence the rate. (See also FARROWING RATES.)

Conceptus

The embryo or fetus together with the tissues, such as the placenta, that nourish it.

Concrete

The precise composition of concrete may prove important where floor feeding is practised. Suspected iron poisoning from the licking of concrete made with sand rich in iron has been described in fattening pigs. Concrete floors of piggeries, etc., should be made with integral air spaces in order to have some insulating effect, and should not be abrasive. If they are, they can lead to injuries, followed by staphylococcal or other infection which may cause severe illness or death even in a new pig pen. Pigs should never be allowed to lie on freshly set concrete; skin burns may result from chemicals in the mix. (See under FOOT-ROT OF PIGS; HOUSING OF ANIMALS; BEDDING AND BEDDING MATERIALS.)

Concussion

(See under BRAIN DISEASES.)

Condensation in Buildings

(See NITRITE POISONING; CALF HOUSING; PNEUMONIA; YORKSHIRE BOARDING; VENTILATION.)

Condition

(See under MUSCLE.)

Condition Score

A method used to evaluate the thinness or fatness of cattle, sheep, goats, pigs and horses. It is used to monitor feeding and check that animals are fit to breed and maintain pregnancy.

VetBooks.ir

Condyle
Condyle is the rounded prominence at the end of a bone; for instance, the condyles of the humerus are the two prominences on either side of the elbow-joint in animals, while the condyles of the femur enter into the formation of the stifle joint.

Cone Degeneration
Also called ACHROMOTOPSIA, or gradual degeneration or absence of the cones in the retina, leading to colour blindness and day blindness. There are three types of cones each with a maximum response to blue, green or red, and one or more can degenerate. The condition is seen in ALASKAN MALAMUTES and GERMAN SHORT-HAIRED POINTERS (DNA test available).

Conformation Assessment in the Cow
(See under PROGENY TESTING.)

Congenital Conditions
These are conditions existing at the time of birth. They may be inherited, environmental or infectious in origin. However, not all congenital conditions are inherited, and inherited conditions may not be obvious at birth. Some congenital malformations can be due to infections entering the fetus via the placenta during pregnancy, and others are just due to illness in the mother, resulting in impaired nutrition and other effects on the foetus.

Congenital Haemolytic Anaemia
This results in the red cells being short-lived and can resemble PYRUVATE KINASE DEFICIENCY. It occurs in some dog breeds including ALASKAN MALAMUTES, BASENJIS and BEAGLES.

Congenital Hydrops
Generalised (subcutaneous) oedema at birth.

Congenital Joint Laxity and Dwarfism (CJLD)
This is seen in the offspring of suckler cows, usually fed pit silage. The cause is unknown but adding other feeds such as concentrates or forages will overcome the problem. Occurrence is infrequent, and not usually repeated. The calves are born with joint over-extension or ankylosis and the number of joints involved varies, but tends to be bilateral. Fully formed dwarf calves may be born and survive. Some cases appear to be manganese deficiency.

Congenital Myopathy
This is mainly seen in the GOLDEN RETRIEVER and LABRADOR RETRIEVER. (See under MYOPATHY, CONGENITAL.)

Congenital Myotonia
A condition at birth with tonic muscular spasms. It occurs in IRISH TERRIERS.

Congestion
The abnormal accumulation of blood in a tissue or organ.

Congestive
Pertaining to, or associated with congestion.

Congestive Heart Failure
This can be caused by a number of different problems which can occur singly or in combination, resulting in the heart being unable to maintain the circulation equilibrium, even at rest. The problem can be predominantly either right- or left-sided. Either results in a dilation and congestion of venous blood vessels, a development of oedema in organs, often initially the lungs; the heart will enlarge and the heart rate will increase. (See under HEART DISEASES.)

Congo Virus Disease, Congo Fever
A tick-bone infection caused by a Nairovirus in the BUNYAVIRIDAE family mainly seen in West and East Africa. It is carried by HYALOMMA ticks and causes transient fever in cattle and goats. It is a ZOONOSIS and causes Congo Haemorrhagic Fever which results in about 30 per cent mortality and is like human Crimean Haemorrhagic Fever.

Coniine
(See HEMLOCK POISONING.)

Conjugated Linoleic Acid (CLA)
This is considered important in human health and is derived from animal products including milk and meat. It is considered to have an anti-carcinogenic effect and control the deposition of fat. Feeding some products such as soya bean oil can increase the levels of conjugated linoleic acid in milk. Feeding products containing CLA and protected against rumen degradation can greatly raise levels in beef and lamb.

Conjunctiva
Conjunctiva is the membrane which covers the front of the eye. It lines the insides of the eyelids of all animals, both upper and lower, and from each of these places it is reflected on to the front of the eyeball. The membrane is transparent in its central portion, where it is specialised to form the covering to the cornea, which admits light into the cavity of the eye.

Conjunctival Goblet Cells
These are found throughout the CONJUNCTIVA and secrete MUCIN to protect the eye. They form

part of the PRECORNEAL FILM. Chronic inflammatory conditions such as ALLERGIC CONJUNCTIVITIS and early 'DRY EYE' result in increased mucin secretion. (See EYE, DISEASES AND INJURIES OF; KERATOCONJUNCTIVITIS SICCA.)

Conjunctival Overgrowth

A condition of unknown origin seen in rabbits. It is a fold of non-adherent conjunctival tissue arising from the limbus and extending over a part of the cornea. It can be removed but may regrow; suturing the fold to the sclera allows vision.

Conjunctivitis

(See under EYE, DISEASES AND INJURIES OF.)

Connective Tissues

These are fibrous types of tissue with different functions. They include: (1) white fibrous (collagenous) tissue, having fibres of collagen produced by fibroblasts, e.g. in tendons, ligaments; (2) yellow elastic tissue, composed of kinked fibres; (3) reticular tissue, composed of fine fibres which form a framework for bone-marrow; (4) adipose tissue or fat; (5) cartilage or gristle; (6) bone.

Connemara Ponies

These are good-tempered ponies, coming from Western Ireland. They are normally grey, but other colours are allowed. A hundred years ago the Irish breeders were concerned that the breed was becoming too small and so a few THOROUGHBRED sires were integrated into the breed. As a result some Connemaras exceed 14.2 HANDS in height, but this is permitted by the Connemara Society.

Conservative Medicine, Conservative Treatment

This usually means monitoring the patient without at the time undertaking active intervention or medication. It is designed not to avoid the undertaking or radical medical, therapeutic or operative procedures. In many instances it means 'letting nature take its course in healing.'

Consolidation

Consolidation is a term applied to solidification of an organ, especially of a lung. The consolidation may be of a permanent nature due to formation of fibrous tissue or tumour cells, or temporary, as in acute pneumonia.

Conspecific

Being of the same taxonomic species.

Constipation

Difficulty or delay in passing faeces. The faeces are passed in a variety of ways among the domestic animals. In the horse, cow and sheep, the excreta appears to be evacuated with very little or even no effort. The horse can defecate perfectly and naturally when galloping in harness, and seems only partly aware of the process. In the case of the dog and pig, on the other hand, the process involves a cessation of all other activities, the assumption of a special position of the body, and an obviously conscious effort. This is not unlike the process in human beings. Similarly, dogs and pigs are liable to suffer from true constipation, while horses, cattle and sheep, although they are liable to suffer from acute obstruction of the bowels, are seldom affected with true constipation.

Causes Anything which is likely to interfere with the normal peristaltic movements of the bowels, such as the use of too dry, bulky, or concentrated foods, overloading of the alimentary tract with unsuitable foods, tumours in the abdomen, pain originating from an enlarged prostate gland, or from obstructed anal glands, predispose to constipation. Inadequate exercise and too much food is a common cause. Changes from one owner to another, or from one district to another, or stress in the case of nervous individuals, are said to be a cause. Certain diseases of the nervous system, e.g. DYSAUTONOMIAS can also cause impaction of the large bowel: GRASS SICKNESS in horses, CONSTIPATIVE MUCOID ENTEROPATHY in rabbits and hares, Key-Gaskell disease in cats.

Treatment (See LAXATIVES; ENEMA.)

Cats It is important that owners do not mistake what may at first appear to be constipation for difficulty in passing, or inability to pass, urine owing to UROLITHIASIS.

Constipative Mucoid Enteropathy

A condition of rabbits which has been blamed on DYSAUTONOMIA, similar to EUROPEAN BROWN HARE SYNDROME and GRASS SICKNESS in horses, in which the animal has an impacted caecum and produces faeces covered in mucus.

Contact Allergic Dermatitis

An allergic dermatitis affecting sparsely haired parts of the body, to be distinguished from dermatitis caused by contact with irritants.

Contagious

The spread of contagion or infection from animal to animal by direct or indirect contact.

Contagious Abortion of Cattle

(See BRUCELLOSIS IN CATTLE.)

VetBooks.ir

Contagious Agalactia of Sheep and Goats

A disease of sheep and goats caused by *Mycoplasma* spp. It causes MASTITIS, ophthalmitis and ARTHRITIS with painful joint swellings in both species. It is NOTIFIABLE in the UK. It can be caused by *M. agalactiae*, *M. capricolum* subspecies *capricolum*, *M. putrefaciens*, *M. mycoides* subspecies *capri* and *M. mycoides* subspecies *mycoides* large colony (LC) type. It is seen in the Mediterranean part of Europe, Asia and North Africa. The organisms involved vary in their distribution.

Contagious Bovine Digital Dermatitis

(See DIGITAL DERMATITIS.)

Contagious Bovine Pleuro-Pneumonia (CBPP)

This disease has decimated herds throughout Europe and in other parts of the world on several occasions, and probably has been directly responsible for the death of more cattle than any other single disease with the possible exception of cattle plague (RINDERPEST). It is a NOTIFIABLE DISEASE in the EU.

It is present in Asia, Africa, Spain and Portugal; while in recent years, outbreaks have occurred in Australia and South America.

Cattle, buffaloes and related species, such as reindeer, yak and bison, are susceptible.

Cause *Mycoplasma mycoides*. (See under MYCOPLASMOSIS.)

Infection may occur by direct contact. Buildings which have housed infected cattle may remain infective for long periods.

Incubation period Three weeks to six months.

Signs The first sign of illness is a rise of temperature to 39.5° C to 40.5° C (103° F or 105° F). In the acute disease this rise of temperature is soon followed by signs of general illness, such as dull coat, debility, loss of appetite, cessation of rumination. Shortly afterwards a dry, short, painful cough makes its appearance.

Pregnant cows are liable to abort.

Death usually follows in two or three weeks after the signs have become pronounced and acute. Recovery is frequently more apparent than real, for a chronic cough remains, and the disease may again become acute and even end fatally.

Post-Mortem appearances Large or small areas of pneumonia in the lungs, which are often of a marbled appearance. The lesion is primarily one of interstitial pneumonia, with thickened septa dividing the lung up into lobules; some lobules show acute congestion, some are in a stage of red or grey hepatisation, while others consist of dead encapsulated tissue, known as 'sequestra'. Evidence of pleurisy with often much fibrinous deposit around the lungs is usual.

Diagnosis The slaughter of suspected animals may be essential for this. Corroboration may be obtained by laboratory tests.

Treatment is not allowed in most countries, but neoarsphenamine and tylosin have proved useful elsewhere.

Immunisation Live vaccines may be used in eradication and control programmes.

Contagious Caprine Pleuro-Pneumonia

A disease of goats, caused by a mycoplasma and occurring in Europe, Asia, and Africa. Acute, peracute, and chronic forms occur. Mortality may be 60 per cent to 100 per cent. Antibiotics are useful for treatment where a slaughter policy is not in force.

Contagious Diseases

Infectious diseases spread by contagion or direct contact between affected animals. Certain of these are notifiable (see under NOTIFIABLE DISEASES.) The responsibilities of animal owners are discussed under DISEASES OF ANIMALS ACTS.

Contagious Ecthyma of Sheep

Contagious ecthyma of sheep is another name for ORF.

Contagious Epithelioma of Birds

(See FOWL POX.)

Contagious Equine Metritis (CEM)

Contagious equine metritis (CEM) is a contagious venereal disease found in mares and transmitted by stallions. This is a NOTIFIABLE DISEASE in the UK, under the Infectious Diseases of Horses Order 1987.

Cause A Gram-negative coccobacillus, *Taylorella equigenitalis* (formerly *Haemophilus equigenitalium)*. This has been isolated from the cervix, urethra and clitoris. The organism is apt to persist in the clitoral fossa after clearance from other parts of the mare's urogenital tract, and routine sampling at this site is therefore necessary or diagnosis may fail to be confirmed.

Control A code of practice for control of the infection was formulated by the Horserace Betting

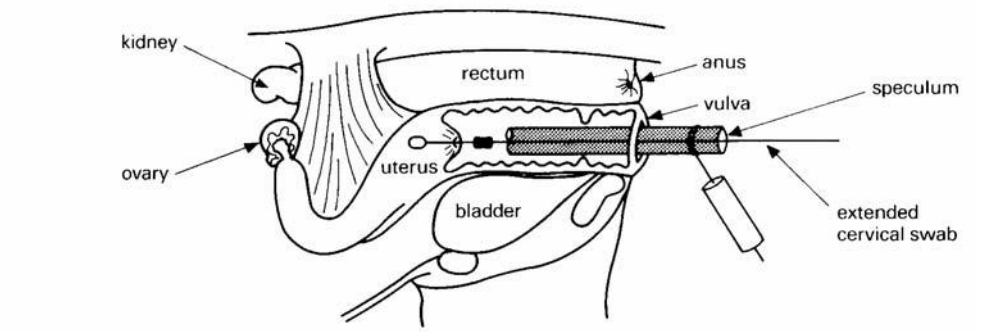

Diagram showing the technique of collecting a cervical swab via a tubular speculum. The swab is passed as far into the open oestrous cervix, and beyond, as possible.

Levy Board in 1977, and supported by the Ministry of Agriculture and the Thoroughbred Breeders' Association. A list of laboratories authorised to test for the CEM organism is published annually in the *Veterinary Record*.

Cervical swab tests are a routine diagnostic and preventive measure on stud farms. Among techniques used for taking swabs is that shown in the diagram.

Measures to control the spread of CEM in non-thoroughbred mares have been in operation since 1978.

(See also CLITORIS - CLITORAL SINUSECTOMY.)

Clitoral swab tests are the standard test for isolating CEM and are used routinely as a preventive measure on stud farms.

Contagious Ophthalmia in Sheep

This is infectious ovine infectious keratoconjunctivitis, also called 'Heather blindness' in sheep. (See EYE, DISEASES AND INJURIES OF - BLINDNESS - CATTLE AND SHEEP; EYE, DISEASES AND INJURIES OF - OVINE INFECTIOUS KERATOCONJUNCTIVITIS.)

Contagious Ovine Digital Dermatitis (CODD)

A disease resembling, but distinct from, foot-rot which causes severe ulcerative lesions of the coronet that may lead to complete separation of the hoof case. It was first identified in the UK in 1997. The cause is a spirochaete similar to that responsible for bovine digital dermatitis. It is differentiated from foot-rot by the absence of interdigital sores (in most cases) and by failure to isolate *Dichelobacter nodosus*, the cause of foot-rot, from the lesions.

For treatment, see DIGITAL DERMATITIS.

Contagious Pustular Dermatitis in Sheep

(See ORF.)

Contagious Stomatitis

(See FOOT-AND-MOUTH DISEASE; also VESICULAR STOMATITIS.)

Contagious Vaginitis

(See EPIDIDYMITIS AND 'EPIVAG'.)

Contraceptives

Contraception is widely practised in companion animals, particularly dogs and cats by spaying or castration. Chemical methods include MEGESTROL ACETATE, proligestone and MEDROXYPROGESTERONE (synthetic progesterones). Megestrol is one of the drugs used to stop dogs and cats coming on heat. Aglipristone is used to terminate early and mid-term pregnancy in bitches. Prostaglandins have been used to control the timing of pregnancy in cattle and to terminate an unwanted pregnancy. Contraceptive drugs have been added to the feed to prevent poultry flocks coming into lay under specific problematic conditions. The contraceptive action affects the whole poultry genital tract so that, following removal, the hens only slowly come into lay, whereas turkey hens start laying 24 hours after drug removal. In wildlife, population control by laying drug-laced food may be tried. Attempts to develop a contraceptive for wild rabbits have been hampered by the problem of drug residues in rabbits caught for food. (See also GOSSYPOL; STILBENES.)

Contracted Foot or Contracted Hoof

A condition of the horse in which some part of the foot, very often a quarter or heel, shrinks to less than its usual size. It is brought about by anything which favours rapid evaporation of the moisture in the horn, such as rasping away the outer surface of the wall; or by conditions which prevent expansion of the hoof, such as paring away the frog so that it does not come into contact with the ground, cutting the bars, allowing the wall at the heels to fall inwards, shoeing with high calkins, etc.

VetBooks.ir

Prevention consists in leaving the frogs as large and well developed as possible; reducing the overgrowth at the heels and bars to the same extent as at the toe and other parts of the foot; shoeing with shoes which allow the frog to come into contact with the ground.

Treatment In severe cases a run at grass with tips on the affected feet, and leaving the heels bare, is advisable. (See also HOOF REPAIR WITH PLASTICS.)

'Contracted Tendons'

1. A congenital condition, in which the foot is not fully extended, seen mainly in calves, lambs and foals. The causes are various and the condition may clear up without treatment in a few days. If it does not, splints may be applied to straighten the foot. Surgical correction by partially severing the tendon is sometimes carried out.
2. Chronic tendonitis in adult horses. The limb is not fully extended and the animal appears to be standing on its toes (sometimes called 'ballerina syndrome').

Contralateral

Affecting or associated with the opposite side. (See also BILATERAL; IPSILATERAL; UNILATERAL.)

Control, Controlled Experiment

In any scientifically conducted experiment or field trial, the results of treatment of 1 group of animals are compared with results in another, untreated, group. Animals in the untreated group are known as 'the controls'.

Controlled Breeding

The manipulation of ovarian activity to enable successful insemination at a predetermined time is widely practised in cattle, sheep and pigs. Synchronisation of oestrus enables groups of animals to be inseminated at a chosen time, and parturition planned to take place when convenient. A PROGESTOGEN preparation is administered for 10 to 14 days according to a specific dosage schedule; the animal comes into heat when the progestogen is removed. Insemination, by natural mating or artificially, then takes place. The progestogen is administered orally, by injection, implant, or intravaginally, according to species and particular product.

An implant of MELATONIN will stimulate early onset of natural reproductive activity and improve fertility early in the season.

Cattle The main method in beef animals or maiden heifers is two doses of prostaglandin injection 10 days apart. An alternative method uses an implant containing norgestomet is inserted under the skin of the ear and then an injection of norgestomet plus OESTRADIOL given immediately. The implant is removed after 9 or 10 en days and the animal inseminated twice, 48 and 72 hours later, or once, 56 hours later. In the other system, a spiral device incorporating progesterone, with a gelatine capsule containing oestradiol attached, is inserted into the cow's vagina and left for 12 days. The cow is inseminated twice, after 48 and 72 hours later, or once at 56 hours.

Alternatively, a progestogen may be administered by injection.

About to withdraw the progestogen-impregnated sponge at the end of the 2-week treatment period. At this time, the ewe receives a single intramuscular injection of PMSG — to complete the controlled breeding treatment.

Sheep A sponge impregnated with a progestogen (flugestone or medroxyprogesterone) is introduced to the vagina and left for 12 to 14 days. The ewes are introduced to the ram 48 hours after removal. The sponge may be used in conjunction with an injection of pregnant mare serum gonadotrophin, given on removal of the sponge, to advance the breeding season by up to 6 weeks. (See illustration on previous page.)

Pigs A suspension of altrenogest is added to the feed once daily; for sows for 3 days, for gilts for 18 consecutive days.

Farrowing may be induced, within 3 days of the expected normal time, by an injection of a luteolytic agent such as cloprostenol or dinoprost. Farrowing then occurs between 24 and 30 hours later.

Mares Induction of ovulation in mares to synchronise ovulation more closely with mating can be achieved by an injection of buserelin, a synthetic releasing hormone analogue for both gonadotrophin and follicle stimulating hormone. An implant containing deslorelin acetate (Ovuplant) is now used for inducing ovulation.

Warning: Progestogen products should be handled with great care, particularly by pregnant women. They must not come in contact with the skin.

Controlled Drugs

Controlled drugs are those which are regulated by the Misuse of Drugs Act and the Misuse of Drugs Regulations (as amended) which dictate the extent that is lawful to import, export, produce, supply, administer and possess the drug. There are rules imposed concerning prescription writing, record keeping, labelling and safe custody. Drugs are listed under five Schedules according to type of action and use. (See VETERINARY MEDICINES REGULATIONS.)

Controlled Environment Housing

Temperature, ventilation, and humidity are controlled within narrow limits by means of electric fans, heaters, etc., and good insulation. Poultry, for example, are protected in this way from sudden changes in temperature; rearing can be carried out with the minimum loss throughout the year; and increased egg yields and decreased food intake can effect a considerable saving in costs of production. Some of these houses are windowless; artificial lighting being provided: respiratory disease may occur through overcrowding or ventilation defects.

Failure of automatic control Ventilation systems must have fail-safe alarms and back-up systems under UK law. If those are not effective, there may be fatal consequences, as the following example shows.

A thunderstorm blew the fuse in the fan circuit of a controlled environment house, and 'fail-safe' ventilation flaps did not work. As a result 520 fattening pigs died of heat-stroke.

Control of Dogs Order 1992

(See under LAW.)

Conures

A loose term used for some groups of PARAKEETS (medium-sized parrots), mainly from South America. They are from the Genera *Aratinga*, *Pyrrhura*, and a few other Genera of the of the tribe *Arini* (little macaws). (See CAGE AND AVIARY BIRDS, DISEASES OF.)

Conventional Medicine

Conventional medicine is practised by most qualified veterinary surgeons and is science-based. They diagnose, treat and prevent disease. They will and to prescribe conventional medicines which have been through a regulatory process such as VETERINARY MEDICINES REGULATIONS. The philosophy is at some variance with some practices undertaken in ALTERNATIVE MEDICINE.

Convex Sole or Dropped Sole

The sole of the horse's foot, instead of being arched (concave) when viewed from the ground surface, is convex and projects to a lower level than does the outer rim of the wall in many cases. (See LAMINITIS.)

Convolvulus Poisoning

Another name for poisoning by MORNING GLORY.

Convulsions

Convulsions are powerful involuntary contractions (alternating with relaxation) of muscles, producing aimless movement and contortion of the body, and accompanied by loss of consciousness. (See SPASM; FITS.)

Coombs Test, Antiglobulin Test

Coombs (antiglobulin) test is a laboratory test used in the differential diagnosis of various blood disorders.

Coopworth Sheep

A breed of New Zealand sheep derived from the 'Border-Romney' cross.

COPD

(See CHRONIC OBSTRUCTIVE PULMONARY DISEASE.)

VetBooks.ir

Copper (Cu)

Copper (Cu) is one of the TRACE ELEMENTS which is essential in the nutrition of animals. It acts as a catalyst in the assimilation of iron, which is needed in the production of haemoglobin in the liver. It is used in myelin formation, and in the acute phase of an immune response. Its absence from the foodstuffs in some areas leads to a form of anaemia.

In several parts of the world a deficiency of copper in the herbage has been a major obstacle to livestock production, and appropriate dressings of the land have permitted dramatic increases in production.

In cats a copper level of 5mg/kg was recommended by the National Research Council of the USA, but this appears to be too low and can lead to failure to conceive in queens; 10.8mg/kg is now recommended.

(See COPPER DEFICIENCY, below.)

Sheep Caution Sheep and goats tend to be sensitive to too much copper and can develop signs of jaundice and can die if not treated. Indiscriminate dressing of pasture with copper salts is likely to cause poisoning in sheep if the quantities used are too large, or if sheep are re-admitted to dressed pasture before there has been sufficient rain to wash the copper salts off the herbage.

Copper sulphate for pigs Copper sulphate, added to the fattening ration at the rate of 150–180 ppm, has produced an improvement in the growth rate in pigs. However, it is now banned in the UK. (See SWAYBACK; also MOLYBDENUM.)

Copper deficiency In several parts of Britain, copper deficiency is a serious condition. (See HYPOCUPRAEMIA.)

Two types of copper deficiency are recognised: primary and secondary. The former arises from an inadequate intake of copper and, while herbage levels of copper below 5 ppm are uncommon in Britain, a survey showed that over 50 per cent of 1,078 beef herds in mid-Wales had low blood copper levels, probably associated with low intake. Secondary copper deficiency is the more common form in the UK and occurs where absorption or storage of copper within the animal body is adversely affected by a high sulphate or molybdenum intake, even though there is adequate copper in the diet.

An excess of molybdenum in the 'teart' soils and pastures of central Somerset, and of areas in Gloucestershire, Warwickshire, Derbyshire and East Anglia, has long been recognised, giving rise to scouring (especially from May to October), a greyness of the hair around the eyes, staring coats and a marked loss of condition.

Prevention Copper deficiency may be prevented by administering copper sulphate powder containing 254 g/kg mixed with feed at a dose of 2 g per head, or by a ruminal bolus containing small blunt rods ('needles') of copper oxide, once a season.

Treatment of copper deficiency is by parenteral injection of copper, usually in the form of copper edetate or heptonate.

Copper, Poisoning by

Some breeds of sheep and goats are very susceptible to excess copper and develop jaundice and can die. Cattle are less susceptible. Poisoning has occurred in sheep given a copper-rich supplement, intended for pigs, over three months, and in a heifer similarly, as well as in pigs given too strong a copper supplement. Poisoning also occurs when animals are grazed in the vicinity of copper-smelting works, where the herbage gradually becomes contaminated with copper, in orchards where fruit-trees have been sprayed with copper salts and also in sheep grazing land treated with copper sulphate (either crystals mixed with sand, or as a sprayed solution) as a snail-killer in the control of liver-fluke or as a preventative of swayback.

In Bedlington terriers there is an inherited disease resulting in the accumulation of excessive amounts of copper in the liver.

Signs are those of an irritant poison – pain, diarrhoea (or perhaps constipation) and weakness; staggering and muscular twitchings are seen in chronic cases.

Failure to achieve accurate mixing of small quantities of copper sulphate into farm-mixed rations has led to fatal poisoning of pigs. A fatal chronic copper poisoning may occur in pigs fed a copper supplement of 250 parts per million.

Copper poisoning is almost specific to housed sheep. It occurs even in diets ostensibly containing no copper supplement, as the capacity of the sheep to store copper from normal constituents diet is higher than that of other animals. Lambs reared indoors have died because their hay was made from grass contaminated by slurry from pigs on a copper-supplemented diet.

It is dangerous to exceed 10 ppm of copper in dry feeds for sheep over a long period.

There are significant breed differences as regards swayback and copper poisoning.

Treatment Three subcutaneous injections of tetrathiomolybdate (on alternate days) can remove copper from the livers of both sheep and goats without causing any apparent ill-effects.

Copperbottle

Lucilia cuprina, the strike fly, which attacks sheep in Australia and South Africa.

'Copper Nose'
A form of LIGHT SENSITISATION occurring in cattle.

Co-primary Case
A term used in epidemiology to describe cases of illness which occur at the same time or after an existing PRIMARY CASE but within the usual recognised main incubation period. Such cases are unlikely to have been caught from the primary case. It is thus thought that the animal has been exposed at the same time or about the same time as the primary case. (See INDEX CASE; PRIMARY CASE; SECONDARY CASE.)

Coprophagy, Coprophagia
The eating of its own faeces by an animal. In rabbits, this is a normal practice. The rabbit produces two types of faecal pellet: the normal fibrous light-coloured pellet, which is not eaten, and a darker soft pellet, produced in the caecum, which is eaten immediately on being expelled from the anus. The latter pellets are rich in B vitamins and amino acids, but can also serve to recycle parasites. Female parents of several species ingest the faeces of their offspring in order to keep the nursing area clean. Within three weeks of birth, foals will eat their dams' faeces and thereby acquire the various bacteria needed for digestive purposes in their own intestines. Overnight coprophagy has also been reported in adult horses in adjusting to 'complete-diet' cubes when no hay is on offer.

It has been suggested that foals may obtain nutrients, and that coprophagy may be a response to a maternal pheromone signalling the presence of deoxycholic acid which may be required for gut 'immuno-competence' and myelination of the nervous system. Coprophagy in dogs is a sign of exocrine pancreatic deficiency.

Coprophagy also occurs in piglets and non-human primates. (See CAECOTROPHY.)

Copulation
(See REPRODUCTION.)

Coracoid
A paired bone of the pectoral girdle of birds acting as a strut to keep the wings away from the sternum in flight. The coracoid articulates dorsally with the clavicle (fused in birds to form the furcula) and the scapula, and ventrally with the cranial end of the sternum.

Corgi
A long-backed, short-legged dog of medium size with erect ears. There are two forms: the Pembrokeshire, which is orange-brown in colour; and the Cardiganshire, which is black, white and tan. The long back can give rise to intervertebral disc problems. The breed may be susceptible to recurrent corneal ulceration. Cutaneous asthenia, which is skin fragility caused by a collagen defect, is an autosomal dominant trait. The Cardigan variety can also inherit progressive retinal atrophy as a recessive trait.

Coriosis
Degeneration of the CORIUM. (See LAMINITIS.)

Corium
The main layer of the skin, also known as the dermis. It lies below the epidermis and above the subcutaneous tissue. (See SKIN.)

'Corkscrew Penis'
(See under PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Corn Cockle Poisoning
The plant *Lychnis* (or *Agrostemma*) *githago*, a weed of corn fields, is usually avoided by livestock; but they may be poisoned through eating wheat or barley meal contaminated with the seeds. The latter contain SAPONINS.

Dogs and young animals are most susceptible to poisoning; the signs of which are restlessness, frothing at the mouth, colic, paralysis and loss of consciousness.

First aid Large amounts of white of egg, starch paste, and milk may be given to calves and dog as a drench.

Cornea
Cornea is the clear part of the front of the eye through which the rays of light pass to the retina. (See EYE.)

Corneal Endothelial Dystrophy
A congenital, and in some case inherited, condition mainly of dogs and cats. It can result in corneal oedema and ulceration. Dog breeds in which it is seen include BOXERS and BOSTON TERRIERS.

Corneal Epithelial Dystrophy
A congenital, and in some case inherited, condition mainly of dogs and cats. It can result in corneal oedema and ulceration. Dog breeds in which it is seen include BOXERS.

Corneal Lipidosis
The deposition of fat, usually under the corneal epithelium. Occasionally it involves the epithelium itself and then there is irritation; otherwise there is apparently no effect on vision and no discomfort; it is more common in bitches than males. The degree of lipidiosis can fluctuate or even disappear. It is recorded mainly in dogs, involving particularly some breeds including BOXERS, CAVALIER KING CHARLES SPANIELS, GOLDEN RETRIEVERS,

HUSKIES, ROUGH COLLIES, SAMOYEDS and SHETLAND SHEEPDOGS.

VetBooks.ir

Corneal Ulceration

A severe condition involving a loss of corneal tissue. It is extremely painful when only the superficial layers of the cornea are removed but almost without pain when only the deeper layers remain. It can be the result of trauma, foreign bodies, infections, DISTICHIASIS, ENTROPION or KERATOCONJUNCTIVITIS SICCA. If the ulcer becomes deep it can lead to rupture of the cornea and may release the AQUEOUS HUMOUR and the iris may become attached to the inner corneal surface plugging the hole. (See EYE; EYE, DISEASES AND INJURIES OF.)

Cornification

The hardening of the skin into horn or horn-like substance. (See KERATINISATION.)

Cornish Rex

A breed of cat lacking guard hair and so showing a fine curled undercoat or down (a typical rex coat). The long legs and muscled hindquarters are indicative of the ability to run very quickly. The coat colours show many variations, from 'points' similar to Siamese colouring to 'solids' seen in other British self-coloured breeds. The breed is prone to umbilical hernia.

Corns

A bruise of the sensitive part of the horse's foot occurring in the angle formed between the wall of the hoof at the heel and the bar of the foot.

Signs In the majority of cases the horse goes very lame either gradually or suddenly. When made to walk he does so by using the toe of the affected foot, keeping the heels raised. Sometimes the pain is so great that he refuses to place the affected foot on the ground at all, but hops on the sound foot of the other side.

Treatment The shoe should be removed as in all cases of lameness, and the hard dry outer horn pared away. Particular attention should always be paid to the region of the heels, for stones often become lodged there. If a corn is present the horse will show pain whenever the knife is applied to the affected part, and efficient paring will necessitate an analgesic.

Mild cases take about 5 to 7 days to recover, while horses with severe suppurating corns may be as long as 6 or 7 weeks before they are fit to work. (See also FOOT OF THE HORSE.)

Coronary

Coronary is a term applied to several structures in the body encircling an organ in the manner of a crown. The coronary arteries are the arteries of supply to the heart which arise from the aorta, just beyond the aortic valve; through them blood is delivered to the heart muscle.

Coronary Band, Coronary Cushion

Coronary band, or coronary cushion, is the part of the sensitive matrix of the hoof from which grows the wall. It runs round the foot at the coronet, lying in a groove in the upper edge of the wall. Its more correct name is the coronary matrix. (See FOOT OF THE HORSE.)

Coronary Thrombosis

Coronary thrombosis, associated with *Strongylus vulgaris*, is a cause of sudden death in yearling and two-year-old horses. (See EQUINE VERMINOUS ARTERITIS.)

Coronaviruses

Coronaviruses cause diarrhoea in calves, foals, dogs, cats, turkeys, sheep and pigs (see TRANSMISSIBLE GASTROENTERITIS OF PIGS); infectious bronchitis in chickens; hepatitis in mice, respiratory disease in mice; FELINE INFECTIOUS PERITONITIS and ENCEPHALOMYELITIS, VIRAL, OF PIGS. Avian coronaviruses have been shown able to be transmitted by flies.

Coronet

(See FOOT OF THE HORSE.)

Coronoid Processes

One of these is present on the mandible (lower jaw) where the temporal muscle is attached to it. On the ULNA they form protuberances which articulate with the radius and humerus.

Corpora Nigra

These are brown irregular shapes seen on the upper border of the iris in some species to shade the pupil. It is seen particularly in horses, cattle, goats, alpacas. On occasions they can become cystic. (See EYE.)

Corpora Quadrigemina

Corpora quadrigemina form a division of the mid-brain. (See BRAIN.)

Corpuscles of Stannius

Small white spots scattered throughout the kidney tissue, and on the surface. Found only in bony fishes, their exact function is not known but they are probably part of the fishes' endocrine system.

Corpus Luteum

Also known as the yellow body, this is formed by the cells lining the empty follicular cavity, under

the influence of the luteinising hormone, as explained under OVARIES.

Corridor Disease

This affects the African buffalo and also cattle, and is caused by the protozoan parasite *Theileria lawrencei*, transmitted by ticks. It resembles East Coast fever, and has a 60 to 80 per cent mortality in cattle.

Corriedale Sheep

A breed which is dual purpose (meat and wool). It is a crossbred sheep developed in Australia and New Zealand from the MERINO and LINCOLN LONGWOOL. It is mainly farmed in Australia, New Zealand, Patagonia and the USA.

Corticosteroids

These comprise the natural glucocorticoids, cortisone and hydrocortisone – hormones from the cortex of the adrenal gland; and, in ascending order of potency, the more potent synthetic equivalents – prednisolone, methylprednisolone, triamcinolone, betamethasone and dexamethasone.

In veterinary medicine, synthetic corticosteroids are used in the treatment of a wide variety of inflammatory conditions. They have been used for the relief of lameness and navicular disease in the horse, and arthritic joints. They find application in a wide variety of conditions: shock, stress, ketosis, acetonaemia, respiratory diseases, colitis.

A corticosteroid given intravenously in late pregnancy is likely to induce abortion.

Corticosteroids are immunosuppressive and produce relief of signs without treating their cause. Their benefits in suppressing signs and allowing increased mobility must be weighed against the risks of increasing joint damage. Overdosage and continuous administration, especially when unsupervised, may bring out latent diabetes.

Corticotrophin

The hormone from the anterior lobe of the pituitary gland which controls the secretion by the adrenal gland of corticoid hormones. These corticosteroids, or steroid hormones, are of three kinds: (1) those concerned with carbohydrate metabolism and which also allay inflammation; (2) those concerned with maintaining the correct proportion of electrolytes; (3) the sex corticoids.

Cortisol

(See CORTISONE.)

Cortisone

A hormone from the cortex of the adrenal gland. In medicine, one of its synthetic analogues is normally used. (See CORTICOSTEROIDS.)

Actions Cortisone raises the sugar content of the blood and the glycogen content of the liver, among many other actions.

Uses Cortisone has been used effectively in the treatment of rheumatoid arthritis, but when the drug is discontinued, signs return. However, because of potential side-effects its long-term use is not recommended (see CORTICOSTEROIDS).

Corynebacterium

A genus of slender, Gram-positive bacteria which includes the cause of diphtheria in man. In veterinary medicine *C. pyogenes* (now renamed *Arcanobacterium pyogenes* and before this *Actinomyces pyogenes*) is of importance, causing 'summer mastitis' and 'foul-in-the-foot' in cattle. A generalised infection has been reported, giving rise in cattle to lameness, slight fever, leg-swellings, lachrymation, and later emaciation and death.

C. suis (or *Eubacterium suis*) is responsible for infectious cystitis and pyelonephritis in pigs.

C. ovis (*C. pseudotuberculosis*) causes caseous lymphadenitis in sheep and some cases of ulcerative lymphangitis and acne in horses.

C. equi, now named *Rhodococcus equi*, causes pneumonia in the horse and tuberculosis-like lesions in the pig.

C. renale is the cause of pyelonephritis in cattle and pigs.

Corynebacteria are also associated with disease in fish causing scattered white lesions throughout the spleen, liver and kidney. It can be severe in Atlantic salmon. Sometimes called Dee disease, after the river Dee at Aberdeen.

Coryza

These describe the signs associated with a 'common cold' in human beings. It is often used when describing profuse discharges from the mucous membranes of the nasal passages of animals and birds. (See INFECTIOUS CORYZA OF CHICKENS.)

Costia

Costia necatrix is a serious parasite of freshwater fish. (See also FISH, DISEASES OF.

Coton de Tuléar Dogs

The name of this breed derives from their cotton-like coat and because they originated from Tuléar, Madagascar. They are small (4 kg to 6 kg; 9 lb to 13 lb for males and 3.5 kg to 5 kg; 8 lb to 11 lb for females) and white, black and white or tricoloured. The breed is susceptible to CANINE MULTIFOCAL RETINOPATHY and VON WILLEBRAND'S DISEASE.

Cotswold Sheep

A dual-purpose breed used for meat and wool and developed in the Midlands. It is about 79 cm (2 ft

VetBooks.ir

7 in) high and weighs 125 kg to 140 kg. In 2009 it was regarded as a minority breed. It is a long-woolled breed whose fleece was known as the 'Golden Fleece' and the breed was called the 'Cotswold Lion'.

Cotton-Seed Cake or Meal

Cotton-seed cake or meal may, if undecorticated, contain up to 25 per cent of indigestible fibre and lead to intestinal impaction if fed to calves or pigs. Gossypol poisoning may also result. (See GOSSYPOL.)

Cotyledons

(See PLACENTA and PREGNANCY AND GESTATION.)

Coughing

NB: Birds, reptiles and other animals which do not have a diaphragm cannot cough. A cough in a parrot or mynah bird is usually mimicry of the owner's cough.

Horses Common causes of coughing in horses include: equine influenza; other virus infections; laryngitis and bronchitis from other causes; an allergic or asthmatic cough often heard in the autumn; and 'broken wind'.

(For a list of viruses which cause coughing (and also other signs) in the horse, see EQUINE RESPIRATORY VIRUSES.) Where coughing occurs with a normal temperature, horses may prove to be infested with the lungworm *Dictyocaulus arnfieldi*.

Clenbuterol is widely used for treatment.

Pigs Coughing may be due to dusty meal or to enzootic pneumonia. It also occurs during migration of the larvae in infection with *Ascaris* worms.

Dogs A cough is often a sign of acute or chronic bronchitis. In the dog – often fat and middle-aged – chronic bronchitis may result in a cough persisting for weeks or months at a time and recurring in subsequent years, and is due to excessive secretion of mucus in the trachea and bronchi. It may follow an attack of pneumonia. A cough is also a sign of valvular disease of the heart. (See also KENNEL COUGH.)

A sporadic yet persistent cough, noticed especially after exercise or excitement, may be a sign of infestation with the common tracheal worm *Oslerus osleri*. Mortality among puppies of four to eight months has been as high as 75 per cent in some litters, following emaciation. Less serious is infestation with *Capillaria aerophilia*, which may give rise to a mild cough. A soft 'blowing' cough is a clinical sign of warfarin poisoning in the dog.

Cats Coughing is (in addition to sneezing) one sign of viral diseases such as feline viral rhinotracheitis and feline calicivirus infection; tonsillitis; as the result of grass seeds lodged in the pharynx; infestation by the cat lungworm; pleurisy; bronchitis; pneumonia; tuberculosis; and some cases of feline leukaemia. (See under separate headings.)

Cattle (See CALF PNEUMONIA; IBR under RHINOTRACHEITIS, INFECTIOUS BOVINE; PARASITIC BRONCHITIS; 'SHIPPING FEVER'; TUBERCULOSIS.)

Coumarin

A chemical compound present in sweet vernal grass, in sweet clovers, and in other plants. Although harmless in itself, coumarin may be converted to DICOUMAROL if hay containing such plants becomes mouldy or overheated.

Coumestans

These are organic compounds derived from COUMARIN. Some are PHYTOESTROGENS and can bind with 17ß OESTRADIOL receptors. They can be found especially in legumes such as some types of ALFALFA and CLOVER.

Council of Europe

An organisation of 49 sovereign European countries that issues conventions from time to time. Those of importance in animals include:

Convention for the Protection of Animals during International Transport
Convention for the Protection of Animals for Farming Purposes
Convention for the Protection of Animals for Slaughter
Convention for the Conservation of European Wildlife and Natural Habitats
Convention for the Protection of Vertebrate Animals used for Experimental and Other Purposes
Convention for the Protection of Companion Animals

The European Union has ratified all of these except those for slaughter and companion animals. The British government has not signed or ratified the Convention of Companion Animals, but the Animal Welfare Act 2006 contains most of its important provisions.

Council of Ministers

This comprises the appropriate Ministers from each member state of the European Union. In the case of most animals the British representative is the Secretary-of-State for Environment, Food and Rural Affairs. For experimental animals it is the Home Secretary. The Council, after consulting

their own experts and the European Parliament, decides the final version of European Directives. A directive is then passed to the European Commission to translate it into the languages of the Union. The other role of the Commission is to ensure that the terms of any directive are complied with by member states.

The Council may issue regulations that are binding on all member states without the need for national legislation. Two of importance to the veterinary profession concern the residue levels in food for human consumption, and the adherence to CITES (Convention on Trade in Endangered Species).

Counter-irritation, Counter-irritant

Production of an inflammation or irritation to counteract and distract from another area of inflammation or irritation. These include BLISTERS and FIRING. The theory dates from antiquity and is now little used.

Cowbane Poisoning

(See WATER HEMLOCK.)

Cowherds

Occupational hazards of those in charge of cattle include ANTHRAX; BRUCELLOSIS; LEPTOSPIROSIS; RINGWORM; Q FEVER; TUBERCULOSIS; cowpox (see under POX); MILKER'S NODULE; salmonella (see SALMONELLOSIS); SPOROTRICHOSIS and BUBONIC PLAGUE (not in the UK).

Cow Kennels

These have become popular as a cheaper (first cost) alternative to cubicle houses, though some have been developed to the point where they are almost cubicle houses, with the wood or metal partitions forming an integral part of the structure. Slurry can be a problem, and sometimes exposure to draughts and rain requires protection with straw bales or hardboard at the ends. (See also CUBICLES FOR COWS.)

Cowper's Gland

The bulbo-urethral glands, which are situated one each side of the urethra (see SEMEN).

Cowpox

(See under POX.)

Cowpox, Pseudo-

(See MILKER'S NODULE.)

Cowpuncher

An instrument used at slaughter to render an animal unconsciousness prior to EXSANGUINATION. The head remains intact because the device delivers a shock to the brain. It is not a firearm but a licence is required for its use.

Cows

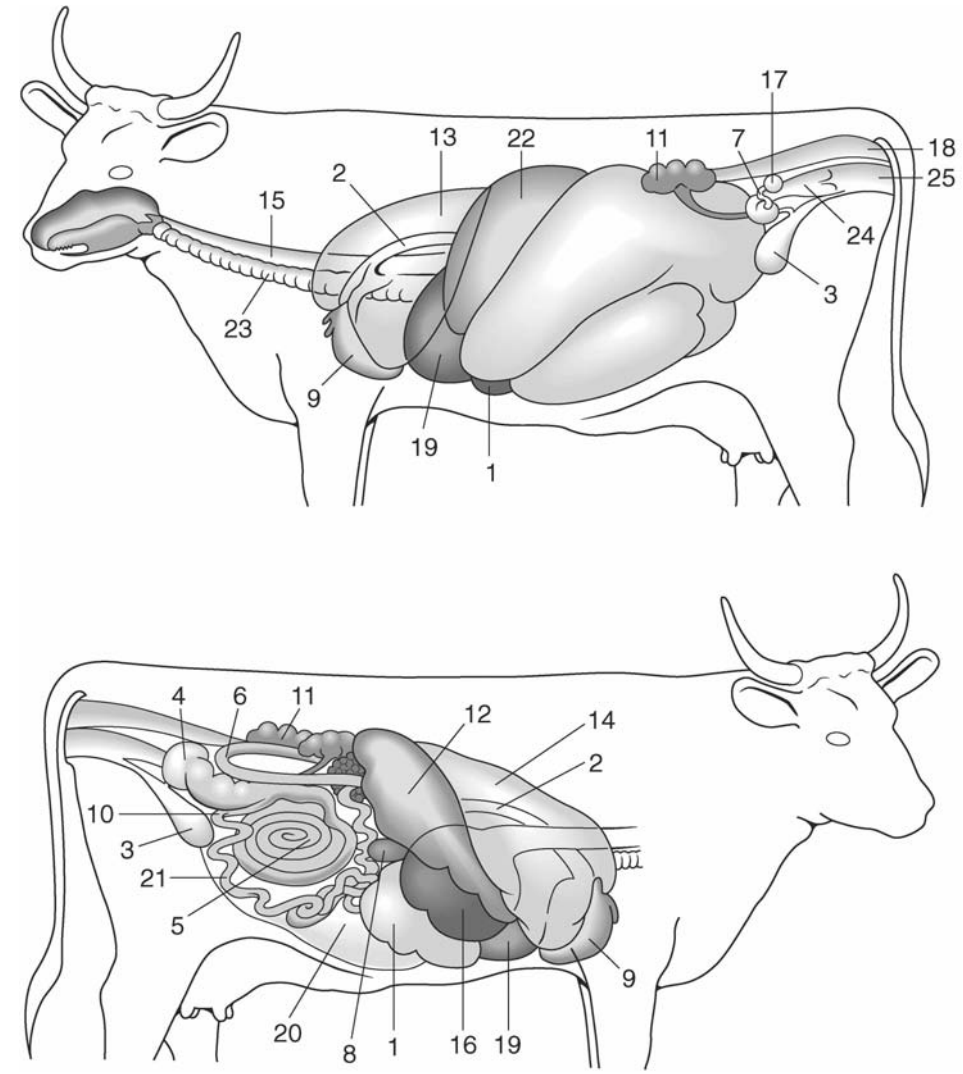
Gentle treatment Cows should at all times be quietly and gently treated. Hurried driving in and out of gates and doors, chasing by dogs or beating with sticks should not be tolerated. A cow in milk must have time to eat, chew and digest her food in comfort, and rough treatment will not only interfere with digestion but will also disturb the nervous system which more or less controls the action of the milk-making glands, thus lessening the milk yield. (See STRESS.)

Gentle treatment should begin with the calf, and be continued with the yearling, two-year-old, and in-calf heifer; when young stock is accustomed to being handled there will be no difficulty in the management and milking of the newly calved heifer; her milk yield will be increased, and much time will be saved. (See MILKING; also VETERINARY FACILITIES ON THE FARM.)

Comfort and fresh air The housing provided should ensure comfort. In winter, sufficient bedding should be provided to keep the cows warm and clean. (See HOUSING OF ANIMALS; RATIONS FOR LIVESTOCK.)

Cow's Milk, Absence of

In a newly-calved cow giving virtually no milk, the cause may be a second calf in the uterus, and a rectal examination is accordingly advised. In rare cases, a normal milk yield may follow the birth of the second calf which may occur a few months later. (See SUPERFETATION; also AGALACTIA.)



COX-1

An abbreviation for cyclooxgenase-1 and also known as prostaglandin endoperoxide synthase 1 or prostaglandin G/H synthase 1. COX-1 is different from COX-2 by having ISOLEUCINE at position 523. It is found in inflammatory situations and is the key enzyme in biosynthesis of PROSTAGLANDINS from ARACHIDONIC ACID. Pharmacological inhibition of COX-1 by drugs such as NSAIDs can provide relief from pain and inflammation.

COX-2

An abbreviation for cyclooxgenase-2 and also known as prostaglandin endoperoxide synthase 2. COX-2 is different from COX-1 by having VALINE at position 523. It is found in inflammatory situations and is the key enzyme in biosynthesis of PROSTAGLANDIN H2 from ARACHIDONIC ACID. Until recently, pharmacological inhibition of COX-2 by NSAIDs providing relief from pain and inflammation was non-specific. However there are now some medicines which more specifically target COX-2.

VetBooks.ir

INTERNAL ORGANS OF THE COW

1. abomasum
2. aorta
3. bladder
4. caecum
5. colon
6. duodenum
7. fallopian tube
8. gall bladder
9. heart
10. ileum
11. kidney, left
12. liver
13. lung, left
14. lung, right
15. oesophagus (gullet)
16. omasum
17. ovary, left
18. rectum
19. reticulum
20. rumen
21. small intestine
22. spleen
23. trachea (wind-pipe)
24. uterus
25. vagina

Coxalgia

Coxalgia means pain in the hip-joint.

Coxiella

Micro-organisms in the order Rickettsiae (see under Q FEVER).

Coxitis

Inflammation of the hip-joint.

Coxsackie B Virus

A group of enteroviruses which mainly infects horses. Infection in dogs may be a cause of diar-

rhoea; swine vesicular disease is antigenically related to coxsackie B7 virus. Infection in laboratory workers has caused influenza-like symptoms, and sometimes heart disease and meningitis.

Coyotes
Coyotes are rabies-vectors in the USA.

CP
Abbreviation for crude protein, used as a measure of protein in feed.

CPK
Abbreviation of creatine phosphokinase. (See CREATINE KINASE.)

CPRA
(See CENTRAL PROGRESSIVE RETINAL ATROPHY.)

Crab Lice, *Phthirus pubis*
Crab lice (*phthirus pubis*) occasionally infest dogs, but this happens only in a household where people are infested.

Crabs
Hermit crabs (*Paguroidea*) are kept as pets especially in the USA. There are different types including land, freshwater and seawater, and they tend to be nocturnal feeders. They have long soft bodies and protect themselves by using empty sea shells and other molluscs. Tanks must be large (at least 45 litres [10 gallons]). They require a temperature of (21° C to 24° C) (70° F to 75° F) with a humidity greater than 70 per cent in an aquarium, with about 5 cm to 7.5 cm (2 in to 3 in) of sand. They can be infected with a fungal infection 'shell disease'.

(See also FOOD POISONING IN MAN.)

Cramp
Painful involuntary contraction of a muscle. Cramp is of importance in the racing greyhound, which is observed to slow down and drag both hind-legs, or – in severe cases – may collapse and struggle on the ground. The animal's gait and appearance are 'wooden'. The muscles of the hindquarters are hard to the touch. Cyanosis may be present. Recovery usually takes place within a quarter of an hour, aided by rest and massage. Possible causes include: fatigue, defective heart action, bacterial or chemical toxins, sexual repression, a dietary deficiency, poor exercise, and cold. (See also 'SCOTTIE CRAMP'; MUSCLE – Action.)

Craniad
An anatomical term meaning 'towards the front end of the body'.

Cranial Meningocele
The meninges protruding through the cranial fissure.

Cranial Nerves
Cranial nerves are those large and important nerves that originate from the BRAIN.

Craniocele
The protrusion of any part of the brain through a defect in the skull.

Craniomandibular Osteopathy
An inherited proliferative condition of the skull and jaws in breeds of dog, especially the West Highland White terrier and including Boston terriers and Cairn terriers. Symmetrical bony enlargements of the temporal bone, mandible, and occasionally the long bones, may be seen and pain experienced. There may be difficulty in breathing and swallowing. Steroid therapy may be effective although the condition can recur in dogs less than a year old. It is rarely seen in older animals.

Craniopagus
A double-headed monster of cattle. In a double-headed calf delivered by Caesarean section in Trinidad, major abnormalities involved skeletal structures and included: fusion of both crania at the parieto-occipital-temporal regions; presence of cleft palate involving both the palatine process of the maxilla and the horizontal plate of the palatine bone; and malalignment of the mandibles.

The cranial fusion resulted in the existence of a single complete occipital bone which articulated with both crania at their ventrolateral surfaces, and bounded a single foramen magnum articulated with the occipital bone interposed between them.

Craniorhachischisis
A congenital condition involving EXENCEPHALY and HOLORRACHISCHISIS.

Cranioschisis
A congenital fissure of cranium.

Craw
(See CROP; synonym INGLUVIES.)

'Crazy Chick' Disease, Nutritional Encephalomalacia
'Crazy chick' disease, or nutritional encephalomalacia, is caused by vitamin E deficiency associated with a diet too rich in fats, or containing food which has gone rancid, and vitamin E has been used in its prevention. It is seen at two to four weeks of age. Signs include falling over, incoordination, paralysis and death. Similar signs are seen in avian encephalomyelitis, a virus disease of chicks under six weeks of age.

VetBooks.ir

CRD

(See CHRONIC RESPIRATORY DISEASE.)

Creatine Kinase (CK)

Creatine kinase is an enzyme found mainly in muscle. The activity of this enzyme in serum or plasma is used as an aid to the diagnosis of skeletal or heart muscle lesions. (See MUSCLE - ACTION OF MUSCLE.)

Creatinine

A nitrogenous compound produced as an end-product of creatine metabolism. Small amounts are produced in the muscle, go via the blood and are excreted in the urine. High blood levels indicate renal disease.

Creep-Feeding

The feeding of unweaned piglets in the creep – a portion of the farrowing house or ark inaccessible to the sow and usually provided with artificial warmth. Creep-feeding often begins with a little flaked maize being put under a turf, and is followed by a proprietary or home-mixed meal from three to eight weeks. Creep-feeding of in-wintered lambs and calves is also good practice.

Housed calves usually creep-feed hay or silage plus concentrates from a few weeks of age. Excessive creep-feeding with concentrates before turnout of autumn-born calves depresses gains at grass.

Creep-feeding at grass from the late summer can improve calf performance. With autumn-born calves, creep-feeding a total of up to 100 kg barley will improve weaning weights by up to 23 kg. But as the calves grow larger it is difficult to allow them access to a creep while excluding smaller cows. Some producers wean early, graze the calves on high-quality aftermaths and use the cows to eat down rougher areas. Because milk contributes more to the growth of spring-born calves, creep-feeding can be delayed until later in the season. But in the last few weeks before weaning, a total of 40 kg barley can be expected to increase weaning weights by up to 15 kg.

Creep-feeding of calves prior to weaning also has the advantage of conditioning them for future diets and guarding against any check in growth rate that may occur as a result of weaning. (See table below)

Effects of creep feeding on calf weaning weight

	Supplementary feed (kg)	Extra calf weaning wt. (kg)
Autumn-born calves	76	19
Spring-born calves	30	10

Creep-Grazing

Creep-grazing is a method of pasture management, enabling lambs to gain access to certain areas of pasture in advance of their dams.

Cremation and Burial of Pet Animals

This service is offered by a number of companies, or a veterinary surgeon can advise. Often animals are cremated simultaneously in numbers. Individual cremation should be ordered if return of the ashes is required.

Crenosoma

A genus of lungworms. *Crenosoma vulpis* infects dogs and some wild carnivores. *Crenosoma striatum* infests hedgehog lungs.

Creosote

A mixture of PHENOLS from wood tars and used as a wood preservative. It has been used as an external ANTISEPTIC and also internally as an EXPECTORANT in chronic BRONCHITIS. Poisoning can particularly occur in dogs and cats from grooming. (See POISONING - DOGS AND CATS).

Creosoted Timber

Creosoted timber may give rise to poisoning in animals, particularly young ones, where wooden housing has been freshly treated. For disease in cattle from this cause, see under HYPERKERATOSIS.

Cats are prone to creosote poisoning. Contaminated paws may be cleaned by coating them with cooking oil, and then washing this off with a mild detergent. Great care must be taken that the animal does not lick the affected area until it is adequately cleaned.

Crepitus

Crepitus is: (1) the grating sound of fractured bones when handled; (2) a dry crackling sound in the lung; (3) the discharge from the bowels of flatus.

Cresol Solutions

(See DISINFECTANTS.)

Cretinism

Dwarfism caused by an insufficiency of the hormone THYROXINE. (See also THYROID GLAND.)

Creutzfeldt-Jakob Disease (CJD)

Creutzfeldt-Jakob disease (CJD), which has a worldwide distribution, is characterised by spongiform degeneration of the brain. Once symptoms appear, it is invariably fatal. Transmission has occurred through a corneal transplant.

In 1995 a 'new variant' of CJD (Variant CJD [vCJD]) appeared in young people; it has been linked to the consumption of BSE-infected meat products. Up to and including 2010 the total

deaths recorded were 171, with a peak of 28 deaths in 2000 and three in 2010. Recorded cases are now very few and treatment has prolonged life but does not cure the condition.

Cria
An infant camelid.

Crib-Biting and Wind-Sucking
Crib-biting and wind-sucking are stereotypies. They can develop in any age of horse kept in an unnatural environment, e.g. in a box for 23 hours out of 24 hours. They are similar vices but they are not learnt from other horses. Air is only partially swallowed into the oesophagus but does not reach the stomach. A 'crib-biter' effects this by grasping the edge of the manger or some other convenient fixture with the incisor teeth; it then raises the floor of the mouth; the soft palate is forced open; a swallowing movement occurs; and a gulp of air is passed down the gullet into the stomach. A 'wind-sucker' achieves the same end, but it does not require a resting-place for the teeth. Air is swallowed by firmly closing the mouth, arching the neck, and gulping down air in much the same way.

In crib-biters the incisor teeth of both jaws show signs of excessive wear. Careful consideration of the horse's environment should be taken with professional advice being sought.

Crimp
The regular wavy formation of wool. It is particularly represented in the wool of the MERINO breed. METHIONINE and COPPER are important in crimp formation.

Crocodiles, Farmed
In mainland Europe and also England the Nile crocodile (*Crocodylus niloticus*) is reared. Farms are found in Africa and Australia where they are reared for their leather and meat. Males usually measure 3.5 m to 5 m or more with females about 30 per cent smaller. The largest recorded male was 6.45 m and weighed 1,090 kg. In the wild crocodiles live 70 to 100 years. Adult crocodiles have 66 to 68 TEETH. The Nile crocodile is relatively free of disease, although skin conditions do occur. Sudden loss of the righting reflex was the outstanding feature of a thiamine-responsive disease in softwater crocodiles (*Crocodylus porosus*). Affected hatchlings were found floating or lying on their sides, unable to right themselves.

Treatment Two intramuscular injections of 30 mg thiamine hydrochloride 24 hours apart.

Crohn's Disease
A regional granulomatous enteritis primarily of the large intestine occurring in man. There are equivalent conditions in animals, including Johne's disease (paratuberculosis) in cattle, equine proliferative enteritis, enterocolitis in Cocker spaniels, and histiocytic ulcerative colitis in Boxer dogs. A similar condition, if not identical to this, is seen in ferrets.

Cromoglycate, Sodium
The sodium salt of cromoglicic acid. It is used as an aerosol to prevent bronchial asthma and allergic rhinitis. The drug prevents the release of inflammatory chemical mediators of immediate sensitivity such as histamine from mast cells and basophils. Its main use has been in horses with RECURRENT AIRWAY OBSTRUCTION (see CHRONIC OBSTRUCTIVE PULMONARY DISEASE).

Crooked Toe Deformity
A condition seen in chicks brooded under infrared lamps. The birds have difficulty in walking; the toes are turned out because of malformation of the lower metatarsal and foot bones. The cause is unknown.

Crop
The crop (INGLUVIES or CRAW) of birds is a dilatation of the gullet at the base of the neck, just at the entrance to the thorax. In it the food is stored for a time and softened with fluids. It acts as a reservoir from which the food can be passed downwards into the stomach, gizzard, etc., in small amounts or regurgitated to feed chicks.

Crop, Diseases of
By far the commonest trouble affecting the crop of the bird is that known as 'crop-bound', in which food material collects in the crop through the swallowing of bodies which cannot pass on to the stomach and gizzard. This may include feathers, wool, straw, small pieces of stick, etc. Other cases are due to a lack of vitality in the walls of the crop, which become too weak to force the contents onwards.

The dilated crop can often be noticed pendulous and distended. Death occurs from exhaustion unless relief is obtained. Massage of the impacted food material from the outside, along with the introduction of warm liquid in small amounts through a rubber tube, may be sufficient to dispel mild impactions, but usually surgical opening is required.

Ingluvitis or inflammation of the crop may be due to a primary or secondary infections (bacterial or fungal) – the latter follows the feeding formula to hand-reared chicks and so is common in cage birds. (See under CAGE AND AVIARY BIRDS, DISEASES OF.)

VetBooks.ir

Cross-Eye
(See STRABISMUS.)

Cross-Immunity
Immunity resulting from infection with one disease-producing organism against another. For example, measles infection in dogs gives rise to a degree of immunity against canine distemper virus.

Cross Pregnancy
Development of a fetus in the opposite horn of the uterus to that side on which ovulation occurred. Migration from one horn to the other may occur.

Croup
Croup of the horse is that part of the hindquarters lying immediately behind the loins. The 'point of the croup' is the highest part of the croup, and corresponds to the internal angles of the ilia. The crupper of the harness passes over the croup, and derives its name from it.

Crows
Carrion crows (*Corvus corone*) often cause injury, and sometimes death, to ewes and lambs, and in addition they may transmit CAMPYLOBACTER infection.

In India, house crows (*Corvus splendens*), which live in close contact with people and domestic animals, can be important in the transmission of Newcastle disease to domestic poultry. The crows themselves may show no signs, but can excrete highly virulent virus over a short period. (See WEST NILE VIRUS.)

Cruciate Ligament Rupture
In some dog breeds the stifle is normally carried in a very straight conformation, which predisposes to rupture of the anterior (cranial) ligament. The knee joint becomes unstable and this can lead to other problems with a meniscal cartilage injury and osteoarthritis. It is rare for the posterior (caudal) cruciate ligament to be damaged. Some dog breeds are particularly susceptible to cruciate ligament rupture. This is partly because some breeds are engaged in more strenuous exercise than others, including gun dogs and sheep dogs, and are more likely to damage the ligament whether or not previously damaged or degenerated. The cause of the degeneration is not known but it is suggested that in the susceptible breeds the cranial ligament is weaker than in less susceptible breeds. Those breeds susceptible include BOXERS, GOLDEN RETRIEVERS, LABRADOR RETRIEVERS, MASTIFFS, NEWFOUNDLANDS, ROTTWEILERS and WEST HIGHLAND WHITES. Rupture can occur at a relatively early age (one to three years); it is suggested that obese dogs are more susceptible and both legs can be affected.

Various techniques have been used to stabilise the joint after ligament rupture, including surgical reshaping the proximal tibia: tibial plateau levelling operation, tibial tuberosity advancement and triple tibial osteotomy. Less invasive surgery involving application of a ligament transplant or synthetic material to the outside of the joint is also used.

Cruciate Ligaments
Cruciate ligaments are two strong ligaments in the stifle-joint which prevent any possibility of over-extension of the joint. They are arranged in the form of the limbs of the letter X. In some dog breeds the stifle is normally carried in a very straight conformation, which predisposes especially to rupture of the anterior (cranial) ligament.

Cruelty, Avoidance of
(See LAW; ANAESTHETICS, LEGAL REQUIREMENTS; CASTRATION; TRANSPORT STRESS; WATER AND WATERING OF ANIMALS; EUTHANASIA; DOCKING; NICKING; WELFARE CODES FOR ANIMALS; NUTRITION, FAULTY; STRESS; TETHERING; OVERSTOCKING.)

Crural
Relating to the leg.

Crush
A pen constructed of wood or tubular steel, and used for holding cattle, etc., in order to facilitate tuberculin testing, inoculations, the taking of blood samples, etc. It is used in many species and provides safe handling for both animals and people. The animal is usually restrained by the narrow sides, a yoke to hold the head and some form of tail bar or gate. In mobile crushes there should be a floor so that the crush is not capable of being moved by the animal. This should have cross bars to prevent slipping. All crushes must be kept in good working order so that all mobile parts work well and there should be methods of quick release if an animal slips over or starts to asphyxiate itself. Crushes for deer when applied suspend the animal off the ground.

A wooden crush is less noisy than a metal one; clanging metalwork can be alarming to cattle. Nevertheless, metal is more often used, particularly for making mobile crushes. Collecting cattle in darkened pens or boxes an hour before testing is due to begin makes for better behaviour in the crushes.

An efficient type of crush is one constructed in a building through which the cows always come on leaving the parlour. The two ends are solid and fixed in concrete. The sides consist of iron gates hinged one on the front and the other on the back of the crush. Before an animal enters, the gate

hinged on the front is opened back against the wall. This provides a wide space and she is not asked to enter a narrow confine. When she is in, the gate is shut and the neck secured with a rope. The other gate may now be opened and testing done without reaching through the side of the crush.

A funnel-shaped pen for filling the crush is useful, and if the crush is big enough to hold two animals, the second will enter more readily. Fast working can be achieved with a race to hold seven or eight cows; there being two men each with a rope on the side opposite to the veterinary surgeon. The whole batch is tested before release.

The traditional neck-yoking feature of cattle crushes is often abandoned for a design in which the animal is restrained by pressure from the sides of the crush moving together. Cattle are said to enter it more readily and to stand more quietly in it.

Various automatic crushes are available as well as ones which allow rotation of the animal to allow foot trimming. (See also VETERINARY FACILITIES ON THE FARM.)

Crushed Tail Head Syndrome

A condition in dairy cows in which there is tail paralysis, hind-limb weakness and knuckling of the fetlock joint. It occurs suddenly, usually in healthy cows showing recent oestrus activity. The clinical signs follow damage to the sacral vertebrae which affects the sacral and coccygeal nerves, Vigorous mounting by a bull may be the cause of the trauma. Recovery is more likely in those cases less badly affected.

'Crutching'

'Crutching' means shearing of wool from a sheep's breech, tail, and back of hind-legs. It is done before May and in autumn as an aid to controlling 'STRIKE'.

Cryospray

The use of liquid nitrogen in cryosurgery.

Cryosurgery

Destruction of unwanted tissue (e.g. of a tumour) by the use of very low temperatures. For example, a metal rod, cooled in liquid nitrogen to –196° C (-321° F), may be applied to the tumour.

Dogs Cryotherapy has been found useful in several conditions, including intractable interdigital cysts and LICK GRANULOMA.

Cats It has been used for the relief of highly irritant eczema, and also eosinophilic granulomatous lesions; especially those involving the lips and hard palate, and in cats suffering from chronic gingivitis/stomatitis.

Horses Cryosurgery may be used in the treatment of sarcoids, squamous cell carcinoma and other neoplastic conditions of the skin, and for the removal of excessive granulation tissue. In ophthalmology it can be used for the treatment of retinal detachment, iris prolapse, glaucoma and the extraction of cataracts.

Cryptocaryon

A parasite inhabiting the skin of salmonid fish kept at high density in salt water conditions.

Cryptococcosis

Infection with the yeast *Cryptococcus neoformans* occurs occasionally in all species. Lungs, udder, brain, etc. may be involved. It has been described as the least rare of fungal infections in the cat – in which it may give rise to sneezing, a discharge from the eyes, and sometimes to a nasal granuloma. Other signs include cough and dyspnoea.

Bone and eye lesions may be produced. (See also EPIZOOTIC LYMPHANGITIS.)

Cryptorchid

An animal in which one or both testicles have not descended into the scrotum from the abdominal cavity at the usual time. It is also termed a RIG. When one testicle is not descended it is called a MONORCHID. The condition may cause some irritability or aggression in the animal. The retained testicle(s) may be defective. (See also under GELDING.)

It is seen occasionally in all species and in the horse and pony (where it is relatively common) it is inherited.

In several breeds of pigs it has been shown that some individual males start with two apparently normal testicles in the scrotum at birth, but that within a few weeks or months one testicle may decrease in size and then may disappear from the scrotum, ascending back into the inguinal canal inside the abdomen. Absorption of this testicle may occur, so that by the time the animal is six months old there may be no remains, or virtually none, of the missing testicle to be found.

The name 'late cryptorchids' has been given to animals that have two testicles in the scrotum at birth, but subsequently only one. A study referred to the finding of 44 such late cryptorchids out of 110 cryptorchid Lacombe boars. In equines where a testicle cannot be found, the animal should be referred to a specialist equine surgeon. (See also under MONORCHID; CASTRATION.)

Cryptosporidiosis

Disease caused by protozoan parasites of the genus *Cryptosporidium* and of the order Coccidia. *Cryptosporidia* are not host-specific like other coccidia. The oocyst is the infective stage. It causes diarrhoea

VetBooks.ir

in mammals and may also cause respiratory disease in poultry. Both farm and companion animals may be affected. The disease is more severe in young animals; some older ones may become carriers. Infected animals grazing near rivers or on the banks of reservoirs may contaminate water supplies; the parasite is not usually removed in the normal filtering process and so public water supplies may be a source of infection for humans or animals. Diagnosis is by identifying the parasite in faecal smears; special staining techniques are required.

Public health In humans, cryptosporidiosis causes a severe and malodorous diarrhoea which may last up to two weeks. Cases usually arise from drinking contaminated water, although animal to human transmission has occurred. It can contaminate swimming pools if the water is treated inadequately. It is an important zoonotic problem in children and precautions need to be made on open and petting farms.

Treatment Halofuginone is used for treatment and prophylaxis in calves.

CSF

Abbreviation of Classical Swine Fever. (See SWINE FEVER.)

CT Scanning

An abbreviation for COMPUTED TOMOGRAPHY using a CT scanner. (See X-RAYS - COMPUTED TOMOGRAPHY; DIAGNOSTIC IMAGING.)

Cubes and Pellets

Animal feed compressed into small cubes or pellets. A cow takes about 10 minutes to eat 3.5 kg (8 lb) of cubes: a fact of some importance if the animals are fed in the milking parlour where time may not permit of a high-yielder receiving her entire concentrate ration. (The figure for meal is about 2.75 kg (6 lb) in 10 minutes.) (Compare also with LIQUID FEEDING.)

It is sometimes suggested that cubes can replace hay for horses on pasture in winter, or for rabbits, chinchilla, etc. which are not out at grass. However, roughage is needed in addition for peristalsis and health of the digestive system. (See also HORSES, FEEDING OF; DRIED GRASS.)

The type of lubricant used in cubing and pelleting machines is important; hyperkeratosis can arise in cattle if an unsuitable one is used. (See LUBRICANTS.)

Cubicles for Cows

Cubicles were introduced over 35 years ago and have varied in size and design. One of the earliest was the Newton Rigg design, a type which allows the cattle to be loose housed but, once built, is difficult to alter to accommodate different sizes of cattle. Cubicles designed for Friesian cows have had to accommodate the larger Holstein animal, with resulting problems including lameness and mastitis. The large modern Holstein cow requires longer cubicles to be suitably housed.

The ideal cubicle will allow the cow to take up her normal resting positions and give room to get up and down easily. Cubicles are usually built from metal tubing or wood, although division rails are sometimes of wire or tensioned rope.

Dimensions are, typically, length 2.4 m (8 ft), width 1.2 m (4 ft), rear step not more than 150 mm (6 in), fall from front to rear 100–125 mm (4–5 in), division height 1.125 m (3 ft 9 in), lower division rail 400 mm (1 ft 4 in), brisket board 105 mm (4 in) deep, brisket board from rear 1.7 m (5 ft 8 in), brisket board from front 0.75 m (2 ft 6 in), head rail 150–250 mm (6–10 in) below average wither height. The passageway between the cubicles should be greater than 2.4 m (8 ft) wide to minimise build up of slurry. Comfortable, clean bedding should be provided. It is essential that both passageway and cubicle are kept clean to avoid transmission of faeces from the cows' feet to the udders when they lie down.

There are several types of cubicle. It appears that the type of heelstones, floor and the width are important factors in determining whether cows take to cubicles or not. (See also COW KENNELS.) Bad design can lead to injury and lameness.

Cuboni Test

Cuboni test for pregnancy involves a single urine sample taken after 150 days of pregnancy. It is an alternative to rectal palpation in the mare but is not as reliable as that method or as a blood test for oestrone sulphate.

Cud and Cudding

(See RUMINATION; QUIDDING.)

Cuffing Pneumonia

A pneumonia of calves caused by a virus or mycoplasma. A chronic cough is the usual sign. It is so called because a 'cuff' or sheath of lymphocytes forms around the bronchioles.

Culard

Muscular hyperplasia, or so-called 'DOUBLE MUSCLING'.

Culicoides

This is a Genus of biting midges with about 500 species. Studies are defining the genetic sequencing of the midge. They are dipteran insects from the Family *Ceratopogonidae*. They occur in many parts of the world with different species adapted to the prevailing climate conditions and are altering

locations and invading new ones with climate change. Their life cycle involves egg laying and larval development in areas that vary between species, but may be on vegetation, often rotting, in manure heaps, damp soil, or slow running water. The life cycle in ideal conditions takes three to seven days. Only the females feed on blood and the bite is noticeable and usually occurs at dusk or dawn, but both males and females feed on nectar. The females can be seen as dense clouds in the early morning and late afternoons usually near water, damp areas or where there is rotting vegetation. Some culicoids cause or transmit disease including AFRICAN HORSE SICKNESS, BLUETONGUE, SCHMALLENBERG VIRUS. They produce HYPERSENSITIVITY reactions in horses and ponies, resulting in 'SWEET ITCH'. (See MIDGES, BITING.)

Culling

The separation or removal of live animals from a farm or herd for a variety of reasons. These include disease, disease control to prevent spread (e.g. FOOT-AND-MOUTH DISEASE), and production reasons such as poor production, poor fertility, old age or injuries.

Culture Medium

That substance in or upon which bacteria and other pathogenic organisms are grown in the laboratory. Such media include nutrient agar, broths, nutrient gelatin, sugar media, and many special ones adapted to the requirements of particular organisms. Viruses cannot be grown in such media but require living cells, e.g. of chick embryos.

Curare

Curare is a dark-coloured extract from trees of the Strychnos family, which causes muscular paralysis. It is used by South American Indians as an arrow poison. Curare-treated arrow-heads were used by a veterinary surgeon in 1835 in treating tetanus in a horse and a donkey.

Curare, when injected, is one of the most powerful and deadly poisons known, but by the mouth it is harmless, since the kidneys are able to excrete it as rapidly as it is absorbed, and it does not collect in the system. Its action depends on the presence of an alkaloid, curarine, which paralyses the motor nerve-endings in muscle, and so throws the muscular system out of action yet leaving the sensory nervous system unaffected. A standardised preparation of tubocurarine is used to obtain muscular relaxation during anaesthesia. (See also under MUSCLE RELAXANTS.)

Curb

Curb is a swelling which occurs about a hand's breadth below the point of the hock, due to sprain, or local thickening of the calcaneocuboid ligament, or to similar conditions affecting the superficial flexor tendon. Lameness is usually present at first.

'Curled Tongue'

A deformity occurring in turkey poults, due to feeding an all-mash diet composed of very small particles in a dry state, during the first few weeks of life. If a change is made to wet feeding many of the poults will become normal.

Cushing's Syndrome, Hyperadrenocorticism

This has been recognised and treated in the dog, occurring usually after the age of five years, and in the cat. It is also seen in old horses and ponies with hairy coats, lethargy, polydipsia or laminitis.

Cause Excessive production of corticosteroids by the adrenal cortex. In some cases there is a tumour affecting the adrenal gland or the pituitary; in others merely excessive growth of the adrenal cortex. It may result from over-administration of glucocortisoids.

Signs These include lethargy, premature ageing, baldness, skin eruptions, excessive thirst, 'pot belly', and a ravenous appetite. Wasting of the temporal muscles may be seen. Skin changes may not occur until up to a year after thirst becomes noticeable.

There may also be a change of coat colour and texture. A six-year-old male poodle, clipped eight months previously, developed a sparse and fluffy coat; instead of being an apricot colour it was now pure white. The dog was drinking over 800 ml of water per day and scavenging for food. A diagnosis of Cushing's disease was confirmed by means of the adrenocorticotrophic hormone (ACTH) test.

Treatment Mitotane given orally is used in dogs. A daily dose calculated by weight is given until thirst becomes normal, followed by a weekly or fortnightly maintenance dose. (Mitotane is obtainable by a veterinary surgeon only on completion of a special Treatment Authorisation.) The drug trilostane has been used successfully in treating dogs with pituitary-dependent hyperadrenocorticism.

This treatment is a preferable alternative to surgery, but success has followed surgical removal of both adrenal glands where intensive care has been provided both before and after the operation. Salt supplementation and implants of desoxycorticosterone acetate (DOCA) are necessary following the adrenalectomy. In horses treatment is based on a daily oral dose of a licensed product, pergolide, at 1 mg per 500 kg.

VetBooks.ir

Cutaneous
(See SKIN.)

Cutaneous Asthenia
Cutaneous asthenia is associated with defects in the formation and maturing of collagen fibres. The skin becomes fragile and more elastic than normal, and a dog's skin may appear 'too big for its body'. (The human equivalent is the EHLERS-DANLOS SYNDROME.)

Cutter
A pork pig weighing 64 kg to 86 kg (140 lb to 190 lb) liveweight or 45 kg to 64 kg (100 lb to 140 lb) deadweight.

Cutting
(See BRUSHING AND CUTTING.)

Cuttlefish
The internal bone of the cuttlefish is used as a dietary supplement and exercise toy for caged birds.

CVH
(See CANINE VIRAL HEPATITIS.)

Cyanides
Cyanides are salts of hydrocyanic or prussic acid. They are all highly poisonous. (See HYDROCYANIC ACID.)

Cyanobacteria, Blue-Green Algae
Cyanobacteria (blue-green algae) are micro-organisms able to convert nitrogen from the air to ammonia, using the enzyme nitrogenase and sunlight as the energy source. The presence of cyanobacteria in plankton and scum accumulating along leeward shores of the UK, etc. is a cause of death among fish and birds. It is also seen in reservoirs, and inland water such as the Norfolk Broads. Amongst others, it affects, birds, dogs, cattle and horses. Dogs swimming in lakes affected by blue-green algae have died. In Spain, greater flamingo chicks died in a marsh lagoon in Donana National Park when a dense bloom of cyanobacteria occurred in 2001.

Cyanocobalamin
Cyanocobalamin is the water-soluble vitamin B_{12}. At the nucleus of molecules of cyanocobalamin is cobalt, a deficiency of which leads to a deficiency of the vitamin. Some intestinal parasites have a very large requirement for cyanocobalamin, to the extent that infected animals may show a vitamin deficiency. In such cases, cobalt should be given as well as anthelmintics.

Hydroxocobalamin is an antidote in cyanide poisoning.

Cyanosis
A blue or purple discoloration of the tongue, lips and gums when there is a shortage of oxygen in the blood. It sometimes results when excessive strain is put upon the heart, in animals that have been hunted or chased. It is a sign of nitrite poisoning, and also occurs in a few cases of feline pyothorax, and in ASPHYXIA.

Cyathostomiasis
Infestation by one, or several, species concurrently of Cyathostome worms. They are a cause of chronic diarrhoea in horses. However, they can also cause acute diarrhoea when some trigger factor, as yet unknown but likely to be radical changes in temperature, allows encysted larvae to emerge and cause massive mucosal damage of the large intestine. The condition is life-threatening and requires treatment with large doses of corticosteroids. The disease is prevented by treatment in the autumn with moxidectin.

Cyclonite Poisoning
A plastic explosive, known as PE4, has as its active ingredient cyclonite, and this has caused poisoning in a police dog trained to detect explosives. In both dogs and man the poison causes epileptiform convulsions, best controlled by diazepam given intravenously, plus barbiturates if necessary. In the above case, the dog bit into some of the PE4 which had been concealed for a training exercise.

Cyclophosphamide
A drug used in the treatment of lymphoma, and certain other cancers, in cats and dogs. It can cause severe side-effects and must be used only under strict veterinary supervision.

Cyclopia
A congenital complete fusion of the eyes.

Cyclopiazonic Acid
A mycotoxin, which in chickens causes dilation of the proventriculus, with the mucosa being hyperplastic and ulcerated; gizzard mucosa necrosis may also occur.

Cyclopropane-Oxygen Anaesthesia
A costly but otherwise useful form of anaesthesia for dogs and cats. It has also been used for horses and goats. Cyclopropane is an inflammable gas.

Cyclops
This genus of minute crustaceans acts as the intermediate host of the broad tapeworm of man, dog, and cat.

Cyclosporin, Cyclosporine
Administered orally, it is a supporter of the reticuloendothelial system used to treat some cases of AUTO-IMMUNE DISEASES, such as canine atopic dermatitis. It may be used topically in cases of KERATOCONJUNCTIVITIS SICCA.

Cymric
The name, meaning Welsh, given to a breed of cat established from long-haired kittens born to Manx parents in Canada. The breed is known as Manx longhairs in the USA. It suffers from the same defects and problems as the MANX CATS.

Cypermethrin
A pyrethroid ectoparasiticide. It is used in sheep dips and in insecticidal ear tags for cattle.

Cypress Poisoning
Leaves of the cypress are toxic, although poisoning is rare. Two yearling heifers died in a field where several cypress trees (*Cupressus sempervirens*) were felled one morning. One heifer was dead by the afternoon; the other two nights later.

Cyromazine
An INSECT GROWTH REGULATOR which can be applied to the back and around the tail and crutch of sheep to prevent FLY STRIKE.

Cyst
A closed sac or capsule lined by epithelium and containing fluid or semisolid material. Most cysts are harmless. However, they can become malignant growths, or become infected or obstruct a gland. There are four types of cyst: embryonic cysts, exudation cysts, parasitic cysts, and retention cysts.

Varieties (a) *Retention cyst* This may be no more than a swollen sebaceous gland, filled with its normal secretion which has been unable to reach the skin surface owing to blockage of its duct. Retention cysts of other glands arise similarly.

(b) *Ovarian cysts* (see OVARIES, DISEASES OF).

(c) *Developmental cysts* The most important of these is the DERMOID CYST.

(d) *Hydatid cysts* are produced in internal organs through the ingestion of the eggs of tapeworms from other animals. They occur in the peritoneal cavity, liver, spleen, brain, etc. Commonly seen in rabbits due to infestation by the tapeworm *Coenurus serialis*.

(e) *Hard tumour cysts* sometimes occur in tumours growing in connection with glands, such as the adenocarcinomata, which may occur in the mammary gland of bitches.

(f) '*Interdigital cysts*' in between the toes of dogs are in reality often granulomas or abscesses. (See INTERDIGITAL CYST.)

Cystadenoma
(See CHOLANGIOMA.)

Cysteine
A sulphur-containing amino acid important in the detoxification of many chemicals, hair growth, promoting healing and developing the immune system.

Cystic Calculi
(See CALCULI.)

Cysticercosis
Infestation with TAPEWORM.

Cysticercosis in Man
Infestation with a *T. saginata* or *T. solium* (TAPEWORMS - CYSTICERCOSIS IN MAN).

Cystic Ovaries
(See OVARIES, DISEASES OF.)

Cystine
An amino acid (and a constituent of some urinary calculi).

Cystinuria
A congenital condition seen in humans and some dog breeds resulting in the presence of excessive amounts of the amino acids cystine, arginine, lysine and ornithine. It is due to impaired renal resorption and is seen as the presence of urinary cystine calculi. It is common in IRISH TERRIERS, LABRADOR RETRIEVERS and NEWFOUNDLANDS.

Cystitis
Inflammation of the urinary bladder. There are many causes, some of which are complicated by secondary bacterial infection. Clinical signs include frequency of MICTURITION, usually with STRANGURY. (See URINARY BLADDER, DISEASES OF.)

Cystocentesis
Aspiration of the contents of the urinary bladder by a hypodermic needle or catheter, approached through the body wall.

Cystopexia
Surgical fixture of the urinary bladder to the wall of the abdomen.

Cystotomy
The surgical opening of the URINARY BLADDER, usually to remove CALCULI or excise a TUMOUR. The incision in the bladder wall is then

VetBooks.ir

repaired. (See also CALCULI - URINARY CALCULI; URINARY BLADDER, DISEASES OF - URINARY CALCULI; URINARY BLADDER, DISEASES OF - TUMOURS.)

Cythioate
An organothiophosphate compound used as an INSECTICIDE particularly for FLEAS and an ANTHELMINTIC.

Cytocetes
(See EHRLICHIOSIS.)

Cytochrome
A group of HAEMPROTEINS, widely distributed in animals and plants and used in electron transport.

Cytogenetics
The study of chromosomes and the genetics of cellular constituents involved in heredity.

Chromosome analysis Usually, white blood cells are used, and these are inoculated into a liquid tissue culture medium, supplemented with serum and antibiotics. Phytohaemaglutinin, a plant extract which stimulates the white cells to divide, is added. The cultures are incubated for two days at 38° C (100° F). Then colchicine is added to arrest the dividing cells at the metaphase stage. Hypotonic solutions are used to swell the cells and spread out the chromosomes. The cells are then fixed, dropped on to slides, and stained.

Suitable cells containing well-spread chromosomes are selected on the slides after examining them under the microscope at 1000x magnifications. Some of the cells are then photographed, and the individual chromosomes cut out from the prints, paired and stuck on to a card. This is called the karyotype.

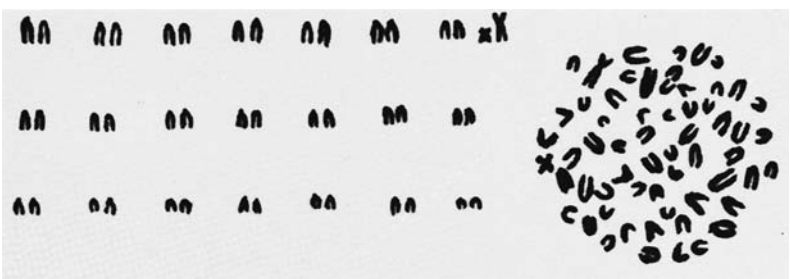
An example of chromosome abnormalities in cattle is the FREEMARTIN.

Centric fusions (Robertsonian translocations) are the result of two chromosomes fusing to form one, so that the total number of chromosomes in the cells is reduced. The 1/29 translocation was discovered by Gustavsson in about 1 in 7 of the Swedish Red and White breed of cattle, and has since been found in many other breeds. This autosomal abnormality, involving a member of each of pairs 1 and 29, has been found to be inherited through both the male and the female in Red Poll and Charolais cattle in Britain, and appears to be associated with lowered fertility in the female.

Many other chromosomal abnormalities have been found. (See MOSAIC; TRISOMY; TRANSLOCATION; POLYPLOIDY.)

Cytogenetics has also proved useful in confirming or detecting the origins of some breeds of cattle.

Chromosome abnormalities have also been detected in infertile mares.



Cytokines
Naturally occurring compounds which cause tumours either to grow more slowly, or to destroy the malignant cells. (See INTERFERON, the first to be discovered.) Genetic engineering has made possible large-scale production of cytokines.

Cytology
The study of cell function, origin, structure, formation and pathology. Cytological examinations of specimens taken by FINE NEEDLE ASPIRATION BIOPSY (FNAB) are frequently used by veterinary diagnosticians.

Cytoplasmic Matrix
(See INTRACELLULAR FLUID.)

Cytosine
A pyrimidine compound which is attached to DNA to code for certain proteins.

Cytosol
(See INTRACELLULAR FLUID.)

Cytogenetics. Left: the karyotype. Right: a bull's lymphocyte in metaphase of mitosis. (With acknowledgements to Dr C. R. E. Halnan and the *Veterinary Record*.

Cytotoxic Drugs

Drugs which act on cell growth and division; they are used in the treatment of certain types of cancer. Their use in chemotherapy is limited by their toxicity, and dosage must be very carefully controlled.

Hazards Use of these drugs presents serious risks to health from residue disposal, spillage, etc. Miscarriage in nurses was twice as frequent in those who had been exposed to anti-cancer drugs, according to a study in Finland at 17 hospitals, as compared with unexposed nurses.

D

Dachshunds
Small long-bodied breed of dog with very short legs and three coat varieties – smooth, long and wire; originating in Germany, where they were used for badger hunting. The long body makes them prone to INTERVERTEBRAL DISC PROTRUSIONS. They are also liable to inherit CLEFT PALATE, DEAFNESS, DIABETES MELLITUS and ununited ANCONEAL PROCESS. SPONDYLOSIS DEFORMANS may also be inherited, while EPILEPSY appears to be sex-linked. DISTICHIASIS is seen in the miniature long-haired dachshund. OVERSHOT jaw (brachygnathia) and progressive renal atrophy may be congenital; the latter, especially in miniature long-haired and miniature short-haired, is inherited and can be tested for by DNA. PERSISTENT PUPILLARY MEMBRANE is seen in wire-haired dachshunds and OPTIC NERVE HYPOPLASIA in miniature long-haired dachshunds. LAFORA'S SYNDROME is seen in about 10 per cent of miniature wire-haired dachshunds. Other inherited conditions for which there are DNA tests include NARCOLEPSY, PYRUVATE KINASE DEFICIENCY and CEROID LIPOFUSCINOSIS.

Dactylogyrus
A commonly-occurring monogenetic gill fluke (about 1 mm in length) of fish which attaches itself by hooks and suckers.

Dactylomegaly
A congenital problem with abnormally enlarged fingers or toes (phalanges).

'Daft Lambs'
Lambs affected with cerebellar atrophy – a condition associated with incoordination of head and leg movements. The lambs are normal at birth but have problems walking; there is incoordination of limbs, straddled leg stance, head arched backwards and muscle tremors. It is to due to a recessive gene. (See GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.)

'Dagging'
Removal of soiled wool by the shepherd from sheep's hindquarters as an aid to preventing STRIKE.

Dairy Breeds of Cattle
There are two subspecies of cattle: *Bos taurus*. the typical animals found in Europe; and *Bos indicus* or 'Zebu-type' found in and adapted to hot climates. The main dairy species are European and based on black-and-white and on red-and-white cattle. The black-and-white are mainly based on the HOLSTEIN breed, which has largely superseded the FRIESIAN; this is a slightly smaller and stockier breed which produces less milk but whose male calves are better suited to beef production. The red-and-white breed is less common; in the UK the most frequently found are AYRSHIRE CATTLE. Elsewhere there are the DANISH RED, NORWEGIAN RED, SWEDISH RED AND WHITE, MONTBÉLIARDE, etc. Many breeds with red coats have been based on the SHORTHORN. The other main breeds are used for producing high butterfat milk and include the Channel Island breeds, JERSEYS and GUERNSEYS. Breeds such as BROWN SWISS also produce milk of higher solid content but they are larger. Some breeds, such as SHORTHORN, are basically dual purpose and may be used for both milk and beef (although most now used for one or the other).

DairyCo
This was the successor to the MILK DEVELOPMENT COUNCIL and it now forms part of the AGRICULTURE AND HORTICULTURE DEVELOPMENT BOARD.

Dairy Herd Management
Great changes have occurred in the UK dairy industry over the past 40 years, with an enormous reduction in herd numbers, increased numbers of cows per herd and increased yield per cow. In 1970, herd size averaged only 30 in the UK, and 80 per cent of cows were still tied up in cowsheds. There was, however, a growing movement towards larger herds, and today there are several 1000-cow units, and a few larger still. The imposition of milk quotas by the EU in 1984 led to herd sizes becoming static, but numbers are again increasing. Milk quotas were due to finish in 2015.

Increase in herd size has been accompanied by other changes: notably, milking in a parlour and housing in a cubicle house instead of in a cowshed. (See CUBICLES FOR COWS; COW KENNELS.) The number of dairy herds has reduced greatly and in 2010 in the UK they numbered 15,691, containing 1.85 million dairy cows. There has also been a marked increase in average cow milk yields which are now about 7,406 litres/annum. There is some concern about the greenhouse gases produced by cattle, although the higher-yielding cow produces less methane gas than a lower-yielding animal. As herd numbers and yields increase, higher standards of management are required. Labour levels have been reduced and problems can arise: these include poor fertility because less time is available to spend on oestrous detection. Milking often takes place in the a herringbone parlour (see illustration on next page.)

VetBooks.ir

Milking in a rotary herringbone parlour.

Parlour feeding, if and when it occurs, is usually related automatically to milk yield; this both makes for economy and avoids the problem of cow identification in the big herd, so far as the milker is concerned. Identification is still necessary, however, for use in conjunction with herd records and in the parlour where the milker or relief milker (who will rarely know all the cows) must feed according to yield in the absence of automated equipment. Plastic numbered collars, anklets, discs on chain or nylon, freeze branding and even udder tattooing are among methods used. In the UK, measures to deal with BSE have led to the introduction of a comprehensive system of herd and individual cow identification, with a national database (see IDENTIFICATION OF CATTLE). There are strict regulations in place for dealing with animals that die (see DISPOSAL OF CARCASES).

A variety of computer programs are available to aid management by optimising feeding, milk recording, etc. Most herds have a Herd Health Plan, which should be updated regularly. The majority of these are drawn up by a veterinary surgeon, but some are drawn up by the milk processor receiving the milk, in which case the herd health plan is in effect a list of feed, etc. supply conditions.

Feeding outside the parlour has been mechanised in many large units. Most farms have mixer wagons to produce a total mixed ration (TMR, also called complete diet) made from forage, grass or maize silage, straw, concentrates or straights feeds. Fed ad lib, this system allows better utilisation of feed and increased dry-matter intakes. In others, side-delivery trucks are drawn by tractor down the feeding passages and deliver into the long mangers. Self-feed silage, with the clamp face in or near the cubicle house, is another labour-saver. Group feeding (e.g. of dry cows, high yielders, and low yielders) is convenient management practice but may give rise to stress (see BUNT ORDER). (See also under 'STEAMING UP' and the advice on feeding given under ACETONAEMIA – Prevention.)

Adequate feeding is needed in early lactation and only the highest quality food should be fed: whether it is good hay, early cut silage, or 1.5 kg (3½ lb) per gallon cake.

Zero-grazing, where cattle are kept in paddocks, and grass is cut and brought to them, is seldom used in the UK. With a very large herd on a very small acreage (such as an American 550-cow herd on under 5 acres), zero-grazing obviously becomes essential.

Paddock grazing now forms an important part of dairy herd management, and includes the two-sward system in which separate areas are used for grazing and for conservation.

Dung disposal presents difficulties with large herds, especially in nitrogen vulnerable zones (NVZ). There are two options: it may be treated as

VetBooks.ir

a solid or as a liquid. Straw bedding lends itself to solid-muck handling, with the liquid (urine, washing-down water, rainwater) being taken separately to a lagoon or to an underground tank. Slatted floors can be used in a cubicle house, either over a dung cellar which is cleared out once a year, or over a channel leading to an underground tank. With the semi-solid method, dung may be spread on the land by tanker, or the slurry may pass to a lagoon or be pumped through an organic irrigation pipeline system. Where this is used, cows must not be expected to graze pasture until there has been time for rain to wash the slurry off the herbage. The use of organic irrigation is not entirely free from the risk of spreading infectious diseases.

'POACHING' must be avoided by the use of concrete aprons at gateways, by mobile drinking troughs, by wide corridors between paddocks with an electric fence dividing the 'corridor' so that one half can be kept in reserve, or by moveable ramps.

In the large herd, one of the biggest problems is spotting the bulling heifer or the cow on heat. Properly kept herd records can help alert farm staff to the approximate dates. (See CALVING INDEX; OESTRUS, DETECTION OF, IN COWS; CONTROLLED BREEDING.)

On large units, regular weekly visits by veterinary surgeons help in the detection and treatment of infertility and the application of veterinary preventive medicine. (See HEALTH SCHEMES FOR FARM ANIMALS; VETERINARY FACILITIES ON THE FARM, CALF HOUSING; also CONTROLLED BREEDING and CATTLE HUSBANDRY.)

Dairy Shorthorn Cattle

The breed originated in North Eastern England: County Durham, Northumberland and Yorkshire. It known as the Milking Shorthorn in Canada, New Zealand and USA. The average size of American cows is 140 cm (55 in) and they weigh 650 kg to 680 kg (1,400 to 1,500 lb), and produce 7,000 kg (15,000 lb) of milk in a 305-day lactation with 3.8 per cent butterfat and 3.3 per cent protein. They are white, red or roan (mixed red and white hairs) and were one of the foundation breeds of DANISH RED CATTLE together with the ANGELN CATTLE and Illawarra breeds. In Britain few Dairy Shorthorns remain. (See also BEEF SHORTHORN CATTLE.)

Dalesbred Sheep

The breed was derived from the SWALEDALE and the SCOTTISH BLACKFACE. They are found in Wharfdale and central Pennines of England. Ewes are horned with the rams having long curly horns; they have black faces with a white spot on either side of the muzzle, with a white fleece. Ewes weigh 45 kg to 60 kg and rams 55 kg to 75 kg. The ewes were crossed with the TEESWATER ram to produce the MASHAM breed.

Dales Ponies

These strong ponies originate from the English Pennines; they have marked FEATHERING of their legs. Usually black, but other colours are seen. They are susceptible to FOAL IMMUNODEFICIENCY SYNDROME.

Dalmatian

A medium-sized dog, white with regular black or brown spots, that originated as a carriage dog in the Balkans. Unlike most dogs, it excretes uric acid in the urine, it can have HYPERURICOSURIA (DNA test available) and could be affected by gout. It may inherit DEAFNESS and ATOPIC DERMATITIS. It is also appears unable to produce a stable immunity to DEMODECTIC MANGE.

Damalina

A genus of biting lice.

Damiana

Damiana aphrodisaca is a herb included in a remedy for lack of alertness and stamina in dogs and cats and a reputed, but unsubstantiated, aphrodisiac.

Dandie Dinmont Terrier

Named after a character in the novel *Guy Mannering* by Sir Walter Scott. The breed is prone to GLAUCOMA and may also suffer from INTERDIGITAL CYSTS; the congenital condition of GONIODYSGENESIS is recorded. The breed is on the Kennel Club's Vulnerable Native Breeds List.

Dandy-Walker Syndrome

A condition reported in dogs, kittens and cattle. It involves the central nervous system with specific lesions including cerebellar vermian hypoplasis, the presence of a fluid-filled cyst in the posterior fossa and hydrocephalus. It may be inherited or congenital.

Dangerous Dogs Act 1991

This requires that certain breed types (pit bull terrier, Japanese tosa, fila brasileiro, dogo argentino) must not be taken out unless on a lead, muzzled, and by someone at least 16 years old.

Owners of these dogs must register them with the police, and either comply with the exemption scheme or arrange for euthanasia to be carried out by a veterinary surgeon.

To comply with the exemption scheme, owners must take out 3rd-party insurance, arrange for the animal to be neutered, and to be identifiable by a tattoo and a microchip. The dog must also be kept under escape-proof conditions.

VetBooks.ir

The Act has proved controversial; in a number of cases there has been confusion over identification of dogs as pit bull terriers. Several attempts have been made to have the Act amended.

Dangerous Wild Animals Act 1976

This requires people keeping animals listed in the Act, such as lions, tigers, poisonous snakes, certain monkeys, crocodiles and bears, to obtain a licence – authorised by a veterinary surgeon. Certain 'exotic' species such as bison, camels, wild boar, ostriches and emus are classed as dangerous wild animals under this Act. They are farmed in the UK and the farmer needs to register with the local authority. The premises must be inspected by a veterinary surgeon nominated by the local authority before a licence is granted.

Local authorities have power to refuse licences, on the advice of an authorised veterinary surgeon, on such grounds as safety, nuisance or inadequate or unsuitable accommodation.

Before a licence is granted, local authorities must be satisfied about arrangements for the animal's food, exercise and general comfort, fire precautions, and precautions against infectious diseases.

People with such animals must take out insurance.

Conviction for the keeping of an animal without a licence or contravening a condition of one could result in a fine of up to £400 and a ban from holding a licence.

Zoos, circuses, pet shops and research workers are exempted but are covered by other legislation under the Licensing Act 1981.

Danish Red Cattle

More than half the cattle in Jutland, and 97 per cent of those in the Islands, belong to this breed, which is a very old one, though its official name (meaning Red Danish Milk breed) dates from 1878.

Danish Reds are strong, dual-purpose animals with a good 'barrel', teats and udders, and weigh between 500 kg and 770 kg (1,100 lb and 1,700 lb). (See also BRITISH DANE.)

Danofloxacin

A fluorquinolone antimicrobial drug which is registered for use in cattle and pigs. Use in other species is subject to the terms of the 'CASCADE'.

DARD

The acronym for the DEPARTMENT OF AGRICULTURE, AND RURAL DEVELOPMENT, the responsible agricultural department in Northern Ireland.

Darkling Beetle

This beetle (*Alphitobius diaperinus*) can cause a problem in animal houses by burrowing in wooden and insulating structures. It was once thought to be a vector of the Marek's Disease virus.

Darnel Poisoning

The grass known as 'darnel' (*Lolium temulentum*) is a common weed in cereal crops and in pastures in some parts, but it does no harm when eaten before the seeds are ripe (or almost so). Many instances are on record where harmful results to man and animals have followed the use of meal or flour which contained ground-up darnel seeds.

Toxic Principle is a narcotic alkaloid, called temuline, which is said to be present to the extent of about 0.66 per cent. A fungus, *Endoconidium temulentum*, is often found in darnel seeds; it contains the poisonous alkaloid temuline.

Signs Darnel produces giddiness and a staggering gait, drowsiness and stupefaction, dilatation of the pupils in the horse, and interference with vision in almost all animals. Vomiting, loss of sensation, convulsive seizures and death follow when it is eaten in large amounts. Death usually occurs within 30 hours of eating the seeds.

Darrow's Solution

Darrow's solution is used for fluid replacement therapy in cases of a potassium deficiency, and contains potassium chloride, sodium chloride and sodium lactate. It is rarely used in veterinary medicine; it is unsuitable for cases of neonatal diarrhoea. (See under DEHYDRATION.)

Dart Guns or Syringes

(See under PROJECTILE SYRINGE.)

Darting

A method of administering SPECIFIC CHEMICAL INJECTIONS to wild animals and fractious or uncontrollable domestic animals. It can be via a blowpipe or a dart gun. There are laws concerning their use. (See PROJECTILE INJECTION.)

Dartmoor Ponies

Many of the ponies on Dartmoor are semi-feral and are only rounded up once a year. They are between 11 hands and 12.2 HANDS high. They are distinct from EXMOOR PONIES. Any colour is allowed except piebald and skewbald.

Dartmoor Sheep

This is a native breed, heath- and moor-adapted, believed to date from prehistoric times, and possibly developed from Iron Age SOAY SHEEP. There are three types of sheep with the name Dartmoor – Dartmoor Greyface, Dartmoor Whiteface and Dartmoor Scottish Blackface.

VetBooks.ir

Dartmoor Greyface Bred from Nottinghamshire and LEICESTER LONGWOOLS in the 19th century. Ewes weigh about 60 kg (130 lb) and the wool weighs 7 kg to 7.5 kg (15.5 lb to 16.5 lb). They are hornless, deep bodied, short legged with long lustrous wool which can be used for blankets, carpets, cloth and serge. It is also used for meat.

Dartmoor Whiteface These have a white face which is wool-free and survives cold and wet weather. Average wool clip is about 5 kg to 7 kg (11 lb to 15.5 lb). The lambing percentage was 150 per cent. Numbers have been declining since the 1940s.

Dartmoor Scottish Blackface This is the most common breed on Dartmoor.

Daturine
An alkaloid. (See under STRAMONIUM.)

Day Blindness
(See HEMERALOPIA.)

Daylily
(See LILY POISONING.)

Day-Old Chicks
(See CHICKS.)

DCAB
(See DIETARY CATION-ANION BALANCE.)

DCAD
Abbreviation of dietary cation-anion diet. (See DIETARY CATION-ANION BALANCE.)

DCM
Abbreviation of dilated cardiomyopathy (See CARDIOMYOPATHY; HEART DISEASES.)

DDT
The common abbreviation for dichlorodiphenyltrichlorethane, a potent parasiticide, lethal to fleas, lice, flies, etc. DDT was once used incorporated in dusting powders, for applying to animals; and dissolved in solvents for use as a fly-spray. DDT-resistant insects are now found in nearly all countries, unfortunately, and dangers of DDT residues in human and animal tissues have led to its abandonment in the UK and elsewhere.

DDT preparations should not be applied to animals, owing to the risk of poisoning. Signs of poisoning include coldness, diarrhoea and HYPERAESTHESIA. DDT sprays may contaminate milk if used in the dairy; and may lead to poisonous residues in food animals when applied in livestock buildings, with consequent danger to human beings eating the contaminated meat. DDT can also contaminate streams and rivers, and prove harmful to fish.

However, in the control of human trypanosomiasis in Africa, both DDT and dieldrin have been extensively used for ground spraying, often by aircraft. Currently DDT is restricted to the control of mosquitoes and tsetse fly vectors of malaria and Trypanosomiasis by spraying on the inside walls of at-risk dwellings. (See TRYPANOSOMES.)

Dead Animals, Disposal of
(See DISPOSAL OF CARCASES.)

Deadly Nightshade
Deadly nightshade is the popular name of *Atropa belladonna*, from which the alkaloid ATROPINE is obtained. It is a deadly poison, and parts of the plant are sometimes eaten by stock. (See also BELLADONNA.)

Deafness

Congenital deafness is common in white bull terriers and also in blue-eyed white cats. In the USA the Dalmatian breed is reported to have the highest prevalence of deafness of all breeds of dogs, with a risk factor of 40 per cent to 50 per cent. In the UK, 7.4 per cent were totally deaf with 14 per cent unilaterally deaf. Other breeds affected include AUSTRALIAN CATTLE DOGS, BORDER COLLIES, BULL TERRIERS, DACHSHUNDS, ENGLISH SETTERS, ENGLISH COCKER SPANIELS, GREAT DANES, OLD ENGLISH SHEEPDOGS, ROTTWEILERS, SCOTTISH TERRIERS, SEALYHAM TERRIERS, SMOOTH-HAIRED FOX TERRIERS and WIRE-HAIRED FOX TERRIERS. One or both ears may be affected.

Conductive deafness is that caused by interference with the transmission of sound waves from the external ear to the organ of Corti in the inner ear. Such interference may be due to: (1) excess of wax in the ear canal; (2) perforation of, or infection involving, the eardrum; (3) osteoarthritis of the ossicles of the inner ear. (In human medicine otosclerosis is another cause, being a loss of flexibility between the bones of the middle ear and the membrane connecting them with the inner ear.)

Nerve deafness results from pressure upon, or damage to, the auditory nerve; it can also be a side-effect of antibiotics such as streptomycin and neomycin, and possibly chloramphenicol.

Deafness is or may be also a sign of santonin poisoning, coal-gas poisoning, of a vitamin deficiency, and, in human medicine, a side-effect

VetBooks.ir

of streptomycin and aspirin. Other causes include damage to the internal ear, to the Eustachian tube, nervous system, etc.

Death, Causes of Sudden

In the majority of cases either failure of the heart or damage to a blood vessel is the direct cause, but nervous shock following an accident or injury, CEREBRAL HAEMORRHAGE, ANTHRAX, BLACK-QUARTER, LIGHTNING STRIKE, BRAXY, HYPOCALCAEMIA in cattle, HYPOMAGNESAEMIA (also in sheep) and over-eating of green succulent fodder in young cattle, are all capable of producing sudden death. In the case of pigs, sudden death has sometimes resulted from heat stroke. (See also BOWEL, OEDEMA OF THE.) In both cattle and pigs sudden death due to *Clostridium perfringens* type A has been reported. In countries bordering the Red Sea, horses that have not been bred locally are sometimes attacked by a form of heat stroke with fatal results. Sudden death, without obvious preliminary signs, may occasionally occur in cases of RABIES and BOTULISM. (See also POISONING, ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION and (with reference to dogs) CANINE PARVOVIRUS; CANINE VIRAL HEPATITIS).

Death, Signs of

The physical signs of death are well known, but there are occasions when it is difficult to state whether an animal is dead or not. In deep coma an animal may have all the superficial appearances of being dead, and yet recovery is possible if effective measures are taken. In the later stage of MILK FEVER a cow has been mistaken for dead but found to be living, suitably treated, and within two hours up on her feet again looking well. Foals have been discarded soon after being born and considered dead, have been removed to the outside of the loose-box while attention was paid to the dam, and later have been found living, the fresh cold air having revived respiration and stimulated the circulation, etc.

When an animal dies, the essential sign of the cessation of life is said to be the stopping of the heart. This, however, is not strictly correct, for it is possible by massage to resuscitate an already stopped heart, and to recover an apparently dead creature. Strictly speaking, it is almost impossible to say exactly when death takes place, but it is considered that when heart and respiration have ceased, when the eyelids do not flicker if a finger be applied to the eyeballs, when a cut artery no longer bleeds, and when the tissues lose their natural elasticity, life is extinct. A few of the common tests that are applied in uncertain cases are as follows. The animal is dead when (1) a piece of cold glass held to the nostrils for three minutes comes away without any condensed moisture upon it; (2) a superficial incision in the skin does not gape open; and (3) the natural elastic tension of the tissues disappears. Changes that follow death in a variable period depending upon the species of animal, and upon the weather at the time, are: (1) the clotting of the blood in the vessels; (2) the onset of rigor mortis (the stiffness of death); and (3) the commencement of decomposition of the carcase, usually first evident along the lower surface of the abdomen.

De-Beaking

De-beaking is done by poultry-keepers when birds are kept in groups and there is a potential problem of feather-picking or cannibalism. No more than one-third of the upper beak, usually much less, is removed; more than this can expose the sinuses and lead to infection. If performed when very young there are few after-effects. De-beaking older birds can result in neuromas at the cut tip, resulting in hypersensitivity of that region. Management practices should be improved to try to eliminate the need for de-beaking but the problem can be difficult to resolve.

There are moves to phase out the practice, on welfare grounds. (See also BEAK TRIMMING.)

Debridement

The removal of dead tissue and infected material from a wound surface. This can be achieved by enzymes or combinations of organic acids. The use of maggots free from pathogenic organisms is an old method of wound treatment currently being revived in human medicine.

Decongestants

Used to reduce congestion in the upper respiratory track, especially the nose.

Decoquinate

A coccidiostat originally developed for use in poultry but mainly administered to control coccidiosis in lambs and calves.

Decubitus

(adjective, Decubital)

Decubitus is the recumbent position assumed by animals suffering from certain diseases. It can include any posture, e.g. sternal RECUMBENCY, lateral RECUMBENCY.

A decubitus sore is an ulcer from decubitus, i.e. a bedsore.

Decussation

Decussation is a term applied to any place in the nervous system at which nerve fibres cross from one side to the other; e.g. the decussation of the pyramids in the medulla, where the motor fibres

from one side of the brain cross to the other side of the spinal cord.

Deep-Freeze

(See ARTIFICIAL INSEMINATION - STORAGE OF SEMEN.)

Deep Litter for Cattle

This is a very satisfactory system if well managed. It is mainly practised in straw yards. Straw, shavings and sawdust can be used, in adequate quantity. The bedding must be kept dry and no contact must occur between the udder and dung in the litter. Warmth given off as a result of the fermentation taking place in the litter makes for cow-comfort; and there is, of course, the added advantage of a thick layer of insulation between the cows and the concrete of a covered yard.

Deep Litter for Poultry

Chopped straw, shavings, and sawdust are commonly used. Musty straw could cause an outbreak of aspergillosis. Peat-moss is apt to be too dusty. Oak sawdust should not be used as it may discolour the egg-yolks. The depth should be at least 10 cm (4 in). The litter should be forked over, and added to from time to time. If it gets damp, the ventilation should be attended to. Many coccidia larvae get buried in the litter, and this is an advantage. After each crop of birds, the litter should be removed and heaped, so that enough heat will be generated to kill parasites. If deep litter is returned to a house, the succeeding batch of birds sometimes suffer from ammonia fumes, which may cause serious eye troubles. Compaction of the litter must be prevented by allowing the poultry to 'work' it; otherwise, the litter does not meet the definition specified by EC Directives.

Deep Pectoral Myopathy (DPM)

(See GREEN MUSCLE DISEASE.)

Deep-Rooting Plants

Deep-rooting plants are valuable in a pasture for the sake of the minerals they provide. Examples of such plants are chicory, yarrow, and tall fescue.

Deer, Diseases of

Deer are susceptible to the following infections: BRUCELLOSIS; BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE; ELAPHASTRONGYLUS; EPIZOOTIC HAEMORRHAGIC DISEASE; FOOT-AND-MOUTH DISEASE; JOHNE'S DISEASE; LISTERIOSIS; LOUPING-ILL; malignant catarrhal fever – see BOVINE MALIGNANT CATARRHAL FEVER; MENINGOENCEPHALITIS; PARASITIC BRONCHITIS; TICK-BORNE FEVER OF DEER; TUBERCULOSIS; WARBLES; YERSINIOSIS; and also an enzootic ataxia resembling SWAYBACK in lambs.

Tuberculosis in deer Tuberculosis of deer is a NOTIFIABLE DISEASE in the UK. Tuberculin testing of deer and the establishment of tuberculosis-free herds was the basis of the Deer Health Scheme operated by DEFRA. Tuberculin testing of deer and interpretation of the results are more difficult than in cattle; special training is required.

The Tuberculosis (Deer) Order 1989 provides for the individual marking of farmed or transported deer, and can be used for enforcing movement restrictions on affected or suspect animals.

Farmed deer Red deer (*Cervus elaphus*) and fallow deer (*Dama dama*) are the most commonly farmed.

Around 300 farms, mainly in Scotland, raise deer in the UK. Some 36,000 animals are farmed in total. Most (75 per cent) are red; the rest, fallow. All farmed deer must be identified by tagging; the British Deer Farming Association supervises a tagging scheme.

In Britain the harvesting of antler velvet from live stags is illegal.

In New Zealand, YERSINIOSIS is a serious disease of farmed red deer. It appears to be triggered off by stress, and most cases occur during the winter. The incidence of malignant catarrhal fever (MCF) in red deer herds in Canterbury, New Zealand, ranges from 0.2 per cent to 10 per cent a year.

Meningoencephalitis, caused by *Streptococcus zooepidemicus*, has resulted in the death of farmed red deer exported from the UK and Denmark to New Zealand. Autopsy findings are typically congestion of lungs and liver, the presence of frothy fluid in trachea and bronchi, and acute meningoencephalitis.

Dictyocaulus viviparus is the most important parasite of red deer in New Zealand and frequent drenching with anthelmintics is used to control it. Development of resistant species is hindered by dosing strictly according to the manufacturers' directions and alternating the product used.

Another parasitic worm of importance in deer is *Elaphostrongylus cervi*. It is pale and thread-like, 4 to 6 cm long, and found in the intramuscular fascia and also in the meninges of the brain. This parasite occurs in Scotland, the mainland of Europe, and Australasia.

Eggs reach the lungs via the bloodstream and hatch in the alveolar capillaries, causing slight pneumonia. Nervous signs appear when the brain is involved.

In the UK, one of the most important infections of deer is JOHNE'S DISEASE, caused by *Mycobacterium avium* subspecies *paratuberculosis*

VetBooks.ir

(MAP). It may be seen in animals as young as a year old and results in wasting, with or without diarrhoea.

Deerhound

A large breed of dog originally used in deer hunting. It has a long, shaggy dark grey coat, long neck, and long tail. They weigh about 35 kg to 50 kg (75 lb to 110 lb) and have a proportionally small head. They can suffer from HAEMOPHILIA due to Coagulation factor VII deficiency (DNA test available).

Defaecation, Defecation (US)

Defecation is very differently performed in the various animals, and some diagnostic importance is attached to the manner of its performance. (See CONSTIPATION; DIARRHOEA.)

Deficiency Diseases

These form a group of diseases bearing no clinical resemblance to each other, but having the common feature that they result from omission from the diet of some substance or element essential for normal health and nutrition. The essential element may be one of the inorganic mineral substances, such as calcium, phosphorus, magnesium, manganese, iron, copper, zinc, cobalt, iodine, selenium or more than one of these; it may be a protein or an amino acid; or it may be a vitamin. In the last case the condition is often referred to as an 'avitaminosis', and the particular vitamin is specified, e.g. A, B, D or E. Starvation through inadequacy of general nutritive food intake is not classed as a deficiency disease. Some deficiency diseases are simple, such as iron deficiency in young pigs; while others are more complex, such as phosphate deficiency in South Africa, which is associated with botulism through the gnawing of bones of dead animals contaminated with *C. botulinus*. Some deficiency diseases are due to the presence of a substance in the diet which can form an indigestible complex with the nutrient preventing its absorption and utilisation. (See VITAMINS; TRACE ELEMENTS; NUTRITION, FAULTY.)

Definitive Host

This is the host in which an adult parasite with an indirect life-history lives and produces its eggs. A definitive host is the final host, as compared with the intermediate host or hosts. For example, an ant is one of the intermediate hosts of a species of liver fluke; the definitive host is a sheep or other grazing animal.

Deformities

Deformities of cattle and sheep, etc. are mentioned under GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS. (See also HARE-LIP; MOUTH, DISEASES OF; MONSTER.)

DEFRA

Acronym for Department for Environment, Food and Rural Affairs – the UK Government department that replaced the Ministry of Agriculture, Fisheries and Food (MAFF). Its responsibilities include NOTIFIABLE DISEASES, food safety, environmental law and the welfare of animals in transport, on farms and at slaughter. DEFRA represents the UK in the EU on these matters after consultations with the relevant departments within the devolved authorities. The Home Office is responsible for experimental animals. Address: DEFRA, Nobel House, 17 Smith Square, London SW1P 3JR. Helpline telephone: 0845 9335577; email: defra.helpline@defra.gsi.gov.uk.

Degenerative Joint Disease (DJD)

(See ARTHRITIS.)

Degenerative Myelopathy

Also called CANINE DEGENERATIVE RADICULOMYELOPATHY. This is a progressive degenerative disease of the spinal cord in older dogs, usually over eight years old. The legs are often placed closer together than normal and with unusual foot positions due to a lack of conscious proprioception. The condition is seen in dog breeds such as BOXERS, CORGIS, GERMAN SHEPHERD DOGS, POODLES (STANDARD), CHESAPEAKE BAY RETRIEVERS and RHODESIAN RIDGEBACK. (DNA testing is available for most breeds.)

Degloving

The accidental or traumatic removal or avulsion of skin from a body part. This can occur if the skin has previously been devitalised or, in the case of small mammals if they are handled roughly or badly. (See DEGUS; GERBILS.)

Deglutition

Deglutition means the act of swallowing. During swallowing, breathing temporarily ceases (apnoea); otherwise food might enter the respiratory tract. (See 'CHOKING'.)

Degus

Diurnal rodents (*Octodon degus*) taxonomically related to CHINCHILLAS and GUINEA-PIGS. It originates from central Chile and they were initially bred as a research tool in laboratories in the study of DIABETES MELLITUS. They have recently gained popularity as engaging, sociable pets, provided that they are kept in metal cages (they easily gnaw though wood) and they are given plenty of exercise. They require frequent access to dust baths. Generally degus are not prone to many problems, but dental disease is often found in captive animals. DEGLOVING injuries are common if animals are grasped by the tail.

VetBooks.ir

Dehiscence

A breakdown in the union of a suture of adjoining bones of the skull. The condition can be treated successfully by surgery.

An example of this is a breakdown of the suture line in mandibular fractures. The term is also applied to the re-opening of wounds.

Dehorning of Cattle

(See also GOATS, DISBUDDING OF KIDS.)

Dairy cows are routinely dehorned to facilitate handling and to avoid injury to those handling them and to other cattle. The use of mechanised milking systems makes dehorning virtually essential. Fattening beef cattle in yards or pens are also often dehorned because there is usually one animal that obtains dominance; if it possesses horns it is liable to inflict wounds upon others or upon the attendants.

The most satisfactory method in calves is that known as 'disbudding'. This is best done when the horn bud is fully detectable, which takes a variable time to occur. The buds are then removed, under local anaesthetic, by cauterising with an electric or gas-heated dehorner.

An alternative method consists of painting the young buds of the horns, when they first appear in calves, with caustic compound. While now illegal in the UK, it is used elsewhere. A little petroleum jelly or thick grease may be rubbed on the hair around the base of the bud and care is needed to ensure that no caustic gets into the eyes. The bud of the horn is first cleaned with spirit to remove grease – an essential preliminary – and a second coating of the caustic is given after the first has dried. A scab will form over the bud and drop off, carrying with it the cells which would have produced horn. Little or no pain is occasioned to the calf by caustic collodion (whereas caustic potash sticks, now largely superseded, do cause much pain) and the horn is effectively prevented from growing.

In Britain the operation of dehorning cattle requires the administration of an anaesthetic. (See ANAESTHETICS, LEGAL REQUIREMENTS.) A saw, an electric saw, cutting wire or special horn shears may be used when the horns are more developed.

Bleeding from the matrix and horn core can usually be controlled by using a figure-of-eight tourniquet around the roots of the horns or by ligating the arteries.

Dehydration

Loss of water from the tissues, such as occurs during various illnesses, especially those producing vomiting or diarrhoea; cessation of digestion due to disease (e.g. in impaction of the rumen; DYSAUTONOMIA, and as a result of injury or serious burns.

Diarrhoea is one of the most common causes of dehydration. A scouring calf may lose 100 ml of water per kg bodyweight in 12 hours. As the metabolism attempts to conserve extracellular body fluid (ECF) volume, urine production decreases and blood urea levels rise while pH levels are lowered. Electrolytes are lost, particularly sodium, potassium and bicarbonate, and ketone bodies accumulate.

Treatment Restoration of fluid volume is the immediate priority, and replacement of lost electrolytes and blood nutrients.

Parenteral fluids In the severely dehydrated animal, the restoration of ECF by parenteral (usually intravenous) administration of plasma, if available, or infusion of a sterile isotonic (0.9 per cent) solution of sodium chloride, compound sodium lactate infusion (lactated Ringer's solution) is indicated. In the case of blood or plasma loss through injury or burns, a plasma expander based on dextran or gelatin is added to the electrolyte solution; proprietary solutions are widely available.

The rate of administration of intravenous solutions should be carefully supervised. In severe cases of dehydration or profound shock, up to 50 ml per kg bodyweight per hour may be given initially, reducing to 5 ml to 10 ml/kg/hour. These high rates should not be continued for more than 20 to 30 minutes. A close watch must be kept for signs of too rapid administration: restlessness, lung sounds, tachycardia, tachypnoea.

A formula to convert ml/kg/hour to drops per minute is given in *The Veterinary Formulary*:

$$\text{Drops/minute} = \frac{\text{Drops/ml} \times \text{FR} \times \text{BW}}{60}$$

Drops/ml = number of drops delivered by the infusion set per ml
FR = Flow rate in ml/kg/hour
BW = bodyweight of patient in kg

The total amount given will depend on the amount of fluid lost and the condition of the animal.

Oral rehydration is usually satisfactory in most cases of diarrhoea. Solutions for this purpose usually contain sodium and glucose, which help the water uptake of the dehydrated animal. To help correct any acidosis, citrate should be included, and/or bicarbonate. Such solutions are suitable for calves and most mammals. Many proprietary formulations are available.

For first-aid purposes, glucose-saline may be given by mouth to all animals. UNICEF's 'Oral Rehydration Salts', intended for infants and children, may be used; the sachet contents being dissolved in 1 litre of (sterile or boiled) water (which must not be boiled thereafter).

VetBooks.ir

The formula is:

Sodium chloride	3.5 g
Potassium chloride	1.5 g
Sodium bicarbonate	2.5 g
Glucose	20.0 g

The effectiveness of the above glucose-saline solution can be enhanced by the addition of citrate and/or citric acid. Oral rehydration can be given by stomach tube when the swallowing reflex is poor and so normal drinking is likely to cause inhalation pneumonia a risk.

Glucose-saline can also be administered per rectum, or subcutaneously although this latter application may be compromised by vasoconstriction due to the dehydration.

Dehydroepiandrosterone

It is produced by the adrenal gland in times of severe stress to counteract the effects of cortisol. Excessive or prolonged secretion of cortisol can cause permanent damage to tissues.

Delivery

(See PARTURITION.)

Delmadinone Acetate

Delmadinone acetate is a drug for the treatment of hypersexuality in dogs and cats in an effort to control roaming. It is used to treat some cases of AGGRESSIVENESS, NERVOUSNESS, epileptiform seizures, corticoid-resistant PRURITUS and prostatic HYPERPLASIA in males. In some countries it can be used for OESTRUS SUPPRESSION in cats.

Delvo Test

A test used to detect ANTIBIOTICS or SULFONAMIDES in milk.

Dembrexine

A mucolytic compound used to alleviate the clinical signs of respiratory distress in horses.

Dementia

Signs of dementia can occur in geriatric dogs and cats. It can follow other disease problems. Signs can include disorientation, altered behaviour including sleeping patterns and activity, and decreased grooming (in cats). Adjustments should be made to assist such as ensuring awareness of food, water, resting places, suitable companionship and in cats easily accessible latrine and hiding sites. (See also 'ALZHEIMER'S DISEASE' IN CATS; CANINE COGNITIVE DYSFUNCTION SYNDROME.)

Demephion

An organophosphorous preparation used as an insecticide and acaricide. Livestock should be kept out of treated areas for at least a fortnight.

Demodectic Mange, Follicular Mange

Demodectic mange (follicular mange) is caused by mites of the genus *Demodex*. This parasite, microscopic and cigar-shaped in appearance, with very short stumpy legs, lives deep down in the hair follicles, and is accordingly difficult to eradicate by dressings. It is a common cause of mange in dogs.

D. aurata and *D. critercae* are seen in hamsters. The parasites have been recovered from the skin and eyelids of cattle, sheep, horses, dogs, man and many other species; they are host specific. Amitraz, moxidectin and ivermectin have been used in dogs. Corticosteroids are contraindicated in treatment of *Demodex* infestation and their use in treating other conditions can lead to demodectic mange. (See MANGE.)

Demodicosis

Another name for DEMODECTIC MANGE.

Demulcents

Demulcents are substances which exert a soothing influence upon the skin or the mucous membranes of the alimentary canal, and in addition afford some protection when these are inflamed. Examples of demulcents for internal use are arrowroot, glycerin, bismuth subnitrate, and bismuth carbonate.

Demyelination

Destruction of the myelin, a lipid which surrounds the axis-cylinder of a medullated nerve fibre.

Dendrites

(See NERVES.)

Dendritic Cells

These are important cells of the immune system that engulf bacteria and viruses, separate them into pieces and then attach the parts to their membranes by histocompatibility complex proteins. The pathogen parts are antigens and by their attachment to helper T cells, killer T cells, B cells, memory T cells they start the production of antibodies. Overactive dendritic cells can lead to autoimmune disease.

Dengue

(See EPHEMERAL FEVER.)

Dental Calculus

(See TEETH, DISEASES OF - DENTAL DEPOSITS, TARTAR.)

Dental Plaque

(See TARTAR.)

Dental Problems
(See TEETH, DISEASES OF.)

Dental Scaling
(See TEETH SCALING.)

Dentine
Dentine is the dense yellow or yellowish-white material of which the greater part of the teeth is composed, and which in elephants, etc., constitutes ivory. The dentine is pierced by numerous fine tubules which communicate with the sensitive pulp in the hollow of the tooth-root, along each of which run tiny vessels and nerves which nourish its structure. In the young, newly erupted tooth the dentine is covered over with a layer of hard, dense, brittle enamel, which prevents too rapid wear of the softer dentine. (See TEETH.)

Dentition
Dentition refers to the configuration and conformation of the teeth, with special reference to their periods of eruption through the gums.

Horses The dentition of the horse consists of the following teeth:

	Incisors	Canines	Molars
Upper jaws	6	2	12, 13 or 14
Lower jaws	6	2	12, 13 or 14

There are six incisor teeth in the upper and lower jaws. Temporary incisors differ from the permanents; while each of the former possesses a crown, neck and root, the latter do not. Moreover, the temporaries are smoother, whiter and smaller. When there are both temporaries and permanents present in the mouth it is not usually difficult to differentiate between them. A typical unworn permanent incisor tooth from a horse possesses an infundibulum, or 'tucking-in' from its free edge or crown (see TEETH), and since this results in an infolding of the enamel, two rings of enamel, an outer and an inner, are seen in the partly worn tooth. However, as wear proceeds the inner ring of enamel eventually disappears, since the level of wear has passed the depth of the infundibulum. At the same time, the outline of the tooth changes from an oval to a quadrilateral, and eventually to a triangle, since the tooth is tapered from crown to root. It is upon an examination of these factors that the estimation of the age of an adult horse is based.

The incisors are named centrals, laterals or intermediaries, and corners, according to their situation in the mouth.

There are two canines ('tushes', 'eye-teeth', or 'dog-teeth') in each of the jaws – one on the right and one on the left side. In horses, canine teeth are only typically present in the male, although rudimentary canines may occasionally be found in mares. They are situated between the last incisor and the first cheek tooth, one on either side, being nearer to the incisors than to the molars. The spaces between the canines and the molars are spoken of as the bars of the mouth. In the bridled horse, the bit runs across the bars.

	Incisors	Canines	Molars
Upper jaws	6	0	6
Lower jaws	6	0	6

There are six cheek teeth in four rows (two upper and two lower) which are used by the horse to grind its food. They consist in each row of three premolars which are replaced by permanent teeth as described in the table shown under the heading *Eruption*. However, these times are quite variable and the table should be used as a guide. There are three molars which are not replaced but erupt at approximately the times given. There is also the 'wolf tooth' which erupts between four and six months. This is a vestigial premolar which lies just in front of the first cheek tooth and so technically it is the first premolar and the first cheek tooth is technically the second premolar. Often these 'wolf' teeth are shed and not replaced at the time of the first and second premolar. If they remain they are rarely a problem. However, owners often think they interfere with the bit and request their removal. They are very rare in the lower jaw except in standardbreds.

Eruption The 'eruption' means the time when the tooth cuts through the gums, and not when it comes into wear. It must be remembered that in the table, allowance has to be made for the time of foaling. All thoroughbreds are dated as having their birthdays on January 1 each year, and all other breeds of horses on May 1, so that with an early foal the teeth will appear sooner than the corresponding periods subsequent to May 1 or January 1 in any year, and with a late foal, later.

VetBooks.ir

Time of eruption	Incisors	Canines	Molars
Birth to 1 week	2 temporary centrals	—	—
2 to 4 weeks	2 temporary laterals	—	Nos. 1, 2 and 3 temporary molars
7 to 9 months	2 temporary corners	—	No. 4 permanent molar
1 year 6 months to 1 year 8 months	—	—	No. 5 permanent molar
2 years 6 months	2 permanent centrals	—	Nos. 1 and 2 permanent molars
3 years 6 months	2 permanent laterals	—	No. 3 permanent molar
4 years	—	All 4 canines	No. 6 permanent molar
4 years 6 months	2 permanent corners	—	—

Usually, the teeth in the upper jaw erupt sooner than those in the lower jaw, although there are many exceptions to this.

An estimate of the horse's age from its teeth can only be approximate in later life. Galvayne's groove is not a reliable guide to ageing in any age of horse and it may be indistinct or absent.

Cattle The permanent dentition of cattle consists of the following teeth:

	Incisors	Canines	Molars
Upper jaws	0	0	12
Lower jaws	8	0	12

In the upper jaw there are neither incisors nor canines, while in the lower jaw there are 8 teeth present in the incisor region. The most posterior of these (i.e. 1 on either side) are supposed to be, in reality, modified canines, which have moved forwards in the gums and have assumed the shape and the functions of incisors.

The temporary or milk dentition is as follows:

	Incisors	Canines	Molars
Upper jaws	0	0	6
Lower jaws	8	0	6

Incisors are absent from the upper jaw of cattle, their place being taken by the 'dental pad' – a hard, dense mass of fibrous tissue developed in the upper incisor region, against which the 8 lower incisor teeth bite. Each is a simple tooth possessing a spatulate (spade-shaped) crown, a constricted neck, and a tapered root or fang. The teeth are loosely embedded in the jaw so that a slight amount of movement is normally possible. They are named centrals, 1st intermediates or medials, 2nd intermediates or laterals, and corners; but it is perhaps more convenient to enumerate them from the central pair as 1st pair, 2nd pair, etc.

The corner teeth look like incisors but are considered as modified canines.

Molars are like those of the horse in number and arrangement, except that they are smaller and progressively increase in size from first to last, so that the 1st is quite small, and the length of gum which accommodates the first 3 is only about half that occupied by the last 3. One or more 'wolf teeth' may be present in rare cases.

Eruption In cattle the eruption of the permanent teeth is subject to considerable variations.

Time of eruption	Incisors	Molars
Birth to 1 month	All 8 temporaries	All 12 temporary premolars
6 months	—	4th permanent (molar)
1 year to 1 year 3 months	—	5th permanent (molar)
1 year 6 months to 2 years and 6 months	—	2nd permanent premolars
1 year 9 months	1st pair permanent	
2 years to 2 years 6 months	—	1st permanent premolar and 6th permanent (molar)
2 years 3 months	2nd pair permanent	
2 years to 2 years and 6 months		
2 years 6 months to 3 years		3rd permanent premolar
2 years 9 months to 3 years	3rd pair permanent	
3 years 9 months	4th pair permanent	

Sheep/Goats The terms which were used as applied to cattle, and the description of the various teeth, may be taken to hold good for sheep as well. The sheep has 8 lower incisor teeth but none in the upper jaw. There are 24 cheek teeth (molar and premolar), 12 in each jaw, of which half these numbers are represented in the temporary dentition.

Eruption The following is given as an average eruption table for improved breeds of sheep in Great Britain:

VetBooks.ir

Time of Eruption	Incisors	Canines	Molars
At birth to 1 month	All temporaries	Both temporaries	All temporaries
3 months	—	—	4th permanent
9 months	—	—	5th permanent
12-16 months	Central permanents	—	—
18 months	—	—	6th permanent
20-23 months	Medial permanents	—	1st and 2nd permanents
24 months	—	—	3rd permanents
25-28 months	Lateral permanents—	—Both permanents	—
30-35 months			

Pigs There is probably no farm animal which shows such variation in the eruption of its teeth as the pig, but because of the demand for young pigs for killing by weight and size rather than by age, and because of the intractability of older breeding animals – sows and boars – the actual age of the pig is not of such very great importance, except perhaps for fat stock show purposes.

When the permanent teeth have all erupted they are distributed as follows:

	Incisors	Canines	Molars
Upper jaws	6	2	14 (i.e. 8 and 6)
Lower jaws	6	2	14 (i.e. 8 and 6)

In the molar region there is a little tooth in each of the four jaws, erupting at about five to six months, which is permanent from the very beginning. It is sometimes called the premolar, and in some cases is never developed. The next three teeth behind it are represented in the temporary dentition, the permanents replacing them in the usual way. The last three teeth are true molars, i.e. permanents only.

The temporary dentition is as follows:

	Incisors	Canines	Molars
Upper jaws	6	2	6
Lower jaws	6	2	6

Incisors: the upper incisors are small, and are separated from each other by spaces. The 1st pair (centrals) are the largest, and converge together. The 2nd pair are narrower and smaller; while the corner pair are very small and laterally flattened. The lower incisors are arranged in a convergent manner, and point forwards horizontally in the jaw. The 1st two pairs are large prismatic teeth deeply implanted in the jaw-bones and are used for 'rooting' purposes. The corner pair are smaller, and possess a distinct neck.

Canines, or tusks, are greatly developed in the entire male, and both upper and lower tusks project out of the mouth. The upper canines of a boar may be 7.5 cm to 10 cm (3 in to 4 in) long, while the lower ones may reach as much as 20 cm (8 in) in an aged animal. Each has a large permanent pulp cavity from which the tooth continues to grow throughout the animal's life.

At three months the lateral temporary incisors are well up, and the temporary molars are well in wear.

At five months there are signs of the cutting of the premolars (i.e. the No. 1 molars), and the 5th molar (a permanent) is seen behind the temporaries. It is, however, not yet in wear.

At six months the premolars are cut and the 5th permanent molar is in wear.

At seven to eight months there are signs of the cutting of the corner permanent incisors, or they may already be through the gums. The permanent tusks are also often cutting through the gums at this age in forward animals.

At nine months the corner permanent incisors are well up and the permanent tusks are through the gums, although in many cases there may be still one or two of the small temporary tusks in position. Where they are cut they are not far through the gums.

At one year it is generally held that the central permanent incisors cut through the gums, but there are a large number of animals which do not cut these teeth till about 13 months old. The 6th permanent molar cuts at this time, and is more reliable than the incisors for reference.

Shortly after one year the three temporary molars fall out and their places are taken by the permanents. They are into line with the other molar teeth three months later.

At 17 to 18 months, when the final changes occur, the 7th molar, the last permanent molar tooth, and the lateral permanent incisors are cut through the gums. By this time the pig has obtained its full permanent dentition, and the succeeding changes are not sufficiently reliable to warrant estimations of age being based upon them.

Dogs The average adult dog has 42 teeth. The upper and lower jaws contain six incisors, two canines, eight premolars, and six molars (usually there are four in the upper jaw). (There is some breed and individual variation in the number of permanent teeth, brachycephalic breeds, e.g. Pekingese, Boxer, and Bulldog, having fewer teeth.)

VetBooks.ir

Cats The number of teeth in the adult cat averages 30. In the upper jaw there are six incisors, two canines, six premolars, and two molars; the lower jaw has six incisors, two canines, four premolars, and two molars. Some cats have only 28 permanent teeth; lacking two premolars.

Rabbits are unique in that they are born with permanent teeth. Milk teeth are shed before birth and may be found in the placenta. The dental formula of rabbits is: upper jaw four incisors, no canines, six premolars, four to six molars; lower jaw two incisors, no canines, four premolars, six molars. In rabbits the premolars are difficult to differentiate from the molars, so both are referred to as 'cheek teeth'.

Deoxyribonucleic Acid
(See under DNA.)

Department for Environment, Food and Rural Affairs
(See DEFRA.)

Department of Agriculture, and Rural Development (DARD)
The government department responsible for farming and agriculture in Northern Ireland. Address: Department of Agriculture and Rural Development, Dundonald House, Upper Newtownards Road, Ballymiscaw, Belfast BT4 3SB. Helpline telephone: 028 9052 4999; email: dardhelpline@dardni.gov.uk.

Department of Agriculture, Fisheries and Food (DAFF)
The government department responsible for farming and agriculture in the Republic of Ireland. Address: DAFF, Agriculture House, Kildare Road, Dublin 2, Republic of Ireland. Telephone: 011 607 2000; email: webmaster@agriculture.gov.ie.

Depilation
Depilation is the process of the destruction of hair that takes place during certain skin or other diseases, or after the application of chemical or thermal substances to the surface of the body. (See MANGE; RINGWORM; 'BALDY CALF' SYNDROME; BURNS AND SCALDS; CYCLOPHOSPHAMIDE, ALOPECIA.)

Depluming Scabies
Depluming scabies is a form of parasitic mange affecting the fowl, in which the feathers are eaten through close to the skin surface and fall or break off. It is caused by *Cnemidocoptes gallinae*. (See MITES, PARASITIC.)

Depraved Appetite, Pica
(See under APPETITE.)

Depression
1. A lowering of the consciousness of an animal.
2. A reduction or lowering in the animal's activity.
3. A hollow or depressed area.

Dermatitis
Dermatitis means any inflammation of the skin. (See SKIN; ECZEMA; ALLERGY.)

Dermatographism
This is the tendency of the skin to form weals when rubbed or scratched. It has been recorded uncommonly in the dog and some other species. It has been called, incorrectly, FACTITIOUS URTICARIA.

Dermatophilus
Dermatophilus infection results in a chronic dermatitis, in which the hairs stand erect and matted in tufts, like a wet paintbrush. Many species of animals are susceptible, e.g. horses, cattle, sheep (also dogs and cats).

Cause *D. congolensis*, which is a Gram-positive bacterium having some fungus-like characteristics, e.g. the production of branching filaments.

The disease, also known as cutaneous streptothricosis or mycotic dermatitis, follows the prolonged wetting of an animal and is widespread in the tropics, but occurs also in temperate climates such as Ireland, Britain, etc. (For examples in horses, see GREASY HEEL; 'RAIN SCALD'.)

In sheep, where it is also called 'LUMPY WOOL', it can cause 'STRAWBERRY FOOT-ROT'.

Predisposing causes, other than wetting, include tick and insect bites, wounds from thorns, etc. Fly transmission is recognised. The bacterium can resist drying, but under wet conditions it invades the epidermis, with effects mentioned under 'greasy heel', where first-aid and precautionary measures are given. Antibiotics are helpful in treatment.

In the tropics, dipping to control ticks is regarded as important, and acaricide preparations used in sheep dips are effective against *Dermatophilus*. (See also SENKOBO; STREPTOTHRICOSIS.)

Dermatosis Vegetans
A hereditary disease of young pigs characterised by raised skin lesions, abnormalities of the hooves, and pneumonia. The semi-lethal recessive gene probably originated in the Danish Landrace. UK outbreaks occurred in 1958 and 1964.

Dermatosparaxis
A rare feline disease, resembling the human EHLERS-DANLOS SYNDROME, and characterised by abnormal elasticity of the skin. The latter and its blood vessels also become fragile. Any wound healing takes longer than normal. The disease is inherited. A similar condition is seen in rabbits.

VetBooks.ir

Dermis
The layer of the skin between the epidermis and the subcutaneous tissue (see SKIN).

Dermoid Cyst
Dermoid cyst is one of the commonest of the teratomatous tumours. It consists usually of a spherical mass with a surrounding envelope of skin. In this there are sebaceous glands and hair follicles from which grow long hairs. These, together with shed cells and sebaceous material, form the central part of the mass.

Dermoid cysts develop subcutaneously in various situations, and are also found in ovary or testicle. They arise through the inclusion in other tissues of a piece of embryonic skin, which continues to grow and produces hair, etc., just as does skin on the surface of the body. Owing to the cystic structure (i.e. the cavity being a closed one) there is no means of getting rid of shed hair, debris, etc., and these substances accumulating in the centre cause the cyst to continue slowly increasing in size.

A dermoid sinus is a common congenital abnormality of the Rhodesian Ridgeback dog.

Treatment No local treatment is of benefit. Surgical removal of the cyst wall and its contents, with the necessary means to obliterate the cavity, is desirable with subcutaneous dermoid cysts.

Dermoid Sinus
An inherited condition seen in RHODESIAN RIDGEBACKS. A sinus connects the skin with the DURA MATER in the vertebral canal, or to another structure, before the dura. It is seen as a tuft of hair which protrudes from each sinus. The sinuses may become infected.

Derquantel
An anthelmintic from the SPIROINDOLE (5- SI purple) class. It is used in the oral treatment of sheep gastrointestinal NEMATODES and LUNGWORM in combination with ABAMECTIN and MILBEMYCIN.

Derrengue
A paralysis of cattle occurring in El Salvador, and attributed to the ingestion of a weed, *Melochia pyramidata*, during periods of drought when scrub is the only available fodder. The signs resemble vampire-bat-transmitted rabies (*Derriengue*) and include a paralysis first of the hind legs, with knuckling of the fetlocks. Death usually follows.

Derriengue
The Mexican name for vampire-bat-transmitted rabies. (See VAMPIRE BATS.)

Derris
The powder obtained by grinding the root of a South American plant. It contains rotenone, a parasiticide, useful against warbles, fleas, and lice. It will not kill the nits of the last, however, and hence the dressing must be repeated. Against fleas and lice it can be used as a constituent of a dusting powder, or with soap and warm water as a wet shampoo.

Derris is highly poisonous to fish – a fact which must be borne in mind when disposing of the powder or solutions in circumstances which could lead to river pollution.

Derzsy's Disease
A form of viral hepatitis that can cause a high mortality among goslings. The cause is the goose parvovirus strain 1. Signs include dullness, loss of appetite, conjunctivitis and nasal discharge. A mutant virus is used to immunise layers and so protect their goslings.

Desinewed Meat
This meat is obtained by using a low pressure technique on bones and the resultant product resembles mince. A moratorium was placed on the use of the process in cattle, sheep and goats by the EU in April 2012 although there was no known health risk.

Deslorelin
A gonadotrophin-releasing hormone super-agonist used as an implant in male dogs to inhibit testosterone and spermatozoa production, rendering them sterile for about six months. It is a contraceptive used as an alternative to castration. It is also used as an implant in horses to synchronise insemination and ovulation. It has been used as an alternative to neutering for both FERRET sexes.

Desmitis
Inflammation of a ligament. (See LIGAMENTS - DESMITIS.)

De-Snooding
The removal of a turkey poult's snood, which may be pinched out or removed with a suitable instrument. De-snooding is done by turkey farmers because the snood is one of the first parts of the body to be attacked during a fight. It then provides an ideal site for invasion by *Erysipelothrix rhusiopathiae* or other pathogens.

Desquamation
Desquamation means the scaling off of the superficial layers of the skin. It is a continuous physiological process and is also applied to the peeling process that accompanies some forms of MANGE and RINGWORM, as well as to the state of the skin in dry ECZEMA.

VetBooks.ir

Destruction (Humane) of Animals
(See EUTHANASIA.)

Detergent Residue
Detergent residue in syringes used for spinal injections has caused serious demyelinating complications in humans. Similarly, an unrinsed 'spinal outfit' has led to paraplegia in a dog.

Detergents
Detergents are substances which cleanse, and many are among the best wetting agents (i.e. substances which lower the surface tension of water and cause it to spread over a surface rather than remain in droplet form). Detergents are inactivated by soaps, and the 2 must not be used together. Detergents are widely used in the cleansing of milking equipment, etc., and formulated in skin lotions and shampoos. They will remove gross contamination but are not themselves disinfectants, which, if necessary, must be applied after detergents. Examples of detergents are cetrimide and sodium lauryl sulphate. See also LAUNDRY DETERGENT POD POISONING.

Determinant
A term sometimes used in epidemiology to describe a variable which results in an increased or decreased risk for an animal developing a disease, infection or illness. Thus it is a RISK FACTOR.

Detomidine
Given by intravenous injection, this drug has been found useful for the sedation of horses during radiography, endoscopy, etc. Sedation lasts for 20 to 30 minutes. An analgesic such as butorphanol or morphine is needed in addition to provide pain relief and deepen sedation. It is also used as an equine anaesthetic, administered in conjunction with ketamine, and an oromucosal gel.

Devil's Claw
A herb (*Harpagophytum procumbens*) used in mainland Europe for the treatment of arthritis and also in veterinary preparations as an alternative to phenylbutazone. Such treatment usage in a horse means that it will not give a positive blood test to phenylbutazone.

Devon Closewool Sheep
A breed originating in the Exmoor region of Devon, England. It originated in the late 19th century by crossing EXMOOR ewes with DEVON LONGWOOL rams with the first flocks being registered in 1894. They have a white face, a dense medium-length fleece and are naturally polled. Rams weigh 90 kg (200 lb) and ewes 55 kg to 60 kg (120 lb to 132 lb). They were selected for lowland and upland living.

Devon Longwool Sheep
An old breed, now fairly rare, developed from the Devon Longwool crossed with the South Devon breed. It is found mainly in the South West of England; there is a Devon and Cornwall Longwool Association, founded 1977. They have a white face with black nostrils, both sexes are polled and they have long woolly forelock. The back and legs are well woolled. They produce one of the heaviest sheep fleeces, with long curly wool. The fleece is used for rugs and carpets as well as clothing including tweeds, braids and linings. They are well muscled, with good conformation and are used for meat. Rams weigh about 136 kg (300 lb) and ewes 100 kg (220 lb).

Devon Rex Cat
A breed of domestic cat lacking guard hairs and so showing a fine, almost bald, towelling-like coat. The breed has large eyes and ears, slightly upturned noses and heavily curled whiskers which appear to be almost absent. They are prone to hip dysplasia and a form of MYOPATHY peculiar to the breed. They have contributed to producing the SPHYNX CAT.

Devon Ruby Cattle
(See NORTH DEVON CATTLE.)

De-Wattling
The removal of a fowl's wattles. In England, Scotland and Wales it is no longer legal as it is not a 'permitted procedure'. (See also DUBBING.)

Dew Claws
Dew claws in cattle are sometimes torn off or injured by slatted floors. (For dew claws in dogs, see NAILS; CLAWS.)

Dewlap
A loose fold of skin under the jaw or neck. It is found in some cattle and dogs, e.g. bloodhounds.

Dexamethasone
One of the synthetic CORTICOSTEROIDS. It is used as an anti-inflammatory agent in cases of shock, allergies, ketosis, etc.

Dexmedetomidine
One of the ALPHA (A)-2 ADRENERGIC AGONISTS showing ANALGESIC properties with few cardiovascular side effects. (See also MEDETOMIDINE.)

Dexter Cattle
One of the smallest European cattle breeds; adult cows weigh 270 kg to 320 kg. Dual-purpose cattle, they are commonly black in colour but some are dark red or dun. Only Short-legged Dexters are carriers of the ACHONDROPLASIA (or BULL-DOG CALVES) gene.

Dexter-Kerry Cattle
(See DEXTER CATTLE.)

Dextran
A water-soluble polysaccharide used as a plasma substitute. It may be infused intravenously instead of whole blood in cases of severe haemorrhage, etc.

Dextran Sulphate
An alternative anticoagulant to Heparin. Its effects last longer.

Dextrin
Dextrin is a soluble carbohydrate substance into which starch is converted by diastatic enzymes or by dilute acids. It is a white or yellowish powder which, dissolved in water, forms mucilage. Animal dextrin, or glycogen, is a carbohydrate stored in the liver.

Dextrocardia
A congenital transposition of the heart to the right side. Also called CARDIANASTROPHE.

Dextrogastria
The stomach being transposed to the right side.

Dextrose
Dextrose is another name for glucose.

Dhrek
An Asiatic tree of which the leaves and fruits are poisonous to farm animals. (See MELIA.)

Diabetes Insipidus, Polyuria
Diabetes insipidus (polyuria) is a condition in which there is secreted an excessively large quantity of urine of low specific gravity. It results from a deficiency in the bloodstream of the antidiuretic hormone (ADH). It is treated with vasopressin or desmopressin. (See PITUITARY GLAND.) Diabetes insipidus has been reported to occur in dogs as a result of fright; signs include poor appetite, dull coat and frequent urinating in the house. (See also POLYURIA.)

Diabetes Mellitus
Diabetes mellitus is a condition in which there is excessive glucose in the blood (hyperglycaemia). This produces various signs: thirst, polyuria, weight loss, recurrent infection; in more severe cases, diabetic coma (ketoacidosis), and progressive disease of the kidneys and retina, which may lead to blindness, may occur.

Cause Pancreatic disease in which the insulin-producing cells (islets of Langerhans) are deficient. A second, less common, type of diabetes is caused not by a deficiency of insulin but by an excess of insulin antagonist in the bloodstream. Insulin-dependent diabetes is seen in cats and dogs; the second type is more usually seen in equines.

Treatment with certain medicines – for example, glucocorticoids and megestrol acetate – may predispose to diabetes.

A study in cats found that breed had no detectable effect on the risk of the animal developing diabetes, but bodyweight, age, sex and neutering had significant effects. Overweight cats were twice as liable to develop diabetes as those of normal weight. Male cats, those over 10 years old, and neutered cats are also more likely to become diabetic. In birds, the condition is due to an excess of glucagon rather than a deficiency of insulin.

Signs These are vague at first. The diabetic animal develops an excessive thirst, and passes more urine than formerly. Appetite remains good, and sometimes becomes almost ravenous. Loss of weight occurs over a period of weeks or months. A previously active animal tends to become sluggish. The urine contains an abnormal amount of sugar. Sometimes the liver becomes enlarged.

These signs may progress to sudden depression and vomiting, which alert the cat- or dog-owner to the illness. Great weakness, a fall in blood pressure, prostration and diabetic coma may ensue as the result of ketoacidosis.

(The temporary presence of sugar in the urine, due to a metabolic disorder, involving liver and other tissues, is encountered from time to time in the course of fever, some forms of poisoning or overdosage with chloroform, chloral or morphine, and when excessive amounts of sugars or starchy foods have been eaten. These cases return to normal with recovery from the cause.)

Treatment The only effective method of treatment is injection of insulin (which is ineffective if given by mouth), at regular intervals for the rest of the animal's life, together with attention to the diet. This is a matter which must be undertaken under expert supervision, and with dedication on the part of the owner.

There are three types of insulin injection: short acting (soluble insulin); intermediate (insulin zinc suspension and isophane insulin); and long acting (protamine zinc insulin). The duration of activity ranges from about eight hours for soluble insulin to about 36 hours for protamine zinc insulin. Treatment is begun by establishing the correct dosage regime – individual animals differ in their response to a given dose. Small doses of 0.5 ml or 1.0 ml per kg bodyweight are given and the dose increased gradually until the optimum glucose level is reached. In many cases, a single daily

VetBooks.ir

VetBooks.ir

injection of a longer-acting insulin will suffice. A regular, fixed routine of insulin, feeding and exercise must be observed, with meals being given when insulin activity is at a peak. It will take a few days to achieve stabilisation of dosage and routine. Animals vary considerably in their response to treatment but most dogs and cats tolerate the injection procedure quite well once they are accustomed to it.

Oral antidiabetic drugs such as chlorpropamide and tolbutamide, or biguanides may be effective in some cases where some insulin activity remains; control by diet alone is rarely effective, except in early cases.

Birds do not respond to administration of insulin as it increases further glucagon production. Oral medication, such as glibencamide, which impedes intestinal absorption of glucose, is more appropriate. The substitution of INULIN (a carbohydrate found in Jerusalem artichoke and sweet potato) as dietary glucose is also claimed to be effective.

Hypoglycaemia if mild, as after too strenuous exercise, is corrected by feeding the animal or giving glucose or sugar dissolved in water.

Severe hypoglycaemia must be treated as soon as possible in order to avoid irreversible brain damage.

In the emergency situation, when ketoacidosis is approaching the coma stage, dehydration must be countered by intravenous infusion of 50 per cent glucose solution at a rate of 1 ml per kg bodyweight, or by glucagon injection, 20 mcg/kg subcutaneously, intramuscularly or intravenously.

Diagnostic Imaging

Relatively non-invasive methods of investigating disease in man and animals. Examples include COMPUTED TOMOGRAPHY, ENDOSCOPY, MAGNETIC RESONANCE IMAGING (MRI Scans), RADIOGRAPHY, ULTRASONOGRAPHY. (See X-RAYS; RADIOISOTOPES.)

Diagnostic Tests

(See LABORATORY TESTS.)

'Diamond Eye'

This is the common name for an ophthalmic condition which is a combination of ECTROPION and ENTROPION. It is seen particularly in some dog breeds such as ST BERNARDS.

Diamorphine, Heroin

A potent, but addictive, analgesic drug not used in animals. Sniffer dogs are trained to detect smuggled heroin at ports and airports. If a package leaks the dog may inhale or ingest the material. If it swallows the drug, the dog should be given an emetic as quickly as possible so that the dog associates the drug with vomiting. This training helps prevent the dog becoming addicted.

Diaphoresis

Diaphoresis is another name for perspiration (see SWEAT).

Diaphoretics

Diaphoretics are remedies which promote perspiration.

Diaphragm

Diaphragm is the muscular and tendinous structure which separates the chest from the abdominal cavity in mammals. It is an important organ in respiration. (See MUSCLES.)

Diaphragmatocele

A rupture in the diaphragm. This allows some of the abdominal organs, often the small intestine, stomach, and perhaps spleen and liver, to obtrude, so that they become located within the chest cavity. It occurs during falls, when jumping from a great height, and sometimes in cats and dogs hit by a car. The breathing becomes very much disturbed and the animal usually shows an inclination to assume an upright position, whereby the organs are encouraged to return to the abdominal cavity and pressure on the lungs is relieved. Treatment is by repair of the hernia under general anaesthetic. (See THORACOTOMY.)

Diaphysis

The part of a long bone that lies between the two epiphyses, i.e. the main shaft of the bone.

Diarrhoea, Diarrhea (US)

Diarrhoea is not, of course, a disease in itself, but merely a sign, which may indicate nothing more than the result of an 'error of diet', or a 'chill'. A sudden change of diet, or the feeding of unsuitable, mouldy, rancid, or fermenting material will give rise to diarrhoea – a sign of enteritis. It is the formation of unformed liquid faeces usually with an increased frequency. Some drug treatments can also cause diarrhoea as a side-effect.

Continuing diarrhoea is always serious because not only are the digestive processes and the absorption of nutrients impaired, but the loss of fluid gives rise to DEHYDRATION – a frequent cause of death unless treatment is undertaken in time. If diarrhoea persists for 48 hours or more, veterinary advice should be sought by livestock-owners.

Other causes include poisons such as lead, arsenic and mercury; infection with tuberculosis in some part of the bowel wall; the presence of

VetBooks.ir

parasites such as worms, flukes, or coccidiae; infection with specific diseases, such as JOHNE'S DISEASE, SALMONELLOSIS, LAMB DYSENTERY, WHITE SCOUR IN CALVES, etc.; or the excessive action of purgatives given in too large doses. In all of these instances there are other signs which help in the diagnosis of the condition, and examination of the diarrhoeic material will often show the presence of the agent responsible (see SALMONELLOSIS).

Treatment The treatment of diarrhoea from specific causes is dealt with under the appropriate headings. (See also WORMS, FARM TREATMENT AGAINST.)

If diarrhoea persists, the mere loss of large amounts of fluid from the body may itself become serious, and it becomes essential to replace this fluid. (See under DEHYDRATION.)

Irrigation of the bowel with warm saline is useful in some cases of severe diarrhoea in puppies.

Adult cattle The best first-aid measure is to feed hay only. If 'scouring' persists beyond 48 hours, obtain veterinary advice. Specific diseases in which diarrhoea is a sign include AMYLOIDOSIS; FASCIOLIOSIS; JOHNE'S DISEASE; SALMONELLOSIS; PARASITIC GASTROENTERITIS; TUBERCULOSIS; CRYPTOSPORIDIOSIS and BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE.

Calves Neonatal diarrhoea is still regarded as the most important disease of young calves in both dairy and beef herds. Mortality varies widely from 0 to 80 per cent, and in non-fatal cases the resultant poor growth-rate and the cost of life-saving treatment can be a source of considerable loss to the farmer.

The causes are various. Although pathogenic strains of *E. coli* are important in the septicaemic and enterotoxaemic forms of the disease, there is doubt concerning the role of *E. coli* in all outbreaks of typical calf scours.

Of the many other bacteria which have been associated with the disease, few – with the exception of salmonella – can be shown to be the cause.

For viruses associated with diarrhoea in calves, see ROTAVIRUS; CORONAVIRUSES; REOVIRUS.

The coronavirus was originally isolated from scouring calves in Nebraska, USA, and shown to be present also in the UK. This virus resembles that causing transmissible gastroenteritis of pigs (TGE). (See also WHITE SCOUR IN CALVES; SALMONELLOSIS; COLOSTRUM.)

Sheep Lamb dysentery, *E. coli* infection, coccidiosis, parasitic gastroenteritis, salmonellosis, poisoning and a sudden change to grain feeding are among the causes of diarrhoea. (See also JOHNE'S DISEASE; WORMS, FARM TREATMENT AGAINST; SOIL-CONTAMINATED HERBAGE; CAMPYLOBACTER INFECTIONS; COCCIDIOSIS; COPPER, POISONING BY; ROTAVIRUS.)

Pigs The causes are numerous and include: iron deficiency; high fat content of sow's milk at about the third week; stress, caused by e.g. long journeys; cold, damp surroundings; change of diet; vitamin deficiencies; poisons; transmissible gastroenteritis (TGE), swine dysentery, porcine intestinal adenomatosis and other disease. Viruses responsible include coronavirus and rotavirus. Bacteria include *E. coli* (some strains), *Campylobacter*, *Salmonella cholerae suis*, *S. dublin*, *Clostridium perfringens*, *Erysipelothrix rhusiopathiae* (the cause of erysipelas); also protozoa, e.g. *Balantidium coli*, *coccidia*; fungi; yeasts; worms.

E. coli is regarded as being associated with a high proportion of outbreaks of scouring, though it can be obtained from the gut of virtually any healthy pig. Its precise importance and roles are explained under *E. Coli*. *E. coli* vaccines have been administered to sows before farrowing on farms where scouring is a problem. (See also K88 ANTIGEN.)

Scouring piglets need plenty of drinking water, for there is always danger of DEHYDRATION. (See also SWINE DYSENTERY; SOWS' MILK; SWINE FEVER; ILEUM; NECROTIC ENTERITIS.)

Dogs Diarrhoea may be associated with a number of infections, distemper, toxoplasmosis, tuberculosis, nocardiosis; parvovirus; occasionally with pyometra; with allergies; tumours; parasites, and poisoning.

Diarrhoea may also result from an infestation of dog biscuits or meal, stored in large bins, by flour/forage mites (see FLOUR-MITE INFESTATION). (See also SALMONELLOSIS; *E. Coli*; STRESS; PANCREAS; WORMS; CANINE PARVOVIRUS; *Campylobacter* SPP. INFECTIONS; ROTAVIRUS; YERSINIOSIS; GIARDIASIS.)

Chronic diarrhoea is occasionally caused by *Clostridium difficile*.

Cats Similar causes (except distemper) apply. (See also FELINE INFECTIOUS ENTERITIS; FELINE INFECTIOUS PERITONITIS; FELINE LEUKAEMIA; COCCIDIOSIS; AEROMONAS; CORONAVIRUSES.)

Horses Clinical evidence has suggested a possible association between diarrhoea, stress, and antibiotic therapy. For example, a horse which is undergoing stress and happens to be a salmonella carrier may develop diarrhoea, and this may be exacerbated by tetracycline therapy which removes normal bacterial antagonists of the salmonella.

VetBooks.ir

Diarrhoea may, of course, be unassociated with stress, and among the many other causes is ulceration of the colon and caecum – probably caused by the thrombo-embolism associated with migrating larvae of the worm *Strongylus vulgaris*. (See also FOALS, DISEASES OF; SALMONELLOSIS; EQUINE INFECTIOUS ANAEMIA; EQUINE VIRAL ENTERITIS; HORSES, WORMS IN; GLOBIDIOSIS; CANCER; and POTOMAC HORSE FEVER.)

Whenever an apparently simple diarrhoea lasts for more than one or two days, it is wise to seek professional advice rather than attempt what must at best be only empirical treatment. The temperature is a useful guide to the severity of the condition, especially in young animals such as foals and puppies, and in all cases where it is high it is an indication that there is some serious condition complicating the diarrhoea which demands immediate attention.

Rabbits True diarrhoea is rare in adult rabbits but often the adherence of CAECOTROPHS to the fur around the anus is often confused by owners as diarrhoea. In weaning rabbits (i.e. at about three weeks of age) pathogenic diarrhoea can be life-threatening.

Diastasis
Diastasis is a term applied to separation of the end of a growing bone from the shaft.

Diastema
A gap between the front and cheek teeth in ruminants. In horses, the term refers to a gap between teeth of the same type, e.g. cheek teeth diastema – one of the most painful oral conditions in the horse. Also it is the gap between primary and secondary wing feathers in some species of birds including raptors. The plural is diastemata.

Diastematomyelia
A cleft spinal cord, also called MYELOSCHISIS.

Diastole
Diastole means the relaxation of a hollow organ. The term is applied in particular to the heart, to indicate the resting period that occurs between the beats (systoles) while the blood is flowing into the organ.

Diathermy
Diathermy is a process by which electric currents can be passed into the deeper parts of the body so as to produce internal warmth and relieve pain, or, by using powerful currents, to destroy tumours and diseased parts bloodlessly. Short-wave diathermy has been used in the treatment of muscle, tendon, and ligament strains. In horses with e.g. flexor-tendon trouble, 20-minute treatments over a period of a week may be effective. See also RADIOSURGERY.

Diazepam
A benzodiazepine tranquilliser used in the treatment of epilepsy and some abnormal behaviours in the dog. It is also used in foals and young camelids. Valium is a proprietary name.

Diazinon
An organophosphorus compound formerly used in dips for sheep scab and other ectoparasites.

Diazinon granules are used for the control of wireworms on lawns and larger areas of grassland. If applied too liberally there is a risk of poisoning to birds, and also to young cattle. Diazinon was placed under voluntary and then compulsorily banned by the Environmental Agency in the UK and it was banned in the USA in 2005.

Dibasic
A compound containing two replaceable hydrogen ions.

Dichlorophen
A drug formerly used against tapeworms in the dog. Dichlorophen ointment and a spray preparation have been used in the treatment of ringworm in cattle.

Dichlorvos
An organophosphorus insecticide and parasiticide formerly used in a range of internal and external applications. For example, it has been used against fowl mites on laying hens and turkeys, and as an aerosol and in FLEA-COLLARS for treating flea infestations in cats and dogs. However, in common with other organophosphorus compounds dichlorvos carries the risk of toxicity.

Diclazuril
A drug used for the treatment and prevention of coccidiosis in turkeys, meat-producing chickens, rabbits and lambs.

Diclofenac
A NSAID which was licensed in EU countries such as Italy and Spain. Death of treated livestock resulted in the subsequent loss of vultures in the Indian subcontinent. The bird deaths were due to toxicity. India, Pakistan, Nepal and Bangladesh withdrew veterinary medicine sale.

Dicoumarol
Dicoumarol is chemically related to WARFARIN; it is an anti-coagulant and a cause of internal haemorrhage. The latter condition may develop after cattle have eaten mouldy hay containing sweet vernal or sweet clovers, the COUMARIN content of

which has been converted to dicoumarol.

Dicrocoelium
(See under LIVER-FLUKES.)

Dicrotic
Dicrotic pulse is one in which at each heartbeat, two impulses are felt by the finger that is taking the pulse. A dicrotic wave is normally present in a tracing of a pulse as recorded by special instruments for the purpose, but in health it is imperceptible to the finger.

Dictyocaulus arnfieldi
The equine lungworm: it is primarily found in donkeys where it does not usually cause clinical signs. It may infest horses without signs or it can result in illness.

Dictyocaulus eckertii
The lungworm found in deer. There is some argument as to whether it is different to *D. viviparus*.

Dictyocaulus filaria
One of the lungworms found in small ruminants, especially sheep. It can cause disease but is less of a clinical problem than *D. viviparus* is in cattle. The parasite can cause severe problems in goats.

Dictyocaulus viviparus
(See PARASITIC BRONCHITIS.)

Dicyclanil
Dicyclanil is available as a pour-on preparation for the long-term prevention of blowfly strike in sheep and lambs. It stops the development of fly larvae by interfering with moulting and pupation. Used correctly, the effect should last 16 weeks. It cannot be used in animals producing milk for human consumption and the withdrawal period in animals used for meat is 40 days.

Didelphic
Having or related to a double uterus.

Dieldrin
A persistent organochloride insecticide formerly used against the maggot-fly of sheep. Dieldrin is highly poisonous to birds and fish. The signs of dieldrin poisoning in foxes (which have eaten poisoned birds) are stated to resemble closely those of fox encephalitis. Dogs and cats have been poisoned similarly. (See also DOG, KENNELS.) Dieldrin has been suspected as a cause of infertility in sheep, and residues in the fat may be a danger to people eating the mutton or lamb. The use of dieldrin sheep-dips was banned in the UK in 1965, following similar bans in Australia and New Zealand. Dieldrin was also banned as a dressing for winter wheat early in 1975. Dieldrin is still used for ground spraying in Africa (see under DDT; and CHLORINATED HYDROCARBONS).

Diesel Oil Poisoning
Thirsty cattle have drunk diesel oil with fatal results. Cattle with access to canals may drink water contaminated with diesel oil from boats. The results are less severe and recovery is possible.

Signs include loss of appetite, depression, vomiting, tympany of the rumen, and emaciation. Death (sometimes from lung damage) may occur after several weeks.

Diesel poisoning occurred in a ewe after eating grass contaminated by oil from a fuel tank sited in a field. Breath, urine and faeces all smelt strongly of the oil.

The most important part of animal husbandry is sound feeding of the animals. This is not by any means, as might be supposed, a simple matter.

In order fully to understand rational feeding, owners of livestock (and of companion animals) must be conversant with the various food constituents and what part they play in the body; they must have an idea of the composition of the many foods that are available; and they must know how to make the best use of them. The importance of palatability should never be underrated.

Composition of foods By ordinary chemical analysis, foods can be split up and separated into water, proteins, fats or oils, soluble carbohydrates, crude fibre or insoluble carbohydrates, minerals and trace elements. In addition to these there are vitamins.

Water An essential need for livestock, water is discussed under the appropriate heading, It is found in greatest amount in roots, succulents such

VetBooks.ir

as cabbages and kale, wet brewer's grains, silage, and pasture grasses, which contain from 7 per cent to 90 per cent. Cereal grains, such as wheat, oats, barley, etc. average 11 per cent. Meadow grass yields from 70 per cent to 80 per cent of water, but when it is air-dried and made into hay under favourable circumstances this is reduced to 12 per cent to 14 per cent.

Carbohydrates The carbohydrates in foods are divisible into two groups: the crude fibre, and the soluble carbohydrates.

Oats contain 10 per cent of fibre and hay and wheat-straw 25 per cent and 40 per cent respectively.

Crude fibre is a mixture of celluloses, lignin, cutin, and some pentosans (polysaccharides), etc. Cellulose forms the cell-wall of plants. In its simplest form it is easily digested, but with the growth of the plant, cellulose becomes associated with lignin, which gives stiffness to the parts of the plant requiring support, and also cutin, which is a waterproofing material.

The carbohydrates are made up of carbon, hydrogen, and oxygen. Foods containing much carbohydrate are called carbonaceous foods, e.g. the cereal grains, potatoes, molasses, etc. The cereals contain from 60 per cent to 70 per cent of carbohydrate. The simplest of the carbohydrates, such as the simple sugars, are absorbed directly from the gut, while the more complex sugars, and still more complex starches, have to be reduced by processes of digestion to more simple forms before they can be absorbed and be of use to the body.

Fats or Oils Fat is present in all foods, but the quantity varies greatly; in hay there is 3 per cent, in turnips there is 0.2 per cent, in cereals from 2 per cent to 6 per cent, and in linseed as much as 40 per cent. Linseed cake, from which most of the fat has been expressed, contains on an average rather less than 10 per cent per cent. In feed produced from fat-rich sources, such as cotton seed or linseed, by extraction with a solvent, all the oil except some 1 per cent or 2 per cent is removed.

Cattle cakes and other foods in which the fat has gone rancid are dangerous for animals, and often cause diarrhoea. (See LIPIDS; COD-LIVER OIL POISONING.)

Proteins The proteins or albuminoids in a food contain, in addition to carbon, hydrogen, and oxygen, nitrogen, usually sulphur and sometimes phosphorus. Proteins are complex substances, and are made up of AMINO ACIDS.

Mineral matter or ash Plants have their own mineral peculiarities; for example, the leguminous plants are rich in calcium which is so necessary for animals; other foods, such as maize, are deficient in calcium, but contain phosphorus; while others again, such as the wheat offals, have an unbalanced mineral content.

Vitamins (See under VITAMINS.)

Function of food constituents

Carbohydrates The carbohydrates are chiefly utilised for the production of energy and heat, and what is not required for immediate use is stored as fat which is to be regarded as a reserve story of energy.

Fibre A certain amount of crude fibre is necessary in the diet of all animals except those under 24 days old, when all young domesticated animals are on a fluid diet and most are supported solely by suckling. If animals, especially herbivorous animals, are given insufficient fibre they fail to thrive, are restless and uncomfortable, and every cattle-feeder knows that without 'bulk' to the ration the animals do not do well. Breeding gilts and sows need extra fibre to stretch their stomachs so that they can accommodate enough concentrated feed during lactation to provide for their litters.

Adequate fibre is necessary for cattle and rabbits for the proper muscular activity of the whole digestive system. Secondly, the proportion of fibre in the diet has an important bearing upon the actual digestion done by living organisms within the rumen and the herbivores' CAECUM. Thirdly, a high-protein and low-fibre intake may lead to bloat. Fourthly, adequate fibre is necessary in the cow's rations if she is to give a high yield of butterfat and solids-not-fat.

On the other hand, if too much fibre is given in the ration, the animals cannot digest enough food to get sufficient nutriment. Ruminants make the most use of fibre, then horses, pigs and dogs, in that order. In rabbits the size of the fibre particle is all important, smaller particles being further digested in the caecum, while larger particles are used for transportation of nutrients to the colon. Fattening pigs, though requiring a certain amount of fibre, must have the allowance strictly limited.

Fat The fat that is digested and absorbed may be oxidised to form energy direct, or it may be built up to form body fat. Generally speaking, fat has 2.5 times the value of carbohydrates or protein as an energy producer. While a certain amount of fat is necessary in the daily diet of animals, an excessive amount does harm.

Protein It is not only the amount of protein in the ration which is important, but also the quality of that protein.

VetBooks.ir

Cereal protein is of poor quality, being deficient in LYSINE and METHIONINE; and wheat is worse in this respect than barley. Accordingly, herring, (other) fish, and soya-bean meals are relatively good sources of the desirable AMINO ACIDS.

For substitution of some of the protein in a ration or diet, see under UREA.

For health in all animals, adequate protein of good quality is essential in the diet. Failure to provide it can result in economic loss to farmers; losses often being far higher than the cost of the 'extra' necessary protein. Excess protein, on the other hand, can bring its own problems. (See under ACETONAEMIA, for example.)

Minerals, trace elements These are essential for bone formation and maintenance, milk production, fertility, and the metabolism as a whole. The essential minerals and trace elements are phosphorus, calcium, selenium, sodium, potassium, magnesium, iron, manganese, copper, zinc, sulphur, iodine and cobalt. Not only are they essential, but the balance is important, too: the ratio of one to another. For example, as mentioned under CALCIUM SUPPLEMENTS, the ratio of this mineral to phosphorus can mean the difference between health and ill health.

Proprietary concentrates from reputable manufacturers ensure a feed for farm animals and domestic pets with well-balanced minerals and trace elements.

On some soils, deficiencies of certain trace elements may occur so that special supplements may be needed.

For further information, see under METABOLIC PROFILE TESTS; TRACE ELEMENTS; CONCENTRATES; FELINE JUVENILE OSTEODYSTROPHY; PIGLET ANAEMIA; IODINE DEFICIENCY ON THE FARM; COBALT; SALT.

Vitamins (See under VITAMINS.)

Antibiotic supplements (See under ADDITIVES.)

General principles of feeding There is no such thing as a well-balanced ration suitable for all animals and all needs.

Sudden changes, involving a major proportion of the ration, are to be avoided in all stock. Changes should be made gradually or involve only one or two out of several ingredients. In ruminants a sudden change to a predominantly cereal diet can prove fatal. (See BARLEY POISONING.)

Regularity in the times of feeding is essential for success. Only good-quality food should be used; there is no economy in feeding with inferior or damaged fodder. On the contrary, the use of such food has been the cause of much illness. There should not be long intervals between meals; with horses this is one of the common causes of colic. When compounding a ration it should be remembered that a mixture of foods gives a better result than the use of 1 or 2 foods. The ration should contain a sufficiency of energy-producing constituents, sufficient protein, fibre, and mineral matter. (See CONCENTRATES.)

Digestibility of foods Only that part of a food which is digested is of value to an animal. The digestibility of foods varies greatly, some being easily and completely digested, while others, especially those containing much fibre, are digested imperfectly and with difficulty; and, of course, some animals will digest a particular food better than others. (See D-VALUE.)

Preparation of foods Some foods are fed to animals in the natural state, while others are prepared in some such way as by grinding, bruising, cutting, chaffing, boiling, steaming, or soaking in water. Oats may be bruised for hard-working horses, for colts changing their teeth, and for calves; there is undoubtedly a slight increase in the digestibility of bruised over whole grain, but for an economic advantage the total cost of bruising should be less than 10 per cent of the whole grain. Beans should be split or 'kibbled' for horses, as the tough seed-coat makes them difficult to masticate. Maize also is more easily eaten if it is cracked or rolled.

Grinding grains to a meal is advisable for pigs, but it is important that the particle size is not too small. Absence of milk in the recently farrowed sow and bowel oedema may be associated with meal particles that are too fine.

Deterioration with storage Bruised or kibbled seeds do not keep well, especially if exposed to a damp atmosphere, and are liable to turn musty owing to fermentation. So long as the grain is whole and intact it is essentially still a living entity. When crushed, etc., it is killed, and the normal processes of deterioration and decomposition commence.

All feeds tend to deteriorate and become less palatable on storage. With whole cereals this deterioration will be very slight, but with maize meal it can be rapid. It is recommended that the following storage periods should not be exceeded:

Maximum safe storage periods	
Vegetable proteins	3 months
Animal proteins	1 month
Molassine meal	2 weeks
Ground cereals	1 week
Mixed feed	1 week

VetBooks.ir

Flour mite infestation This can very adversely affect the value of animal feed. At the National Institute for Research in Dairying it was suspected that infestation with flour mites of an experimental feed, during prolonged storage, was the cause of reduced performance of growing pigs in a diet trial. A comparison was made between deliberately infested feed and control samples. It was demonstrated that, as the mite-infestation increased, there was a considerable loss of dry matter, carbohydrate and amino acids. Subsequent growth trials showed that the daily liveweight gain and feed:gain ratio were significantly reduced in the pigs on the mite-infested diet. Under the test conditions about one-fifth of the nutritive value of the diet was lost to the pig through progressive infestation with flour mites.

Palatability It is important that foods offered to animals should be palatable and appetising. Some foods are not very palatable, such as palm kernel cake or meal, but may be made more palatable by mixing with some molasses or locust bean meal. On the other hand, foods which are naturally palatable may become very unappetising if they have been allowed to get damp and musty. The inclusion of even a small quantity of musty food – such as foxy oats and mouldy hay – in a ration spoils the whole food. The greatest care should be taken to see that the food is fresh and wholesome and that food-troughs and water-troughs are kept clean.

For dangers of poisoning by mouldy food, see AFLATOXINS and MYCOTOXICOSIS.

Variety and mixtures Animals benefit from variety in their rations. It is often found that while a given ration may give excellent results for a time, there is a tendency for animals to eat the food without zest. This applies less to pigs and horses than to cattle, sheep, poultry, dogs and cats. A change, which may be quite simple, results in a return of the normal zest.

Also, as a rule, mixtures of several different foods are more palatable and are better digested than single food-stuffs. This is partly because during digestion, foods of different origins actually assist to digest each other, and partly because if there is any deficiency in a particular food substance in one food, it may be made good to the animal by being present in another one of the mixture.

Maintenance and production rations Rations given to animals can be divided into two parts, a maintenance ration and a production ration. A maintenance ration may be described as that which will maintain an animal that is in a resting and non-producing condition and in good health, in the same condition and at the same weight for an indefinite period.

A production ration is that part of the daily diet which is given in excess of maintenance requirements, and which is available for being converted into energy, as in working horses, or into milk, or into fat or wool, or is used for growth.

It will be clear that a maintenance ration by itself is uneconomical, since it gives no return.

In devising a maintenance ration it should be clearly understood that any food will not do; wheat straw does not contain sufficient protein for the maintenance of health in yearling bullocks, but wheat straw in combination with good quality hay will do so. (See RATIONS FOR LIVESTOCK - WINTER RATIONING.)

The most practical application of maintenance and production rations is in use where the cows are fed according to their milk yield.

Substitutional dieting A farmer who has fixed a daily ration for, e.g., his dairy cows, and desires to change some of the constituents in the diet by substituting other foods, should note that if foods are merely changed haphazardly weight for weight it is almost certain that the diet will be altered appreciably. For example, if 3.5 kg (7½ lb) of maize is substituted for 3.5 kg of oats in a horse's ration, the animal will be getting more nutriment than formerly, as 36 kg (80 lb) of oats are equal to 27 kg (60lb) of maize. Again, oat straw, pound for pound, has rather less than half the nutriment found in meadow hay, and so on. (See STARCH EQUIVALENT; PROTEIN EQUIVALENT; RATIONS FOR LIVESTOCK; DRIED GRASS; SILAGE; UREA.)

When substituting one food for another it is important that the change be made gradually. Disastrous results have followed the sudden change of a diet. (See also NUTRITION, FAULTY; VITAMINS; HORSES, FEEDING OF; DOGS' DIET; CAT FOODS.)

Texture This is important to acceptance of food in carnivores. The wrong 'feel' of food in the mouth often leads to rejection by pet dogs and cats.

Dietary Cation-Anion Balance (DCAB), Dietary Cation-Anion Diet

(DCAD) A dietary system used for the DRY COW or TRANSITION COW with the aim of producing an acidic diet with lowered blood pH and acidic urine. The diet involves reducing CATIONS (SODIUM, POTASSIUM) levels and increasing ANIONS (CHLORIDE, SULPHUR) in the feed with the aim of priming the system to take up CALCIUM efficiently at and following calving. The aim is to prevent MILK FEVER.

VetBooks.ir

Dietary Fibre

Usually derived from plants and is a major constituent of feeds for animals. Depending on the type of animal, it may or may not be partially digested. It also provides bulk to the diet and is often called ROUGHAGE. The undigested part is expelled in the FAECES. (See also FIBRE; HORSES, FEEDING OF; RATIONS FOR LIVESTOCK.)

Diet During Illness or Convalescence

(See NURSING OF SICK ANIMALS.)

Diet-Induced Dilated Cardiomyopathy

A condition to which large dogs are most susceptible; this is because they have lower taurine biosynthesis rates than smaller dogs and so it is suggested that the former's diets are taurine-supplemented.

Difloxin

A fluoroquinolone antimicrobial that is authorised for use in chickens and turkeys. It is effective against *Escherichia coli*, *Pasteurella* spp., and *Mycoplasma gallisepticum*.

Digestibility

(See DIET AND DIETETICS.)

Digestible Undegraded Protein (DUP)

This is protein which can be digested in the intestines of ruminants. It is able to pass through the RETICULUM and RUMEN with minimal digestion. Often it is known as 'bypass protein'. It is particularly present in SOYA especially after heating, fishmeal and MEAT AND BONE MEAL (banned in Europe).

Digestion, Absorption and Assimilation

Digestion, absorption and assimilation are the three processes by which food is incorporated into the body.

Salivary digestion begins as soon as the food enters the mouth and becomes mixed with saliva secreted by the salivary glands. It is not very thorough in animals, such as the dog, which bolt their food without careful chewing, but in the horse during feeding, and in the ox and sheep while rumination is proceeding, it is more effective, especially when starchy foods are eaten. Raw starches, which are very often enclosed in a matrix of cellulose or woody material, are not acted upon to any great extent until the cellulose covering has been dissolved, through the action of bacteria, in other parts of the system. Saliva has no digestive action upon proteins. In the domesticated dog, however, there seems little doubt that when given dry biscuits, which necessitate a certain amount of chewing, some salivary digestion does occur.

Saliva contains the enzyme ptyalin, an *a*-amylase, which actively changes the insoluble starch of carbohydrate foods into partly soluble sugars, but the process requires consummation by the enzymes of the small intestines. Ptyalin is only able to act in an alkaline medium, and its action therefore ceases as soon as the food has become permeated with acid gastric juice in the stomach. Saliva is produced by carnivores at the sound, sight, or scent of food, and rabbits secrete saliva continuously with these stimuli.

Stomach digestion begins shortly after the food enters the true stomach and continues till it leaves this organ. There are great differences in the domesticated animals, due to the fact that some, e.g. ruminants, have a compound stomach.

In animals with a simple stomach, such as the horse, pig and dog, when food enters the stomach, 'gastric juice' is secreted from the digestive glands situated in its walls. This juice contains the enzyme pepsin, which, in the presence of dilute hydrochloric acid, also produced by these glands, acts upon the protein constituents.

Gastric lipase is another enzyme, present both in ruminants and in simple-stomached animals, which is concerned with preliminary digestion of fats.

In the horse, food stays in the stomach till it is about two-thirds full, and is then hurried through to the small intestine to make room for further amounts entering from the mouth. In spite of this the stomach is practically never found empty after death – unless the horse has been starved.

In the pig and dog, food is retained in the stomach for a variable time according to the state in which it was swallowed, and is thoroughly churned and mixed with gastric juice. During this time the softer portions along with fluids and semi-fluids are squeezed through the pylorus into the intestine.

In the ruminating farm animals – cattle and sheep – stomach digestion is complicated by the presence of three compartments before the true stomach, or abomasum, is reached. These are concerned with the preparation of the food before it enters the abomasum for true digestion. Although the rumen possesses no true digestive glands, a considerable part of the digestive process takes place in it through the activity of cellulose-splitting and other organisms. (See also RUMINAL DIGESTION.)

In the unweaned calf, the act of sucking apparently stimulates reflex closure of the oesophageal groove, so that the dam's milk bypasses the rumen (where it could not be effectively digested).

VetBooks.ir

After the food has been subjected to the action of the organisms in the rumen, and has been chewed for a second time as 'cud', it is sent on into the third stomach or omasum for further breaking up by trituration, and then into the true stomach or abomasum where digestive glands are present, and where a form of digestion similar to that which occurs in the stomach of other animals takes place.

Intestinal digestion The softened semi-fluid material which leaves the stomach is commonly known as 'chyme'; it has an acid reaction, since it has been well mixed with the hydrochloric or lactic acid in the stomach. Shortly after entering the small intestine it meets with alkaline fluids and its acidity is neutralised. This occurs through the action of the bile from the liver and of the pancreatic juice from the pancreas. These fluids are similar in that they are both alkaline, but differ greatly in their functions. The BILE is partly composed of complex salts and pigments. Its function is fourfold: it aids the emulsification of fats, dividing large droplets into tiny globules which are more easily split into their component parts by other enzymes prior to absorption; it assists in keeping the intestinal contents fluid and preventing undue fermentation and putrefaction through its slight antiseptic action against putrefactive organisms; it stimulates peristalsis to some extent; and it gives the faeces their characteristic colour. The pancreatic juice contains at least three enzymes. Trypsin is active in the further splitting up of protein substances which have been partly acted upon by the pepsin of the stomach. Amylopsin acts on carbohydrate constituents, splitting them up into sugars and other substances; it has an action similar to that of the ptyalin of saliva, but can act upon raw starch. Lipase, or steapsin, is the fat-splitting enzyme of the pancreatic fluid. It acts upon the tiny globules of fat which have been emulsified by the bile, etc., and splits them into their compounds – glycerol and a fatty acid, the latter depending upon the origin of the fat.

The intestines produce a number of enzymes of which the most important are erepsin, enterokinase, maltase, lactase and invertase. The first of these completes the breaking up of any remaining protein. Enterokinase is concerned with the formation of trypsin from its forerunner trypsinogen, and the last three enzymes complete the breakdown of carbohydrates into soluble sugars. Bacteria also have a most important digestive function in the intestines. In the large intestines of herbivorous animals they have a cellulose-splitting action similar to fermentation, and like the activity of the organisms present in the first stomachs of ruminants. They act upon fats in a similar manner to the pancreatic juice; they form certain volatile obnoxious substances (indole and skatole) from proteins, which give the faeces their characteristic odour; they produce lactic acid in certain cases; and they may even destroy alkaloidal poisons which have been formed during other stages of digestion.

The large intestine of rabbits has several special functions. From the ileo-caeco-colic junction the nutrients pass either to the caecum or colon, depending on their particulate size, the separation being controlled by the fusus coli, a highly innervated muscular area of the colon. Large particles of indigestible fibre are passed to the rectum and then evacuated.

Absorption Water passes through the stomach into the intestines almost immediately. But it is only after subjection to digestion in the intestines for some hours that the bulk of the food is taken up into the system. The chyme which leaves the stomach is converted by the action of the bile and pancreatic fluids into a yellowish-grey or a brownish-green fluid of creamy consistency called 'chyle', containing in the herbivorous animals particles of hay, oats, grass, etc. From this the fats are absorbed (after emulsification and breakdown) by the lymph vessels or 'lacteals' which occupy the centre of each of the 'villi' of the small intestines. (See VILLUS.) From the lacteals the fat globules are collected by the lymph vessels of the intestines and are ultimately passed into the bloodstream. Sugar, salts and soluble proteins pass directly into the small blood vessels in the walls of the intestines, and are thence carried to the liver and so enter the general circulation.

The food is passed onwards through the various folds and coils of the intestines, each particular part of the bowel wall removing some portions of the food, and the residual, unabsorbable, useless constituents are eventually discharged from the rectum and anus during the process of defecation.

Assimilation takes place slowly. After the products of digestion have been absorbed into the blood- and lymph-streams they are carried round the body, ultimately reaching every organ and tissue, and the body cells extract from the blood in the capillaries whatever nutritive products they may require for growth or repair. For instance, cells in bony tissues extract lime salts and muscles take proteins and sugars, etc. When the supply of food is much in excess of immediate requirements the surplus is stored up, e.g. as glycogen in liver or muscle fibres.

Digital Dermatitis

A condition in cattle usually affecting the skin above the bulb of the heel. The animal is very

lame. The cause is probably a spirochete, *Borrelia burgorferi*.

Treatment Clean the affected area and use an oxytetracycline spray. For herd treatment, lyncomycin/spectomycin footbaths may be used. Antiseptic foot baths may help prevent the infection.

Digitalis

Digitalis is a preparation from the leaf of the wild foxglove, *Digitalis purpurea*, gathered when the flowers are at a certain stage.

The leaves contain glycosides, including digoxin, digitoxin, gitoxin and gitalin; the seeds contain another glycoside, digitalin. The purified glycosides digoxin and digitoxin are used medicinally.

Digitalis was used in the treatment of chronic heart disease, mainly in dogs, but newer modern alternatives have taken its place.

Digitalis is usually used in the purified form as digoxin or digitoxin. It slows the action of the heart, the drug increasing and strengthening the length of diastole. Its use in cats, where it is likely to cause vomiting, is inadvisable.

Digitalis poisoning may occur from a single, large dose or from prolonged administration. The heart's action may become irregular. Diarrhoea may occur.

In grazing animals, poisoning may result from the eating of the plant rosettes. Foxgloves included in hay have also caused poisoning.

Dihydrotachysterol

An oil-soluble steroid used to raise the calcium level of the blood, and so treat or prevent hypocalcaemia.

Dihydroxyanthraquinone

A non-toxic laxative, acting chiefly on the large intestine, effective in all the domestic animals, including horses. It may be given in the food, when it acts in about 24 hours.

Diltiazem

Used in tablet form for the treatment of primary cardiac hypertrophic cardiomyopathy in cats; it acts as a CALCIUM CHANNEL BLOCKER.

Dimethicone

An anti-frothing agent used in the treatment of 'frothy bloat' in cattle (see under BLOAT).

Dimetridazole

Dimetridazole is a drug used for the treatment and prevention of histomoniasis in turkeys, pheasants and chickens and trichomoniasis and histomoniosis in pheasants and partridges. It is the treatment of choice for trichomoniasis in pigeons as no staining of the tail feathers results. It is still used in the UK and elsewhere but is banned in many EU countries.

Dimidium Bromide

A trypanocide effective against *Trypanosoma congolense*.

Dimorphism

(adjective, Dimorphous)
Existing in two distinct forms.

Dinoprost

A synthetic preparation of prostaglandin $F_{2\alpha}$ (see PROSTAGLANDINS).

Dioctophymosis

Infestation with the kidney worm, *Dioctophyma renale*, a parasite of dogs encountered in Europe, America, and Asia. A survey of 500 dogs in Iran revealed an incidence of 1.3 per cent. Stray dogs and jackals have been found infested. Man may become infested through the eating of fish. (See also under ROUNDWORMS.)

Diodone

A contrast medium used in radiography of the kidneys.

Dioestrus

The resting, or inactive, phase of the sexual cycle in the female, during which progesterone is secreted by the corpus luteum. This causes the mare, for example, to reject the stallion and induces changes in the reproductive tract designed to provide a suitable environment for development of the embryo. In the mare, dioestrus normally lasts 15 to 16 days and is terminated by the release of one or more luteolytic factors from the endometrium which induces regression of the corpus luteum. (See OESTRUS.)

Dioxin

Dioxin is a toxic chemical formed as an impurity during the synthesis of trichlorophenol and its derivatives and found in industrial waste. Accidental exposure may lead to cancer; skin, eye, blood and liver damage; and also to abortion, fetal malformation and chromosomal aberrations. Animals outdoors near industrial plants may be at risk.

Dioxin-contaminated milk was discovered on a farm near a toxic waste disposal plant in the Netherlands. The dioxin was emitted during the destruction of polyvinyl plastic (PVC); it may be present in the exhaust from incinerators or other industrial processes. In the Netherlands, after eight hours exposure, free-range hens produced eggs containing up to 8.1 picogrammes Toxic Equivalents/g egg fat while the EU maximum level is set at 3pg/Toxic Equivalents/g egg

VetBooks.ir

fat. Dioxin contamination of animal feed in Belgium led to the condemning of meat and other food products during 1999; and in 2011, feed contamination in Germany led to 4,000 flocks being contaminated and egg products being destroyed in several countries, including Britain. Modern waste incinerators are designed to denature dioxins, rendering them harmless.

Diphtheria, Calf

(See CALF DIPHTHERIA.)

Diphtheria, Guttural Pouch, of Horses

(See GUTTURAL POUCH DISEASE.)

Diplegia

Paralysis on both sides of the body.

Diplomyelia

A congenital problem where there is doubling of the spinal cord; it is seen in certain types of SPINA BIFIDA.

Diplostomum

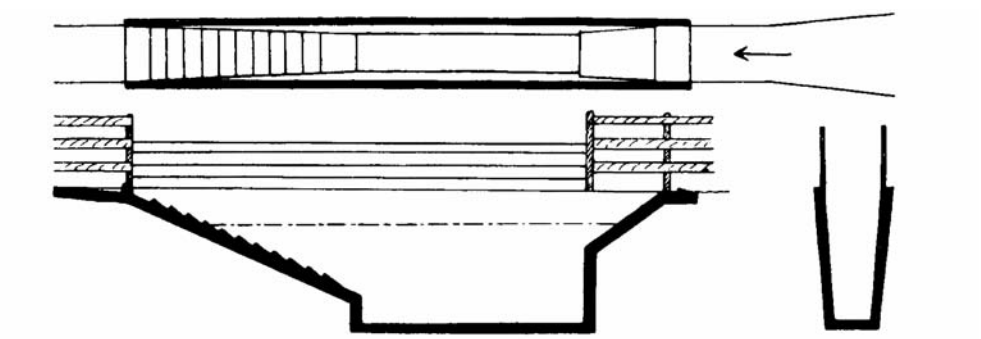
Diplostomum is a fluke which lives in the eye of salmonids. The intermediate hosts are snails and water birds, especially gulls.

Diplozoon

A monogenetic fluke of fish in which two parasites are fused together. It occurs relatively uncommonly and usually is not in sufficient numbers to cause disease.

Diprenorphine Hydrochloride

This is an important antagonist to etorphine (IMMOBILON). It should always be readily available when etorphine is being used. Following accidental human injection with etorphine, diprenorphine (Revivon) must be injected within two minutes. (See ACCIDENTAL SELF-INJECTION; IMMOBILON/REVIVON.)



Diprosopus

Duplication of the face. This is a type of conjoined twinning.

Dips and Dipping

In the United Kingdom mostly sheep are dipped, but beef cattle may also be dipped with advantage. Dipping is an important means of tick control in cattle, and is widely practised in the tropics.

Sheep are dipped in order: (1) to eradicate the commoner parasitic agents, such as keds, lice, ticks, etc.; (2) to act as a check upon the spread of mange in the sheep, commonly called 'sheep scab', and where that disease has broken out, to cure it; and (3) to prevent attack by the sheep-blowflies and consequent infestation with maggots. Dipping is no longer compulsory in the UK and a serious increase in outbreaks of sheep scab has resulted.

Plan of dipping bath. (See table for dimensions.)

	Horses			Cattle			Sheep			Pigs		
	metres	ft	in	metres	ft	in	metres	ft	in	metres	ft	in

VetBooks.ir

In the UK, dips contain amidine, organophosphorus compounds, or pyrethroids. The list of permitted dips is altered from time to time.

Precautions Purchasers and users of organophosphorus sheep dips must hold a certificate of competence in the safe use of sheep dips issued by the National Proficiency Tests Council. Protective clothing must be worn, care taken to avoid inhaling dust or spray, and splashes on the skin washed off immediately. All owners should ensure that any dips they purchase carry on their labels the statement that the dip has been approved by the Ministry of Agriculture and Fisheries (now DEFRA). The following precautions should be observed when sheep are dipped:

1. For up to five weeks after service, ewes should not be dipped lest abortion result. Pregnant ewes require careful handling to avoid injury, but with care they may be dipped almost up to the time they lamb, provided that the weather is favourable.
2. Early spring washing or dipping must be carried out with a solution which does not harm the wool, making the fibres brittle or stained.
3. Summer dipping should take place when there is a sufficiency of fleece to carry and hold the dip, and when parasites may most easily be destroyed, i.e. from three to five weeks after clipping.
4. Autumn dipping should be finished before the first frosts of the season begin, and when the weather is so much settled that rain is not expected during the next 24 hours.
5. Sheep should be offered a drink of water before being dipped in hot weather, as there is some risk of thirsty animals drinking the dip, with potentially fatal results.
6. Sheep should be rested before actual immersion, especially if recently brought in from a hill, or when they have walked a distance to the dipper. This is particularly important in hot weather.
7. Sheep with open wounds or sores, and those that have recently been attacked with maggots or have been ill, should not be dipped until the skin is whole and until they have otherwise recovered. This is another reason why dipping should not immediately follow shearing.
8. Sheep must not be turned out on to grazing land immediately after being dipped, for the drainage from the fleeces contaminates the herbage, and the sheep, being hungry, may eat sufficient dip-sodden grass to produce poisoning. They should be allowed about 15 minutes in the draining pens.
9. After dipping operations are finished the dip should be disposed of in such a way that there is no danger of it contaminating water-supplies, ponds, streams, etc. (See FISH, POISONING OF.)

Baths and Their Use The bath to be used depends on many circumstances, such as numbers to be dipped, land and materials available, and so on. The best material to use is concrete, and the most popular shape is that shown in the illustration. The dimensions for the various animals are as shown in the table (the figures are only given as a general guide).

In order to avoid waste of dip, the farmer needs to know how much liquid the bath will hold, and also needs a calibrated stick or side-marking to indicate the volume of liquid still in the bath at all stages of dipping.

What is sometimes overlooked is the fact that a sheep with wool 2.5 cm to 4 cm (1 in to 1½ in) long will not merely remove permanently at least 2.25 litres (½ gallon) of liquid, but will strain off additional insecticide. This necessitates 'topping up' of the dip wash at double strength as compared with the liquid used for the first filling of the bath.

It is a false economy not to top up before the last 20 or 30 sheep are put through the dip, since any saving of money thereby could later be more than offset by those animals becoming victims of strike. Disappointing results of any dip can also follow if sheep are immersed for far short of 30 seconds; or if they are soaking wet when they enter the bath, for then their fleeces can carry much less than the normal quantity of wash.

In all cases the animal should be totally immersed at least once and special attention should be paid to the ears and tail. Dipping must be thorough.

One dipping will seldom (if ever) be effective in ridding an animal of parasites, as the dip may not affect the eggs. The dip must accordingly be repeated at suitable intervals. Against keds, dips should be repeated in three to four weeks, and against mange in about seven to ten days.

Lameness Especially in warm climates, where the dip has been allowed to remain in the tank and has become dirty, there is a danger of sheep becoming lame after dipping. This results from infection with the bacterium *Erysipelothrix rhusiopathiae* (see under SWINE ERYSIPELAS) through any cuts or abrasions. Such lameness does not follow the use of a freshly-prepared dip. It has been obviated by the addition to the dip of tetramethyl thiuram disulphide; this controls any bacteria which contaminate the dip liquid. Non-phenolic sheep dips have little or no action against bacteria.

Spraying Dipping of all animals involves considerable trouble, expensive equipment, and in most cases is static so that animals must come to the dipper. The use of modern sprays and jets, whereby the chemical agent is directed on to the

VetBooks.ir

animal's skin with considerable force, has some advantages over dipping and is partly replacing dipping in some countries (see SPRAY RACE; also JETTING). In the UK, those who practise spraying, as opposed to dipping, would be unwise to rely on more than three weeks' protection against strike. This is partly because less insecticide remains in the fleece after spraying; also, the organophosphorus insecticides move down the wool but, apparently, not sideways, so that if a patch is left unsprayed it remains vulnerable to strike.

Protective clothing Operators engaged in dipping or spraying **must** use protective clothing. The latest guidance issued by the manufacturers or government agencies should be followed. Basically, protection such as coveralls, waterproof apron or leggings, wellington boots and elbow-length rubber gloves, a face shield and hat should be worn; details vary with the type of product used. There is a National Proficiency Test Council certificate in personal protection equipment for those regularly involved in the use of dips and sprays.

Farmers should familiarise themselves with the guidelines on the storage, use and disposal of dips issued by the manufacturers and the Veterinary Medicines Directorate.

Diptera
(adjective, Dipteran)
This Order of INSECTS includes the true flies. They have two pairs of wings on the thorax. The Order includes FLIES, MIDGES and MOSQUITOES.

Diquat
This herbicide has caused fatal poisoning in cattle, 4 years after the discarding of a container.

Dirlotapide, Slentrol
A product that can be used in obesity management of mature dogs. It should be combined with a dietary and exercise regime and progress assessed and dosage adjusted fortnightly. It must only be used in fully-grown dogs and not pregnant bitches.

Dirofilariasis
(See HEARTWORM.)

Disaccharides
These are sugars which break down into MONOSACCHARIDES.

Disalts
Disalts of organic acids (diformates, dibutyrates, etc.) have been found to be more effective against intestinal bacteria than organic and inorganic salts in some European trials.

Disbudding
Disbudding is the removal of, or the prevention of growth in, the horn buds in calves, kids, and sometimes in lambs. (See DEHORNING OF CATTLE; GOATS, DISBUDDING OF KIDS.)

Disc, Intervertebral
(See under SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Discocotyle
A monogenetic gill fluke without hooks that attaches itself to fish gills with suckers.

Discospondylosis
Inflammation of the intervertebral discs of the spinal column.

'Disease-Free' Animals (In Research)
The availability of animals born and reared free from infection is an important tool in the study of disease. The technique is used in laboratory animals and has had particular application in pigs, as described below.

Piglet mortality is one of the main sources of economic loss to the pig industry, and it is in the study of important piglet diseases that special laboratory pigs are necessary. Without such animals, research work may not only be hampered or even brought to a standstill by natural infections, but complications may also arise.

From the moment the piglet leaves the security of the uterus and enters the birth-canal it becomes exposed to an infected environment. Under natural conditions it is protected, against this environment, to a greater or lesser degree, by the wide range of antibodies received from its dam in the first milk, the colostrum. When deprived of colostrum piglets almost always die. But the research worker wishes to avoid the feeding of colostrum, since it may well contain antibodies against the disease under investigation.

The problem is, then, to rear piglets which are both disease-free and devoid of antibodies. In principle, the solution to the problem is a simple one. All that needs to be done is to obtain the piglets before they reach the infected environment and to rear them away from possible infection, so that colostrum is unnecessary. In practice, these requirements are not easily met. However, by using a technique developed in the USA at the University of Nebraska, 'disease-free', antibody-devoid pigs have been produced.

The piglets are taken direct from the sow's uterus a day or two before the estimated farrowing date. The sow is anaesthetised, the whole uterus carefully but rapidly removed and passed through a bath of disinfectant, into a sterilised hood. The

VetBooks.ir

hood is supplied with warm, filtered air under slight pressure, and two operators, working through long-sleeved rubber gloves, take the piglets from the uterus. Their navel cords are tied off, and they are dried with sterile towels. The piglets are then transferred, by means of a sealed carrying case, to sterile incubator units kept in a heated isolation room. The incubators, each of which holds one pig, are equipped with filter pads so that both the air entering the unit and that passing out into the exhaust system is filtered.

During the first few days of their independent existence, great care is necessary to protect the young animals from bacteria in general. The attendant wears a mask and cap in addition to rubber gloves and overalls. Subsequently, masks and caps are unnecessary. The diet, which consists of pasteurised milk, eggs and minerals, is sterilised by heat for the first three days of life, but not thereafter. The piglets are fed from flat-bottomed trays three times daily – morning, midday and late afternoon. There are no night feeds. After some 10 days in the incubator units the young pigs are transferred to individual open cages in another isolation pen. There they are rapidly weaned to solid food. Later, the pigs are mixed together and treated as ordinary ones except that, of course, precautions are taken to prevent accidental infection.

Pigs reared by this technique are in a state of minimal disease: they are not germ-free. In fact, non-pathogenic bacteria are deliberately introduced by feeding pasteurised, instead of sterilised, milk from the fourth day of life onwards. These pigs are not, therefore, in the same category as germ-free GNOTOBIOTIC animals. Production of 'disease-free' pigs was begun at Cambridge primarily to permit the critical investigation of pig diseases, particularly diseases of sucking pigs, but such pigs have obvious advantages for nutritional and genetic studies because the technique does eliminate that unpredictable variable, disease. (See also SPF.)

Diseases

(See NOSOCOMIAL; IATROGENIC DISEASE; STOCKMEN.)

Diseases of Animals Acts

Legislation relating to animal health, including the Diseases of Animals Act 1950, was consolidated under the Animal Health Act 1981, and then the Act of 2002, which also includes the relevant Orders made under the various Acts. The 2002 legislation extended and supported the Animal Health Acts and gave additional powers for FOOT-AND-MOUTH DISEASE and additional powers to deal with TSEs in sheep. It is administered by the Animal Health Division of DEFRA in England and Wales. In Scotland the Act was updated by Part 1 of the Animal Health and Welfare Act (Scotland) 2006.

It covers the diseases listed under NOTIFIABLE DISEASES. The equivalent legislation in Northern Ireland is the Diseases of Animals Act 2010.

The Act and Orders provide for the compulsory notification of the existence or suspected existence of these diseases; for the immediate isolation or segregation of diseased or suspected animals; for the diagnosis of suspected disease by specially trained persons; for the slaughter, treatment or vaccination of diseased or suspected animals where appropriate and for the disposal of carcases and other waste where necessary; for the payment of compensation to owners in certain cases; for the apprehension and punishment of offenders; for the systematic inspection of markets, fairs, sales, exhibitions, etc., and for the seizure of diseased or suspected animals therein; for regulating the transit and transport of animals by land or water, both within the country and in the home waters; for controlling the importation of animals and things which may introduce one or other of these diseases from abroad; and for inspection at the ports and quarantine or slaughter where necessary.

The following regulations have a general application to all scheduled diseases, but in practically every case there is at least one Order applicable to the particular disease, in which there is set out more fully regulations dealing with that disease. They can be downloaded from the DEFRA website www.defra.gov.uk

Notification of diseases or suspected disease must always be made by the owner of an animal, or by the occupier or person in charge, and by the veterinary surgeon in attendance, to an inspector of the local authority or to a police constable, without undue delay.

Presumption of knowledge of disease. A person required to give notice if charged with failure to carry out his or her obligation shall be presumed to have known of the existence of the disease, unless and until s/he shows, to the satisfaction of the Court, that s/he had not knowledge thereof and could not with reasonable care have obtained that knowledge.

Separation of diseased animals. Every person having a diseased animal shall, as far as is practicable, keep it separate from animals not so diseased.

Facilities and assistance to be given for inspection, cleansing, and disinfection. Persons in charge of diseased animals are required to give every facility for the execution of the above, and must not obstruct or in any way hinder inspectors or other officers in doing their duty.

Prohibition of exposure of diseased animals. It is unlawful to expose a diseased or suspected animal

VetBooks.ir

in a market, sale-yard, fair, or other public or private place where such animals are commonly exposed for sale; to place an affected animal in a lair or other place adjacent to or connected with a market, sale-yard, etc., or where such animals are commonly exposed for sale; to send a diseased animal on a railway, or on any canal, inland navigation or coasting vessels; to allow one on a highway or thoroughfare, or on any common or unenclosed land or in any insufficiently fenced field; to graze one on the sides of a highway or to allow one to stray on a highway or thoroughfare or on the sides thereof, etc.

Digging up carcases. No person may dig up the carcase of an animal that has been buried, without official permission. (See also under each main heading of the scheduled diseases, e.g. ANTHRAX.)

Diseases of Animals (Waste Food) Order 1973

This Order has been superseded by the **Animal By-Products (Amendment) (England) 2001** and similar legislation in Scotland and Wales. It makes it an offence for producers to feed, intentionally or inadvertently, untreated meat or meat products to any livestock their premises. Under the 2001 Amendment Order no person shall feed or allow access to catering waste containing such product or any feeding stuffs which have been in contact with it. Any litter spread on fields must be examined for the presence of carcases, which must be removed.

Diseases of Fish Act

This lists the NOTIFIABLE DISEASES. (See also FISH, DISEASES OF.)

DISH

(See DISSEMINATED IDIOPATHIC SKELETAL HYPEROSTOSIS.)

Dishorning

(See DISBUDDING.)

Dishorning of Cattle

(See DEHORNING OF CATTLE.)

Disinfectants

Disinfectants may be either physical or chemical. Among the former are heat, sunlight and electricity; while among the latter are solids, liquids and gases. Steam may be used.

Chemical disinfectants At the present time these are numerous and diverse. The Department of the Environment, Food, and Rural Affairs tests them from time to time and issues its approval only to those that are maintained up to standard. Consequently, owners should examine the labels on containers and use only those that carry the official approval since this is a guarantee of potency.

The Diseases of Animals (Approved Disinfectants) Order 1970 governs the uses of disinfectants in the UK, and specifies those approved for use in connection with four infection types: foot-and-mouth disease, tuberculosis, fowl pest, and general orders relating to disease control. Dilution rates are also specified.

A full list of disinfectants approved for use in outbreaks of foot-and-mouth disease is given under that entry.

Disinfectants act in one of three ways: (1) as oxidising agents or as reducing agents; (2) as corrosives or coagulants acting upon the protoplasm of bacterial life; or (3) as bacterial poisons.

Most chemical disinfectants are supplied in a concentrated form and must be diluted with water before use. The water should be clean, preferably soft (decalcified), and if it can be used warm the efficiency of the disinfectant is increased. After the active agent has been added, the whole should be well stirred for a few moments to ensure thorough mixing. The solution must be applied so that it remains in contact with the offending material for a sufficiently long time to kill the bacterial life; generally allow 10 minutes to half an hour before disinfecting solutions are rinsed away.

When two or more disinfectants are mixed together, instead of an increased disinfecting power in the mixture they often enter into chemical combination with each other and a useless compound results. (See also ANTISEPTICS.)

For quaternary ammonium compounds, see under this heading.

Cresol solutions: there are many of these, e.g. cresol and soap solution BP, compound cresol solution USAP, lysol, isal, cyllin, creolin, cresylin, Jeyes' fluid, or one of the proprietary preparations. These are used as 3 per cent to 5 per cent solutions for practically all purposes of disinfection about a farm premises, and very often as antiseptics also. Their action is enhanced by the use of hot water instead of cold. None is suitable for use in connection with food, for all are to a greater or lesser degree poisonous. Cresols are not very effective against many viruses or bacterial spores. The cresols are related to PHENOL.

Formalin is sometimes used as a solution for disinfecting floors, about 5 per cent strength being necessary. Formaldehyde gas may be used for fumigation of livestock buildings where viral or other diseases have occurred. (See under DISINFECTION.)

Sodium hypochlorite (bleach) is widely used and effective as a cold solution. Depending on the dilution and formulation it can be used as a general disinfectant and in, for example, sterilising milking machines. It has the advantage of leaving no taint, as it breaks down into salt and water.

VetBooks.ir

Disinfection

Disinfection of buildings cannot be achieved by applying a disinfectant solution to walls and floors which are heavily contaminated with dirt. There are two reasons for this: (1) the disinfectant cannot reach most of the micro-organisms, which will be protected by layers of dirt; and (2) the latter may alter the nature of the disinfectant solution chemically, rendering it ineffective.

Preliminary cleaning is therefore essential. The building must first be thoroughly scraped, brushed, and cleansed. Concrete floors may be power-hosed, and scraped free from all dirt and debris. A boiling hot detergent solution such as 2.5 to 4 per cent washing-soda is then thoroughly scrubbed into floors, walls, stall partitions, mangers, troughs, or other fittings.

Disinfectants After an outbreak of infectious disease, buildings and equipment must be treated to remove traces of infection before animals are rehoused. To be effective, the application of disinfectants is the second stage of the process of disinfection – thorough cleaning being the first stage. (See DISINFECTION.)

In certain cases it may be desirable to fumigate the building. All air entrances and exits are securely closed, the inside of the walls and roof soaked with water, and formaldehyde gas generated (e.g. by pouring on to 250 g of potassium permanganate 500 ml of formalin per 1000 cu ft of air space.) All doors and windows are left shut for a day, and the building is then flushed out with clean water under pressure from a hosepipe.

Steam cleaning may be carried out as part of a disinfection process.

Movable objects All pails, grooming tools, wheelbarrows, shovels, forks, etc. which have been used for the infected animals must also be disinfected before they can be considered safe for further use.

Dislocation

Dislocation is a displacement of a bone from its normal position in relation to a joint. Deformity is produced, and there may be intense pain if the part is interfered with. As well as displacement there is also bruising of the soft tissues around the joints, and tearing of the ligaments which bind the bones together.

Probably the most common dislocation is that of the patella, which becomes lodged on the uppermost part of the outer ridge of the patellar surface (distal condyle) of the femur and is trapped. In the dog, dislocation of the shoulder and elbow joints is by no means rare.

The causes of dislocations are similar to those which produce fracture, e.g. violence applied in such a manner that the structures around the joint are unable to withstand the stress. (For inherited abnormality in dogs, see under PATELLA.)

Signs The injured limb is useless, and as a rule is held off the ground in an unnatural attitude. There is generally little or no pain so long as the parts are not forcibly moved; but if a nerve trunk is pressed upon, the animal may perspire and vocalise with the pain. When the limb is compared with that of the opposite side there is seen a marked difference in its contours or outline – the joint affected shows hollows or prominences where none is seen in the normal limb. There is no grating sound heard when the joint or the whole limb is passively moved, such as occurs when a fracture exists.

Treatment The reduction of dislocations necessitates the use of anaesthesia.

Disomy

An error in MEIOSIS resulting in the offspring receiving both of a chromosomal pair from one parent and one from the other.

Displaced Abomasum

A condition encountered in cattle some weeks after calving and leading to a lack of appetite. Displacement can be left or right; left is more common; right is more serious. (See under LEFT DISPLACEMENT OF THE ABOMASUM; RIGHT DISPLACEMENT OF THE ABOMASUM; STOMACH, DISEASES OF.)

Displacement

Movement of an organ or tissue to an abnormal position or site.

Disposal of Carcases

Carcases must be disposed of under the Animal By-Products Order 1999. It is an offence to leave the carcase of an agricultural mammal unburied for 48 hours. Carcases may be sent to a knacker's yard or a destructor. Burning on the farm is possible, but may only be done by permission of the Environmental Protection Agency. Moreover, where the cause of death has been a contagious disease there is always the risk of healthy animals becoming directly or indirectly affected, and of the disease spreading accordingly. In most progressive countries there are government regulations which provide for the safe disposal of the carcases of animals that have died from any of the NOTIFIABLE contagious diseases, such as anthrax, foot-and-mouth disease, cattle plague, etc., but it is important that **all** carcases should be safely and efficiently disposed of, no matter what has been the cause of death.

The safest and most expeditious manner of disposal is for the carcase to be digested in a special

VetBooks.ir

destructor, either by heat (burning, or by live steam) or by chemical agents. In country districts, however, such plants as these are seldom available, and it is necessary to bury or burn the carcases.

Burial of carcases Horses can be buried subject to local authority policy, which may vary in different districts. Currently it is illegal to bury the carcases of cattle, sheep and goats in most parts of the UK because of the risk of contaminating soil with TSEs. Where it does occur, a suitable site should be selected where there will be no danger of pollution of streams, rivers, canals, or other water-supplies, and where there is a sufficiency of subsoil to allow a depth of 2 m (6 ft) of soil above the carcase. A pit is dug, about 2.5 m to 3 m (8 or 9 ft) deep, in such a manner that the surface soil and the subsoil are not mixed, and a clear approach is left to its edge. Roughly, about 2.5 m to 3 m² (2½ to 3 sq yd) of surface are required for a horse, 1.25 m to 2.5 m² (1½ to 2½ sq yd) for an ox, and about 1 m² (1 sq yd) for each pig or sheep. The dead animal should be arranged upon its back with the feet upwards. The carcase is next covered with quicklime or a powerful disinfectant, and the pit filled in with the soil – subsoil first and surface soil last. If the weather is very wet, or if the soil is naturally loose and soft, the surface of the ground should be fenced off to prevent horses and cattle from passing over it and perhaps sinking into the loose soil. It is not safe to plough over a large burial pit for six months after it has been closed, nor should heavy implements or vehicles be allowed to pass over it.

Cremation of carcases Where a large coal boiler or furnace is used for heating supplies of water, there is no reason why, occasionally, the carcases of small animals that have died should not be burned in it. However, special incinerators are used where small animal carcases are routinely disposed of; they must be sited to conform with local environmental health rules.

Dead horses and cattle, and large sheep and pigs, should not be dismembered and destroyed in such a manner; under special circumstances they would cremated in a specially constructed and licensed incinerator. Otherwise, in some disease outbreaks (e.g. FOOT-AND-MOUTH DISEASE), they must be burned in a specially constructed cremation pit.

There are three methods of cremation: (1) the crossed trench; (2) the Bostock pit; and (3) the surface burning method.

In the crossed trench, two trenches 1.2 m (7 ft) long are dug so that they form a cross. Each is about 40 cm (15 in) wide and 45 cm (18 in) deep in the centre, becoming shallower towards the extremities of the limbs. The soil is thrown on to the surface in the angles of the cross, and upon the mounds so made, two or three stout pieces of iron, beams of wood, or branches from a tree are placed. Straw and faggots are piled in the trenches to the level of the surface of the ground, the carcase is placed across the centre of the trenches, and more wood or coal is piled around and above it. Two gallons of paraffin oil are poured over the whole, and the straw is lit.

In the Bostock pit, an oval pit 2.25 m (7 ft) long and 1.25 m (4 ft) wide is dug to a depth of 1 to 1.25 m (3 ft to 4 ft), and a crossed trench 20 cm (10 in) is dug in its floor. Upon the windward side of the pit a ventilation trench 1.25 m (4 ft) long and 50 cm (1 ft 6 in) wide, and a 30 cm (1 ft) deeper than the main pit, and at right angles to it, is dug. A field drainpipe is placed in a tunnel connecting the trench with the pit, and this pipe is stuffed with straw. Straw is laid in the bottom of the main pit, wood or coal is piled above it so that about three-quarters of the pit is filled, and the carcase is next rolled into the pit. More wood or coal is piled around and above it, and paraffin oil poured over the whole. The straw is finally lit in the bottom of the ventilation trench. A carcase cremated by this method takes about eight to ten hours to burn away, and requires little or no attention. When burning is complete the soil is replaced and the ground levelled.

The surface burning method is mainly used where there are numbers of animals to be burned. One long trench is dug about 50 cm (1 ft 6 in) deep and 30 cm (1 ft) wide, and about 1 m (3 ft) length is allowed for each cattle carcase. At intervals along each side there are placed side flues to coincide with each carcase. Fuel (straw, wood, and coal) is placed around the central trench and the carcases are drawn across it. More fuel is heaped around and between them, and paraffin oil or petrol is sprayed over the whole. The straw is lit. More fuel needs to be added at intervals.

Instead of the trench and side flues, battens of stout wood are sometimes laid upon the ground, and the carcases pulled over them. Fuel is piled around them and lit, and more is added as required. This latter method is specially applicable where the ground is very wet, or where there is rock immediately below the soil and digging is impossible.

Precautions Where the carcase of an animal that has died from a contagious disease is being disposed of in one of the above ways, it is essential to ensure that blood or discharges are not spilled upon the ground in the process of removal. An efficient method of preventing this is to stuff tow saturated with some strong disinfectant into all the natural orifices – nostrils, mouth, anus, etc. – and to cover the surface of the improvised sleigh (door

VetBooks.ir

or gate) with pieces of old sacking which have been soaked with disinfectant, so that parts of the carcase do not become chafed through friction with the ground and so leave behind bloodstains. Everything that has come into contact with the carcase must be carefully disinfected before it is removed. Old ropes, sacking, and other objects used for handling the dead animal may be burned. The surface of the soil around the edge of the pit, upon which the carcase rests, should be scraped off and thrown into the fire or pit so that any blood or discharges may be rendered harmless. Finally, all attendants should be impressed with the risks they run in handling diseased carcases, and with the risks there are of contaminating other healthy cattle. Appropriate biosecurity measures, including the use of protective clothing, disinfected or discarded before leaving the premises, must be observed.

Disposal in the tropics (See TROPICS, LIVESTOCK PRODUCTION IN THE - CARCASE DISPOSAL.)

Disposal of Small Animal Carcases In spite of the rules laid down in the Animal By-Products Order 1999, pet animal are often buried on the owner's property. Cremation services are offered in many places and special arrangements may be made for ashes to be returned to the owner for disposal. Often the bond between the bereaved owners and the dead pet is so strong that such an action is required before the psychological closure can be achieved.

Disposal of Veterinary Clinical Waste (UK)

Such waste is defined by the Health and Safety Commission as including animal tissue and excretions, drugs or medicinal products, sharp instruments, or similar materials or substances.

Clinical waste must be separated from other waste in accordance with the system agreed by the local authority, e.g. yellow sacks and reinforced containers. (The Collection and Disposal of Waste Regulations 1989.) That regulation is partly superseded by the Waste (England and Wales) Regulations 2011. (See HAZARDOUS WASTE and INFECTIOUS CLINICAL WASTE.)

Disseminated Idiopathic Skeletal Hyperostosis (DISH)

An unusual condition seen in dogs and of unknown cause. It involves calcification and ossification of the skeletal tissues such as ligaments.

Distemper

Distemper is a name applied to a specific viral disease. As a rule, all members of the Canidae and Mustelidae are susceptible to canine distemper. These classes include dog, fox, wolf, ferret, mink, weasel, ermine, marten, otter and badger. Felidae (cats) are not susceptible except for lions. An outbreak in the Serengeti National Park in Tanzania appears to have been brought under control by vaccination of the dogs belonging to the local population. In the terminal stages of distemper in the fox, the animal becomes paralysed and froths at the mouth, giving rise to the suspicion of rabies.

Injection of dogs with measles or rinderpest virus confers immunity against distemper.

Canine distemper is an infectious disease mainly of young dogs, characterised usually by a rise in temperature, dullness, and loss of appetite, and in the later stages by a catarrhal discharge from the eyes and nostrils. The disease is often complicated by broncho-pneumonia, and in some cases nervous signs develop, either when the febrile conditions subside, or before this happens. Other clinical signs can include IMPETIGO and hyperkeratosis of the pads (so-called Hard-Pad Disease). The incubation period of the disease is from 4 to 21 days, though it may be longer.

Cause Canine distemper virus, a morbillivirus. There is only one antigenic type, though various syndromes (including 'hard pad') may be associated with various strains, some of which can suppress or impair the body's natural defence systems, and this has a bearing upon possible complications due to secondary bacterial infections.

Certain bacteria are responsible for secondary lesions; for example, *Bordetella* is often responsible for bronchitis.

Cases of distemper may be complicated by the coexistence of other infections such as CANINE VIRAL HEPATITIS, LEPTOSPIROSIS and TOXOPLASMOSIS.

Although it is chiefly in young dogs that the disease is encountered, older dogs are often affected; as a general rule, however, young animals between the ages of 3 and 12 months are the most susceptible.

KLEBSIELLA infection gives rise to signs similar to some of those of distemper.

Signs and complications In typical cases the dog becomes feverish, has a discharge from eyes and nose, and a cough. In some cases the eye inflammation become severe. (See KERATITIS.)

Complications include broncho-pneumonia with a hacking cough. (See *Bordetella* SPP.)

Gastroenteritis, and mouth ulcers, complicate other cases.

Sometimes (apart from the fact that the dog has seemed unwell) the first sign of the disease to

VetBooks.ir

alarm the dog-owner is a fit. (See ENCEPHALITIS.) A change in temperament, with a tendency to viciousness, may occasionally be noticed.

Paralysis of face muscles, or of a limb, may occur, and sometimes hindquarter paralysis (see PARAPLEGIA) accompanied by incontinence indicate that the dog is unlikely to recover,

Distemper may be accompanied by pneumonia and/or diarrhoea.

Diagnosis and treatment An early diagnosis is important. A veterinary surgeon should be consulted as soon as any of the above signs appear, and will advise on the use of serum, antibiotics, vitamin preparations, etc., as the situation demands. (See also NURSING OF SICK ANIMALS.)

After recovery from distemper it is important to remember that, unless the dog is looked after with great care, relapses are liable to occur. For a week or 10 days after all signs have apparently subsided, the dog should be given only a limited amount of exercise. A vitamin preparation or special diet may be prescribed.

After-effects CHOREA may occur when the dog appears to be making a good recovery, and often after an otherwise mild illness. A syndrome has been described ('old dog encephalitis') in which, several months after being ill with distemper, even a young dog may become senile and forget its house training.

Prevention Various vaccines have long been available and have included:

1. *Live, egg-adapted distemper virus*
   (a) obtained from embryonated hens' egg
   (b) obtained from cultures of avian fibroblastic tissues.
2. *Live distemper virus adapted to homologous tissue culture* obtained from cultures of dog kidney cells.

Combined vaccines against distemper, infectious canine hepatitis, canine parvovirus, leptospirosis and parainfluenza are on the market.

The timing of vaccination is crucial. Assuming an adequate intake of colostrum, puppies born to bitches immunised against distemper should have sufficient antibody to protect them during the initial weeks of life. The immunity provided by the antibody wanes: by the time the puppy is 12 weeks old, the level of maternal antibody is negligible. It will no longer protect against naturally occurring virus; equally it will not interfere with distemper vaccination.

A booster dose is advisable, and should be given in line with manufacturer's recommendations. It is commonly undertaken at 15 months old and then every two to three years thereafter.

These are general guidelines. Individual manufacturers' dosage instructions for specific vaccines may vary, and must be followed.

(See also COLOSTRUM; GAMMA GLOBULIN; ANTISERUM; MEASLES VACCINE; MATERNAL ANTIBODIES.)

Distichiasis

The presence of ECTOPIC eyelashes in the MEIBOMIAN GLANDS of the eyelids in which they are turned against the eyeball causing inflammation. It usually leads to EPIPHORA. It is common in several breeds of dog including AMERICAN COCKER SPANIELS, BULLDOGS, COCKER SPANIELS, DACHSHUNDS, FLAT-COATED RETRIEVERS, PEKINGESE, POODLES, ROUGH COLLIES and SHETLAND SHEEPDOGS.

Distiller's Grains

A feed, relatively high in protein and energy, for dairy cattle. For hazards of storage, see BREWER'S GRAINS.

Distomiasis

Infestation with liver flukes.

Diuretics

Drugs which increase the amount of urine excreted. They are used mainly in the treatment of oedema (dropsy) in cases of heart failure. They act by inhibiting the reabsorption of sodium and chloride from the loop of Henle (loop diuretics) or the kidney tubule. (See KIDNEYS – Structure.) Furosemide is a powerful loop diuretic. Thiazides, which act in the distal part of the tubule, are less potent. The risk of excessive excretion of potassium presented by loop diuretics may be avoided by the use of potassium-sparing diuretics, which are often given in combination with loop diuretics to enhance their effect or by allowing the animal to 'rest' between doses to 'recharge' their potassium levels. Spironolactone is an example of a potassium-sparing diuretic. A 2nd type of diuretic acts by osmotic action, which causes water retention in the nephron. Osmotic diuretics such as mannitol are used, for example, to promote urine flow in kidney failure.

While diuretics can help, they will not cure the condition which has given rise to the oedema.

Diurnal

Active in or of the day (compare with NOCTURNAL).

Diverticulum

A small pouch formed in connection with a hollow organ. They can be abnormal but there are many normally present in the body, e.g. the diverticulum of the duodenum at the point of entry of the bile and pancreatic ducts, and the posturethral

VetBooks.ir

diverticulum behind the opening of the urethra into the posterior genital tract in the sow and cow. Those found as the result of injury or disease occur in the oesophagus, in the rectum, and sometimes in the intestines. Meckel's diverticulum is found in birds and is the remnant of the stem connecting the yolk-sac to the intestine.

DM

(See DRY MATTER.)

DNA

Deoxyribonucleic acid. This is found in the nucleus of every cell and carries coded information/instructions for reproducing other cells. 'DNA can be visualised as a long coded tape, divided into segments. These segments are individual genes, and each carries information for the assembly of a specific protein. The genes issue the instructions for the cell; the proteins execute the orders. Some genes code for structural proteins such as hair, horn, etc., but most code for enzymes which perform tasks in the cell, such as motility, metabolism, and secretion.' (Professor W. F. H. Jarrett, FRS.)

A chromosome is composed of a giant molecule of DNA, plus supporting protein, and it is the DNA which is the very basis of heredity. (See CELLS; GENES; CHROMOSOMES; GENETIC ENGINEERING.) Bacteria, viruses, and plasmids contain DNA. (See also CANCER.) DNA analysis is often used to perform non-surgical gender determination in MONOMORPHIC birds. (See also DNA TESTING.)

DNA 'Finger-Printing'

DNA 'finger-printing' of human beings was first described by Dr Alec Jeffreys of Leicester University in 1985; and has since been used to prove the identification of sires of many different animal species.

The first case concerned a pack of Siberian huskies, and proving the true identity of puppies born to one of them, prior to registration with the Kennel Club.

Other applications of the technique are positive identification of thoroughbred horses, and of laboratory animals. The technique has been used in the prosecution of robbers of raptor nests by identifying the parents of young raptors found by the police. It has been used to investigate incorrect identification and ear tagging of cattle.

Genetic fingerprinting can also provide an effective means of tracing the source of microbial contamination as it differentiates between closely related micro-organisms, making possible precise identification of individual strains.

DNA Testing

Since the mapping of the domestic dog GENOME in 2005, various DNA tests have been developed for genetic problems and for various breeds. The range of tests is rapidly increasing. Some of those genetic problems for which tests are available in certain breeds are indicated under the various breeds. The cat genome was sequenced in 2014 and again some tests are available for the species.

DNOC

Dinitro-ortho-cresol, a yellow crystalline substance employed in agriculture as a weed-killer spray solution, acts as a powerful cumulative poison. In man the symptoms are excessive sweating, thirst, and loss of weight. Poisoning in domestic animals might well be encountered following contamination by the spray or residue.

DNP

Dinitrophenol, a product somewhat similar to DNOC.

Dobermann Pinscher Dogs, Dobermann Dogs, Doberman

A medium-sized, muscular dog with smooth hair, most often black and tan, but all brown and grey colours can be seen. The ears are naturally pendulous. The breed originates in Germany and is often used as a police or guard dog. It can be affected by NARCOLEPSY, VON WILLEBRAND'S DISEASE, CANINE DILATED CARDIOMYOPATHY (all have DNA tests available). Also CERVICAL SPONDYLOLISTHESIS ('WOBBLER' SYNDROME) and POLYOSTOTIC FIBROUS DYSPLASIA (bone cyst). PERSISTENT HYPERPLASTIC PRIMARY VITREOUS is possibly an incomplete dominant trait and HIP DYSPLASIA appears to be multifactorial in origin.

Docking

Docking is removal of the tail or a part of it. In Britain, docking of the horse (excluding amputation of the tail by a veterinary surgeon for therapeutic reasons) is illegal. Docking is controlled by the subsidiary legislation to the Animal Welfare Act 2006 and the Health and Welfare (Scotland) Act 2006 Part II. (See also NICKING.)

Dogs Since 1 July 1993 it has been illegal for anyone other than a veterinary surgeon to dock puppies' tails in the UK. 47 of the 185 breeds registered with the Kennel Club have traditionally been docked. The RCVS has said it is unethical for a dog's tail to be docked except for therapeutic reasons. Examples of legitimate docking is in the case of a dog that has an injured tail which hinders defaecation, with soiling of the perianal area, or has a tumour on the tail. There is evidence that the

VetBooks.ir

docked end is more sensitive to pain than the rest of the tail. Tails are widely used in communication between dogs and between dogs and people. Dogs with docked tails cannot communicate adequately; their attitude and intentions might be misunderstood by other dogs and fighting may result.

Certain working dogs may be docked, but following this such animals can only be shown as working dogs and not as show dogs. In Wales the breeds of working dogs that may be legally docked are listed in subsidiary legislation.

Sheep It is customary for sheep of lowland breeds to be docked, for if the tail is left long it accumulates dirt and faeces, and these predispose to the attacks of blow-flies. Enough tail must be left to cover the vulva, or anus in the case of the male. The use of rubber rings for docking without anaesthetic is allowed only within 48 hours of birth. (See ANAESTHETICS, LEGAL REQUIREMENTS.)

Many mountain breeds of sheep are left undocked; the long woolly tail helps to keep the hind part protected from frost and wind.

Docks, Poisoning by

Losses of sheep have been occasionally ascribed to eating either the common sorrel dock (*Rumex acetosa*) or sheep's sorrel (*R. acetosella*), both of which contain oxalates. A condition of staggering with dilated pupils, muscular tremors, and later, convulsions and prostration, has been noticed in horses which have eaten large quantities of sheep's sorrel. In sheep, there is a loss of appetite, rapid breathing, exhaustion, sometimes constipation and at other times diarrhoea, with an unsteady gait and occasionally death. Milk of cows that have eaten docks is made into butter only with difficulty.

Docosahexaenoic

An polyunsaturated fatty acid important in humans for heart function, skin integrity, and promoting retinal function in the fetus and young animal. Fish oils are a main source.

'Doctored'

A common name often used for castration. It can also be used when trying to mask or alter a problem or the appearance and is especially used when selling horses.

Doe

An adult female of some species such as deer, rabbits, goats (nanny).

Dog, Feminisation of

(See SERTOLI-CELL TUMOUR; also INTERSEX.)

Dog, Kennels

Former kennels should not, unless they have been thoroughly cleaned and disinfected, be used for the temporary housing of lambs or goatlings; in both, deaths have followed from cysticercosis of the liver. (See TAPEWORMS; also BEDDING AND BEDDING MATERIALS, HOOKWORMS.)

Two sheep dogs died from dieldrin poisoning, their kennel having been washed weekly with old sheep dip.

Dog Bites

Various infections including *Pasteurella septica* infection in man can result from these. (See also RABIES; DOG-BITES.)

Dogo Argentino

A white, large, strong muscular dog used in hunting and named in the DANGEROUS DOGS ACT 1991.

Dogs, Breeds of

The reader is advised to consult textbooks on this subject. (See also KENNEL CLUB, WILD DOGS.)

Dogs, Diseases of

Several are listed under the prefix CANINE. Others include bacterial diseases such as brucellosis, 'kennel cough', salmonellosis, leptospirosis, tetanus, and tuberculosis. For skin diseases, see ECZEMA; MANGE; RINGWORM; HOOKWORMS; ATOPIC DISEASE. Other canine diseases are referred to under the following headings: RABIES; PARALYSIS; PYOMETRA; FUNGAL DISEASES; 'BLACK TONGUE'; CANCER; LEUKAEMIA; *Campylobacter* SPP. INFECTIONS; ANAEMIA; ANTHRAX; AUJESZKY'S DISEASE; BOTULISM; ORF; CHLAMYDOPHILA; CHOREA; CRAMP; CUSHING'S SYNDROME; DIABETES MELLITUS; DIARRHOEA; HIP DYSPLASIA IN DOGS; HYDATID DISEASE; HYSTERIA, CANINE; MYASTHENIA GRAVIS; PARASITES; TGE; TOXOPLASMOSIS; YERSINIOSIS; SPOROTRICHOSIS; COCCIDIOSIS; (See also under the various organs and tissues, e.g. HEART, EYE, PANCREAS, PROSTATE GLAND, KIDNEYS.)

Dogs' pharyngeal injuries are often caused during retrieving, or playing with, sticks thrown by the dog's owner. These injuries can be avoided if a rubber 'bone' or ring is substituted for the sticks. (A rubber ball can also be used, provided that it is too big for the dog to swallow.)

Dogs, Mortality

Larger breeds of dog tend to have a lower life expectancy than smaller breeds, according to insurance statistics. Small breeds have an average life expectancy of about 15 years; large breeds have an expectancy of about eight years.

VetBooks.ir

Dogs, Statistics

The highest number of UK dogs was estimated at 9,074,000 in 2009 and it was decreasing annually at 0.9 per cent. In 2013, 30 per cent of UK households owned a dog. The median longevity was 12 years with crossbred dogs surviving 13.1 years and purebreds 11.9 years. Increased body weight was associated with a shorter life span. When recorded the main causes of death were NEOPLASIA 16.5 per cent, disorders of the MUSCULOSKELETAL SYSTEM 11.3 per cent, and NEUROLOGICAL disorders 11.2 per cent.

Dogs, Transport by Air

This is governed by the Live Animal Board Regulations of the International Air Transport Association (IATA) 1989. In addition, any requirements of the various regulations governing the import and export of dogs must be observed.

Greyhounds are usually transported by air between Ireland and England in wooden kennels similar in size to greyhound racing starting traps.

A study of 12 greyhounds showed that stress varied greatly as between individuals. They were transported either in the wooden kennels or in wider Perspex kennels. These were stowed either in the belly hold or in the main cargo hold of jet freighter aircraft. Stress was greater in the belly hold.

Dogs, Working

(See also SHEEPDOGS.) Working dogs include also guide dogs for the blind, hearing dogs for the deaf, avalanche rescue dogs, and dogs as predictors of human epilepsy. (The way in which some dogs can detect the imminence of fits in people is as yet unknown. Further investigation is being undertaken in Canada and the USA. The service is a valuable one, because it allows the epileptic time to get to a safe place, and to take appropriate medication; or for the dog to warn the person's family.)

Huskies are used in the Arctic for transport purposes (and bred back to wild wolf stock every few generations). Refuse collection is yet another service performed by dogs, and was introduced in Milan, Italy. In a demonstration, dogs were shown picking up plastic and soft drink cans; and one bitch learned to alert her handler by barking when she found a hypodermic syringe on the ground.

Dogs are widely used by customs authorities and police in the detection of cannabis and other substances. Trained 'sniffer dogs' can detect drugs concealed in packing cases, etc.

Dogs, Worms in

(See WORMS.)

Dogs' Diet

Most owners wisely feed their animals on a mixed diet, offering some variety and at the same time providing the essential nutrients. It is a misconception that dogs should be fed only on meat. However, some owners appear to believe that red (muscle) meat, cooked or raw, is a complete food for dogs and cats. It is not, since it does not provide, for example, enough calcium. Cooked meat should be mixed with biscuit meal or pasta, potatoes or vegetables, and fed at room temperature. Most dogs like one or other of the proprietary biscuits.

Dogs should be fed at regular times, once or twice a day; any food left uneaten should be removed. Fresh water should be available always. A bone, or one of the proprietary substitutes, is useful to exercise the jaws and help keep the teeth healthy.

Proprietary dog foods are very widely used nowadays; they may be moist (canned), semi-moist (packeted) or dry. Major manufacturers have carried out extensive research on the dog's nutritional needs and when fed according to their recommendations such prepared diets are perfectly adequate for the normal dog.

Any marked change in an animal's feeding or drinking habits may be an indication of disease; a veterinary surgeon should be consulted. Specially formulated diets are available for a wide range of disorders (for example, diabetes or kidney disease); they are prescribed by a veterinarian as necessary. (See also PET FOODS.)

Dog-Sitting Position

In pigs this may be a sign of pantothenic acid (vitamin B) deficiency, or lameness due to *Mycoplasma hyosynoviae*. In the horse this position may be adopted during severe COLIC. With reference to the newborn Galloway calf, see GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS. Regarding lambs, see SWAYBACK.

Dog's Mercury

A species (*Mercurialis perennis*) of plant Genus of the *Oxalidaceae* Family and a woodland plant found in most parts of Europe. The plants can cause OXALATE toxicity.

Dogs (Protection of Livestock) Act 1953

Dogs (Protection of Livestock) Act 1953 provides that the owner and also the person at the time in charge of a dog, which is worrying livestock on agricultural land, are guilty of an offence. The owner will not, however, be convicted if s/he proves that the dog was, at the time, in the charge of a fit and proper person other than him or herself.

Amendments to the 1953 Act made by the Wildlife and Countryside Act 1981 made it an offence for a dog to be at large in a field or

VetBooks.ir

enclosure where there are sheep unless it is on a lead or otherwise under close control. There are exceptions for a dog owned by, or in the charge of, the occupier of the field or the owner of the sheep or a person authorised by either of these; or a police dog, guide dog, trained sheep dog, working gun dog or a pack of hounds. This requirement applies only to fields or enclosures where there are sheep and not, therefore, to open hill areas.

Dog Ticks

In Britain these include *Ixodes hexagonus* (common on suburban dogs and cats); *I. ricinus* (the sheep tick, commonly found on country dogs); *I. canisuga* ('the British dog tick'); and *Dermacentor reticulatus* (which may infest also cattle and horses). *I. canisuga* may establish itself in buildings, as may *Rhipicephalus sanguineus*, which has infested houses in Denmark as well as quarantine stations. Modern central heating may facilitate the survival of this tick in northern latitudes. In a house in England, a sitting-room sofa, and a bedroom chair used by a dog, were infested. This tick may arrive in travellers' luggage. Hedgehogs are a source of *I. hexagonus*. Under the PET TRAVEL SCHEME (PETS) Regulations, dogs and cats must be treated for ticks before being imported into the UK.

Dogue de Bordeaux

A large and powerful French breed of dog, also known as Bordeaux Mastiff or French Mastiff. It is BRACHYCEPHALIC, and light brown in colour. Weight, 45.5 kg (100 lb) female and 52 kg (115 lb) male. It is susceptible to CANINE MULTIFOCAL RETINOPATHY (DNA test available).

Dolichocephalic Skull

Dolichocephalic skull shape is one which is long and narrower than normal, as distinct from one which is short and broad. The upper jaw slightly protrudes in front of the lower jaw (normal occlusion) Examples of dolichocephalic breeds are the greyhound and collie, and of the latter (brachycephalic), those of the pug and bulldog. (See BRACHYCEPHALIC, BRACHYGNATHISM, MALOCCLUSION, OCCLUSION, PROGNATHISM.)

Domestic Long-haired Cats (DLH)

A general term for those medium or long-haired cats which do not have a pedigree or belong to a recognised cat breed. In different countries they can be of different size and shape, because of different gene pools. Any coat colour or combination of colours is included; the wide genetic pool means that they are less prone to genetic abnormalities. Some are not able to maintain their own coat and need regular daily grooming.

Domestic Short-haired Cats (DSH)

A general term for those short-haired cats which do not have a pedigree or belong to a recognised cat breed. In different countries they can be of different size and shape because of different gene pools. The wide genetic pool means that they are less prone to genetic abnormalities. Any coat colour or combination of colours is included. There are DNA tests for MANNOSIDOSIS and MUCOPOLYSACCHARIDOSIS VI.

Dominant

That member of an allelic pair of genes which asserts its effects over the other dissimilar member (recessive) of a gene pair.

Donkeys

Descendants of the wild ass, donkeys are grey or sable in colour; they are widely used as beasts of burden in some countries. Their life-span in Turkey, Egypt, Tunisia, Ecuador and Peru is only 11 years. In the UK the figure is 37 years. (The Donkey Trust, Sidmouth, Devon.)

They are spared many of the leg and joint troubles common in the horse, but are very prone to lungworm infestation. This may not give rise to signs such as coughing, but the lungworms may lower the donkey's resistance to strangles and equine influenza, from which more young donkeys die than young horses. Donkeys often constitute a source from which horses become infested with lungworms. (See PARASITES.)

For gestation period, see under PREGNANCY AND GESTATION. (See also JENNY; HINNY; MULE.)

Donkey Sanctuary

A charity 'working to improve conditions for donkeys and mules'. Address: The Donkey Sanctuary, Sidmouth, Devon EX10 0NU; Telephone: 01395 578222; website: www.thedonkeysanctuary.org.uk

Dopamine

Dopamine is involved in the transmission of 'messages' in the central nervous system. Early-weaned piglets which develop the 'vice' of nose-rubbing show evidence of decreased dopamine production in the brain.

Dopamine hydrochloride can be useful in overcoming the effects of anaesthesia with halothane, which depresses the cardiopulmonary system of horses.

Doppler

(See ULTRASOUND.)

Doramectin

An avermectin ENDECTOCIDE registered for use in cattle, sheep and pigs.

VetBooks.ir

Dorking Chickens

A breed believed to have been introduced to Britain by the Romans. It is 'rectangular' in shape with very short legs and five toes. Colours include white, silver-grey, red, dark and cuckoo. The comb is large and there are ear lobes; the skin colour is white. Cocks weigh 4 kg (9 lb) and hens 3 kg (7 lb). The hens produce white eggs and are very broody. The large comb means that the birds need shelter in cold weather.

Dorset Down Sheep

The breed originated in the 19th century by crossing local ewes and HAMPSHIRE DOWN ewes with SOUTHDOWN rams. It is not closely related to the DORSET HORN breed which has a white face. Dorset Downs are medium-sized and robust with dark faces and short wool. Before imports into Britain of breeds such as the TEXEL it was a popular TERMINAL SIRE. It is used for meat and wool; the fleece weighs 2.5 kg (5.5 lb). It is now a minority breed but is also found in North America and Australia.

Dorset Horn Sheep

The breed is known for its prolificacy. There is also a POLLED DORSET variety. They are not closely related to the DORSET DOWN SHEEP. It is a white sheep of medium size with a good, well muscled, body; the rams weigh 100 kg to 125 kg (225 lb to 275 lb) and the ewes 70 kg to 90 kg (150 lb to 200 lb) with a fleece of 2 kg to 3.5 kg (5 lb to 9 lb). They have an extended breeding season and so can produce 1.5 to two litters a year. Lambing in March/April; mate May; lamb autumn.

Dosing Injuries

(See DRENCHING; also X-RAYS – Ordinary radiography.)

Double Muscling

Also called muscular hyperplasia or myofibre hypoplasia. An inherited conformation in which there is an increase in muscle fibres with a corresponding decrease in fat, as seen in Charolais and Belgian Blue cattle. It can give rise to dystokia; double-muscled cattle are more likely to develop respiratory problems or muscular dystrophy.

Double Pregnancy

A term applied to the existence of 2 sets of fetuses, of different ages and born with a corresponding interval between litters, in the sow, cow, etc. (See SUPERFETATION.)

'Double Scalp'

A condition seen in older lambs and young sheep, mainly on hill grazings, in autumn and winter. There is unthriftiness associated with a thinning of the bones of the skull. The cause is believed to be related to phosphorus-deficient pastures.

Dourine

Dourine is a venereal disease of horses, donkeys and mules caused by *Trypanosoma equiperdum* which is NOTIFIABLE throughout the European Union. Imported horses have to be declared free from the infection. It occurs in Africa, Asia, parts of Europe, and in areas in both North and South America. (See TRYPANOSOMES.)

Transmission appears to be by coitus only, and is spread by 'carriers' which themselves show no signs.

A discharge from vulva or penis may be the first sign, followed by oedema of the genital organs, with the swellings extending forward along the abdomen. Fever, loss of condition, and painful micturition may be observed. A few weeks later chancres may be seen on the flanks and elsewhere, lasting for a few hours or sometimes days. Later the animal becomes weak, loses weight, may be lame or have paraplegia, and dies.

Identification of 'carrier' animals is of great importance in controlling and eradicating the disease, and depends on the complement fixation test (though this presents difficulties in areas where other trypanosomiasis occur). In most countries slaughter is obligatory.

Treatment Quinapyramine or suramin are medications used against trypanosomes.

Control (See TSETSE FLIES.)

'Downer Cow' Syndrome

Sometimes in cases of 'milk fever' (parturient paresis, hypocalcaemia) a cow goes down and never gets up again, even though the 'milk fever' itself is treated successfully. The critical factor may be the length of time the cow is recumbent with one hind leg (usually the right) underneath her body. If that time extends to 6 hours or more, there may be permanent muscle or nerve damage to that leg. Nerve damage may be the factor determining whether a recumbent cow becomes a downer. It has been suggested that slight differences in body position can account for the fact that some animals suffer nerve damage but not others.

If a cow is found recumbent and showing signs of milk fever, the animal's position should be changed so that tissue damage can be minimised while veterinary aid is awaited. If the cow is in close, cramped quarters, with a floor not providing a good grip, she should be moved to a better place. This can be achieved by sliding her on to a large piece of plywood, which can be used as a sledge.

An inflatable bag, attached to a rigid base, and inflated by an air compressor, is marketed for

VetBooks.ir

lifting a cow on to its feet. The device is placed under the body of the cow (or the cow is dragged onto it); the animal is helped to rise as the bag inflates.

The syndrome may arise from a wide range of conditions; all the following have been implicated: metabolic disorders, such as hypocalcaemia, hypomagnesaemia, hypophosphataemia, hypokalaemia, and bloat; toxaemia, associated with mastitis, metritis, peritonitis, and aspiration pneumonia; rupture of uterus, reticulum, abomasum, and traumatic pericarditis; other injuries, such as a fractured pelvis, displacement of the sacrum, obturator or sciatic nerve paralysis, dislocation of the hip, and rupture of muscles (e.g. adductor, gastrocnemius).

About half of all downer cows get up within four days. After ten days the prognosis is poor, but there have been cases of cows rising to their feet after two or three weeks, or even a month.

Doxapram

A respiratory stimulant used to aid recovery from general anaesthesia or in neonates after a caesarian section or a difficult birth. Doxapram may be used routinely in the recovery stages of reptile general anaesthesia.

Doxorubicin

An anthracycline anti-tumour antibiotic which is effective in treating certain types of cancer in cats and dogs. It can cause severe side-effects and must only be used under specialist supervision.

Doxycycline

A semi-synthetic tetracycline which has a low toxicity and produces high blood levels. It must not be given to pregnant animals and its use in equines should be undertaken with extreme caution. (See TETRACYCLINES.)

Dracunculiasis

(See GUINEA WORM.)

Draft Horses

(See DRAUGHT HORSES.)

Draught Horses

These horses are used to help man to carry out certain heavy tasks such as pulling ploughs or hauling wagons. They are in a different category from race horses and pleasure horses. They are usually from one of the breeds of HEAVY HORSES e.g. CLYDESDALE, PERCHERON, SHIRE, SUFFOLK PUNCH.

Drench

(Verb) to physically give a liquid by mouth to a farm animal.
(Noun) the liquid/suspension given as a drench.

Drenching

The giving of liquid medicine to large animals by a bottle or a drenching gun. It must be done slowly, and with care, in all animals if the medicine is to be effective. The fluid must be directed over the back of the tongue to avoid some of the dose going straight into the abomasum. Pneumonia is a common sequel to liquid medicines 'going the wrong way'.

Another danger is associated with the use on pigs of a drenching gun intended for sheep. Unless these appliances are used with care, severe injury may result. In a series of cases reported in Australia, 24 pigs suffered rupture of the pharyngeal diverticulum – part of the throat – and 12 died. In sheep, rupture of the oesophagus has been caused.

Dressed Seed Corn

Any surplus should **not** be fed to farm livestock owing to the danger of poisoning. Pigs have been accidentally killed in this way after being given corn treated with mercury dressing. Dieldrin dressings kill birds. (See TOP DRESSING.)

Dried Grass

Dried grass has for long been incorporated by compounders into feeding-stuffs for poultry and pigs, but is also fed to dairy cows as part of a ration together with some roughage (straw, hay, silage) and some other concentrate feed, such as barley. In rabbits, dried grass is a useful substitute when fresh grass or hay is unavailable. Dried green crops are also fed on a small scale to sheep and beef cattle.

The dried grass can be either milled and made into pellets or cubes; or left unmilled and pressed into cobs or wafers, which saves the high cost of hammer-milling. Unmilled material may have other advantages, too, for it has been shown that hammer-milling and pelleting decrease the digestibility of the product and, while increasing the efficiency with which digested nutrients are used by non-lactating animals, depress butterfat production of those in milk.

The hardness of the pellets and cobs is an important factor; if too hard, they can give disappointing results. Particle size is also important, especially in rabbits.

Minimum protein content of dried grass for use without supplementary protein is considered to be 18 per cent; minimum digestibility figure about 60 per cent. Crude protein analysis is of little help in indicating digestibility. This (and hence energy equivalent) mainly determines milk production, not protein.

Work at the Grassland Research Institute and in Northern Ireland suggests that dried grass is as good as, or slightly better than, barley as a supplement for silage. Fed with cereals and minerals, dried grass has successfully provided a standard

VetBooks.ir

feed for MLC Bull Performance Tests, giving an average daily liveweight gain of 1.5 kg (3.3 lb) over the 200-day test, with individual gains well over 1.8 kg (4 lb).

Drinking Water
(See WATER AND WATERING OF ANIMALS.)

Droncit
The trade name of a Bayer preparation used in dogs and cats against tapeworms, and for *Echinococcus* eradication schemes. The active ingredient is praziquantel. Preparations are available for oral dosing and also for subcutaneous and intramuscular injections.

Dropped Elbow
(See RADIAL PARALYSIS.)

Dropped Sole
(See LAMINITIS.)

Dropsy
(See OEDEMA.)

Dropwort Poisoning
(See WATER-DROPWORT.)

Droughtmaster
A breed of cattle developed in Australia from Brahman and British (mainly Shorthorn) ancestors. It is claimed to be 10 times more tick-resistant than British breeds, and a more efficient beef producer under the relatively harsh grazing conditions of North Australia.

Drowning
Submersion in water for a period of about four minutes is sufficient to cause asphyxia and death, but shorter periods, while they may cause apparent death, usually only produce a collapse from which recovery is possible. Practically all animals, even the very young, are able to swim naturally, so that immersion in water for this period does not necessarily result in drowning. Animals falling into water are drowned from one of several causes: they may be exhausted by struggling in mud; they may be carried away by a swift current, e.g. during floods; they may be hindered by harness or other tackle from keeping their nostrils above the level of the water; or they may become panic-stricken and swim away from shore. Remarkable instances of the powers of swimming that are naturally possessed by animals are on record; one example being that of a heifer, which, becoming excited and frightened on the southern banks of the Solway Firth, entered the water and swam across to the Scottish side, a distance of over seven miles, and was brought back the next day none the worse. Animals such as CHELONIANS that are able to utilise anaerobic respiration (muscle activity can continue to a limited extent in the absence of oxygen), can survive immersion under water for prolonged periods. Terrapins are known to hibernate at the bottom of ponds in temperate climates.

Recovery from drowning As soon as the animal has been rescued from the water, it should be placed in a position which will allow water that has been taken into the lungs to run out by the mouth and nostrils. Small animals may be held up by the hind-legs and swung from side to side. Larger ones should be laid on their sides with the hindquarters elevated at a higher level than their heads. If they can be placed with their heads downhill, so much the better. Pressure should be brought to bear on the chest, by one person placing all their weight on to the upper part of the chest wall, or kneeling on this part. When no more fluid runs from the mouth, the animal should be turned over on to the opposite side and the process repeated. No time should be lost in so doing, especially if the animal has been in the water for some time. (See ARTIFICIAL RESPIRATION.) Great care should be taken in small animals that pressure to the rib cage is not enough to cause damage. Fracture of the rib cage can easily occur.

After-treatment As soon as possible the animal should be removed to warm surroundings and dried by wiping or by vigorous rubbing with a rough towel to stimulate circulation. Clothing should be applied, and the smaller animals may be provided with hot-water bottles. The danger that has to be kept in mind is that of pneumonia, either from the water in the lungs or from the general chilling of the body, and the chest should be especially well covered. Sometimes the ingestion of salt water leads to salt poisoning in dogs, or to a disturbance of the digestive functions, and appropriate treatment is necessary.

Drug Interactions
For those in which one drug enhances the action of another, see SYNERGISM.

Adverse drug interactions or reactions are indicated by manufacturers in the product data sheet. Unexpected adverse reactions should be reported to the manufacturer or the Veterinary Medicines Directorate.

Drug Residues in Food
Drug residues in food are regarded as very important from the point of view of public health. The permitted maximum level of drugs remaining in meat, milk or eggs after medicines have been administered (maximum residue limit [MRL]) is

VetBooks.ir

specified by regulation for all EU countries. The manufacturer's recommended withdrawal period between the last dose of drug administered and the animal going for slaughter, or the milk or eggs being sold for human consumption, must be observed. Carcases in abattoirs are monitored to ensure that the residues are within allowable limits.

(See also HORMONES IN MEAT PRODUCTION; MILK – Antibiotics in; SLAUGHTER OF FARM ANIMALS.)

Drug Resistance

(See under ANTIBIOTIC RESISTANCE; DIPS AND DIPPING.)

Drugs, Disease Caused by

(See IATROGENIC DISEASE)

'Drunken Lamb Syndrome'

The lambs show ataxia, incoordination, recumbency and unwillingness to suck. It is usually seen in the second and third weeks of life. It appears to be due to D-lactic ACIDOSIS.

Dry, Firm and Dark (DFD)

Dry, firm and dark (DFD) describes the meat of animals that have undergone stress in transport before slaughter. The condition is a result of glycogen depletion in the body. The meat's acidity is reduced but it is safe for consumption.

Dry Cow, Dry Period

The cow during the non-productive period of her life between one lactation and the next. It is a time when the cow can replenish her body reserves, allow the udder to redevelop and later on colostrum to be produced. Ideally the dry period should be about six to eight weeks.

Dry Eye

(See EYE, DISEASES AND INJURIES OF; KERATOCONJUNCTIVITIS SICCA.)

Dry Feeding

Dry feeding of meal may give rise to PARAKERATOSIS in pigs; to 'CURLED TONGUE' in turkey poults; and to SHOVEL BEAK in chicks.

Drying-off Cows

After milking out completely, the teats should be washed, a dry-cow intramammary preparation inserted in each teat and the teat sealed. The cows should be inspected daily.

If possible, keep the cows on dry food or very short pasture for 3 days after drying off.

Dry Matter (DM)

The weight of a plant, or organ after all moisture has been removed by gentle heat It is often used as the method of standardising the concentration of nutrients, minerals etc in feeds and animal organs.

Dry Matter Basis Often used in nutrition when quantifying the concentration of a nutrient, mineral or poison in a plant or in pathology in an animal organ.

Dry Period

In cattle it is considered advisable on health grounds that after a period of lactation, cows should not be milked for about 8 weeks – the dry period. Cows are dry in the weeks before calving.

Drysdale Sheep

A sheep with a very good fleece bred in New Zealand. A natural mutation of the Romney, it was identified and developed by Dr F. W. Dry of Massey University.

Dry Sounds

(See RHONCHI.)

Dubbing

Trimming of the comb may be performed, with scissors, by poultry keepers, and involves removal of a crescent of comb about 1.5 mm ($^1/_{16}$ inch) deep – in day-old chicks. It is credited with increasing egg production by 3 to 4 per cent per year. It is also advocated in intensive rearing, where a floppy comb may be a disadvantage if pecking and cannibalism are rife; and in order to reduce the risk of frostbite. Dubbing can not be recommended from a welfare point of view; it is a cause of stress and an unnecessary mutilation. However, it is a permitted procedure under The Mutilations (Permitted Procedures) Regulations 2007 and The Prohibited Procedures on Protected Animals (Exemptions) (Scotland) Regulations 2009.

Ducks

These are in the same family as geese and swans (Anatidae). Besides the wild species, several breeds have been domesticated both for eggs (KHAKI CAMPBELL) and meat. For about 50 years the Aylesbury duck was used for meat but usually now most meat ducks are various HYBRID strains and are often kept in relatively large flocks, usually outside. MUSCOVY DUCKS are kept both as meat and as semi-pets. Many ducks are kept as pets or for showing. INDIAN RUNNER DUCKS are often kept as a novelty in farms and animal collections because of their unusual locomotory action compared with other ducks. Ducks can succumb to many of the diseases of poultry but they also have some diseases relatively specific to them. (See DUCKS, SEPTICAEMIA IN; DUCK VIRUS HEPATITIS; DUCK VIRUS ENTERITIS; MUSCOVY DUCK PARVOVIRUS.)

VetBooks.ir

Ducks, Septicaemia in

Two forms occur, one due to *E. coli* and one to *Riemerella anatipestifer*.

The former may occur in ducklings 4 to 8 weeks of age. The latter infection causes losses in ducklings under 4 weeks old. Vaccines may prove the most effective method of control.

Duck Virus Enteritis, Duck Plague

The disease is caused by a herpesvirus. It appeared for the first time (so far as is known) in the UK in 1972 among birds on ornamental waters, not on commercial duck farms. One entire group of 72 Muscovy ducks died within 16 days.

Signs, which may not be observed before death occurs, include listlessness and very severe diarrhoea, drooping of wings, and a disinclination to take to water. Adult mortality may be high.

Prevention is by vaccination of healthy birds at 4 weeks of age.

Duck Virus Hepatitis

A virus infection which causes up to 90 per cent mortality among ducklings under 3 weeks of age, but in ducklings a month or more old losses are less. Duck strains resistant to the virus can be bred. A vaccine, administered at 1 day old to susceptible ducklings, has proved effective in most cases although mutant strains can arise in which the vaccine is ineffective. It is a NOTIFIABLE DISEASE. It should be suspected in cases of sudden death if the ducklings' heads are stretched upwards and backwards.

Research at the Animal Health Trust has shown that the fatty kidney syndrome can be reproduced in ducklings following infection with virulent duck hepatitis virus alone. Only birds which are dying or dead show the accumulation of lipid in the convoluted tubules of the kidneys.

Ductless Glands

(See ENDOCRINE GLANDS.)

Ductus Arteriosus

This connects the left pulmonary artery to the arch of the aorta. (See diagram of fetal circulation under CIRCULATION OF BLOOD.) If the duct remains open after birth, it is regarded as a congenital abnormality. (See HEART DISEASES; also LIGAMENTUM ARTERIOSUM for the remains of the duct in the normal animal.)

Dulaa

A reddish, balloon-like organ arising from the soft palate of male camels, it fills with air from the trachea when the nostrils are closed. The dulaa is blown out of the mouth during rutting.

Dumdum Fever

(See KALA-AZAR.)

Dummy, Dummy Syndrome

A state of depressed consciousness in a standing animal, with compulsive walking, stumbling gait, walking into objects and unable to back into narrow spaces. It is seen particularly in foals. The cause can be ENCEPHALITIS, HEPATIC ENCEPHALOPATHY and subacute LEAD POISONING.

Dun

A coat colour in horses, usually ranging from grey-yellow to light yellow, and always with a brown stripe from the withers to the tail butt.

Dung-Fouled Pasture

(See PASTURE MANAGEMENT.)

Dung Heaps

To minimise the possibility of active infection persisting in dung, new dung should be buried under the older. Under natural fermentation conditions a temperature of 70° C can be reached, which will pasteurise the dung. Dung heaps should be fenced off as they are a source of parasites.

Duodenum

Duodenum is the first part of the small intestine immediately following the stomach. Into it open the bile and pancreatic ducts. (See INTESTINES.)

DUP

(See DIGESTIBLE UNDEGRADED PROTEIN.)

Dura Mater

Dura mater is the outermost and the strongest of the three membranes or meninges which envelop the brain and spinal cord. In it also are found the blood vessels that nourish the inner surface of the skull. (See BRAIN.)

Duraznillo Blanco

A poisonous plant of South America. (See ENTEQUE SECO.)

Duroc Pigs

A breed having a red coat; originally from the USA. They are used as part of many commercial crosses as they produce tender meat.

Dusting Powders

Dusting powders containing parasiticides are used to destroy fleas and lice on animals. Powders may be applied to small cage birds by placing them and the powder in a dry paper (not plastic) bag and shaking the bag so that the powder is applied beneath the feathers to the skin. Antiseptic dusting

powders for the topical treatment of superficial wounds were convenient but are now seldom used.

Dusty Atmosphere

In piggeries, this can be a cause of coughing, etc., simulating pneumonia (see MEAL-FEEDING IN PIGGERIES). Inoculations should not be carried out in a dusty shed (see ANTHRAX). Material in dust may give rise to an allergy (see 'BROKEN WIND') and to abortion if fungi are present (see UTERINE INFECTIONS).

Dutch Bantam Chickens

A true BANTAM CHICKEN breed developed in the Netherlands; it has no related larger fowl breed. They fly well and the males weigh about 550 g (1¼ lb), females 450 g (1 lb). There are dozens of acceptable colours, but the breed has a five-pointed comb, white earlobes, white skin and (except for certain varieties) usually slate blue legs.

Dutch Rabbits

A breed of rabbit with distinctive marking: white forequarters but dark coloured (black, agouti, or fawn) rump and hind legs and a dark mask around the ears and the eyes. Standard and dwarf varieties exist. The former are medium sized and adult bucks can attain 2.5 kg bodyweight.

Duvenhage

A rhabdovirus causing a disease similar to rabies. It is carried by fruit bats, which are widely distributed in Africa.

D-Value

This is the percentage of digestible organic matter in the dry matter of the feed.

D-value is used to assess or describe the digestibility of animal feeds, such as dried grass, hay, silage, etc.

DVM

1. Used at times for the Divisional Veterinary Manager in government veterinary organisations.
2. Doctor of Veterinary Medicine. USA veterinarian degree.

Dwarfism

A state of under-development of the body resulting in an animal much below the normal size for its species and of atypical conformation: a dwarf. It is often the result of a developmental anomaly in pregnancy and may be due to nutritional, environmental, infectious and other causes. There may also be a genetic link and this appears to be the case in some dog breeds including ALASKAN MALAMUTES, GERMAN SHEPHERD DOGS (DNA test available), MINIATURE POODLES and NORWEGIAN ELKHOUNDS. In dog breeding such genetic links have been used to produce some toy or miniature variations of some breeds. Dogs with PITUITARY DWARFISM usually die within a year. It can also be seen in DEXTER CATTLE, CHEVIOT SHEEP and wild RED DEER.

'Dwarf Tapeworm', *Hymenolepis nana*

This parasite sometimes completes its life-cycle in a single host (e.g. man or rodent), and sometimes the eggs are ingested by fleas or flour-beetles. Human infestation may follow the eating of contaminated food or, accidentally, a flea.

Dynamite

Poisoning from this has occurred in cattle and sheep in the USA, after they have found mislaid or discarded sticks of the explosive. They apparently relish its taste. Poisoning is due to its nitrate content. (Gelignite, a type of dynamite, could be expected to be similarly toxic.)

Dys-

Dys- is a prefix meaning painful or difficult.

Dysautonomia

A malfunction of the autonomic nervous system, such as occurs in 'grass sickness' in horses, KEY-GASKELL SYNDROME in cats, EUROPEAN BROWN HARE SYNDROME and CONSTIPATIVE MUCOID ENTEROPATHY in rabbits, and which is virtually always fatal. Signs include slowness of the heartbeat in dogs and cats. (See also CANINE DYSAUTONOMIA; FELINE DYSAUTONOMIA.)

Dyschezia

The failure to shed a coat completely. It is a condition in arthropods, crustacea and reptiles. It may be necessary to treat if the old skin interferes with vital functions (e.g. sight), otherwise the condition may resolve at the next moult (ecdysis).

Dyscrasia

Any disease condition; it usually relates to an imbalance of component elements as in blood dyscrasia, which is a term for any pathological condition of the blood.

Dysentery

Dysentery is a condition in which blood is discharged from the bowels with or without diarrhoea. Dysentery is most commonly encountered in certain specific diseases such as anthrax, cattle plague, haemorrhagic septicaemia, purpura haemorrhagica, lamb dysentery, swine fever, and swine dysentery. It may occur when there are large numbers of strongyle worms or coccidiae present in the bowels. Dysentery in young pigs may be due to

Clostridium perfringens infection, which causes death within 36 hours of birth. (See also SWINE DYSENTERY; HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Dysfunction
Abnormal function of an ORGAN or anatomical system.

Dysmelia
A congenital absence of a portion of one or more limbs.

Dysphagia
A difficulty in swallowing. (See 'CHOKING'; BOTULISM; RABIES; MYASTHENIA GRAVIS; also, for one cause in horses, see under GUTTURAL POUCH DISEASE.) (See also GRASS SICKNESS; DOGS, DISEASES OF - DOGS' PHARYNGEAL INJURIES; ABSCESS; FOREIGN BODY; ACHALASIA.)

Dysplasia
Absence of some part of the body (but see HIP DYSPLASIA IN DOGS).

Dyspnoea
Abnormal, difficult or laboured breathing (see BREATHLESSNESS, RESPIRATORY DIFFICULTY).

Dysraphism
This is incomplete closure of the raphe (seam joining two halves), for example, in the neural tube. The defect may be partial or complete.

Dysrhythmia
Abnormal rhythm – usually applied to heartbeats.

Dystokia, Dystocia
This means difficulty during parturition. (See PARTURITION; CALVING, DIFFICULT.)

Dystrophy
(See MUSCULAR DYSTROPHY.)

Dysuria
An absence of or difficulty in excreting urine.

Dzo
A hybrid animal obtained from mating a male yak and a domestic cow.

VetBooks.ir

E

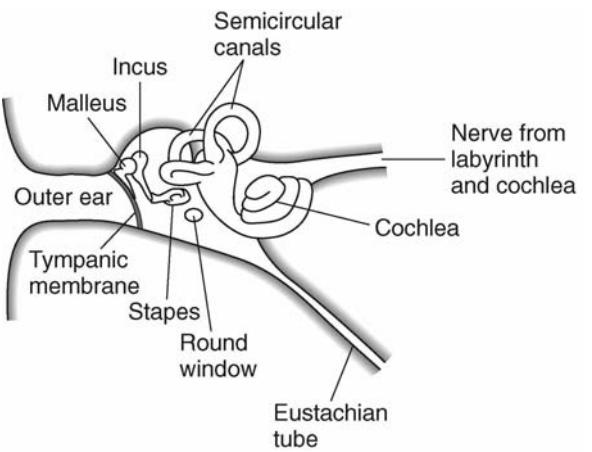
Ear

Sound is appreciated through the mechanism of the outer, middle, and internal ears. Sound waves are collected by the funnel-like external ear (pinna) and transmitted down into an external canal, across the bottom of which is stretched the ear-drum or tympanum against which these waves strike. Their impact causes a vibration of the tympanum, and the sound wave becomes transformed into a wave of movement. This movement is transmitted through a chain of tiny bones, called auditory ossicles, in the middle ear, and then to fluid contained in canals excavated in the bone of the internal ear. The vibration of this fluid stimulates the delicate hair-like nerve-endings which are found in the membranous walls of the canals, and impulses pass to the brain, whereby an animal is able to appreciate external sounds literally by feeling them.

Structure The middle and inner ears are essentially the same in all animals, but the external ears present certain differences in different species. (See also AURAL CARTILAGES.)

External ear

Horses The ears serve to some extent as an indication of the state of the horse's emotions – anger or viciousness being shown by laying the ears flat back against the head, and surprise, anticipation, or pleasure being indicated by 'pricking' the ears. At the base of the ear a complete cartilaginous tube is formed, and this leads into the bony canal or external auditory meatus.



Rabbits In addition to the auditory function, their large ears act as thermoregulatory organs allowing heat loss. Grasping the ears must never be used as a method of restraint. There are two orifices in a rabbit's ear, one is the true orifice and the other is a blind pocket.

Middle ear The tympanic membrane, forming the 'drum', is stretched completely across the outer passage at its innermost extremity.

The cavity of the middle ear is a compartment excavated in the hard mass of the petrous part of the temporal bone which lodges the ossicles. These are the small auditory bones which carry impulses across its cavity and are called the malleus (hammer), incus (anvil), and stapes (stirrup). The Eustachian tube admits air from the throat, and so keeps the pressure on both sides of the tympanum equal.

Horses have a diverticulum (guttural pouch) of the Eustachian tube. (See GUTTURAL POUCH and GUTTURAL POUCH DISEASE.)

Internal ear This consists of a complex system of hollows in the substance of the temporal bone enclosing a membranous duplicate. Between the membrane and the bone is a fluid known as perilymph, while the membrane is distended by another collection of fluid known as endolymph. This membranous labyrinth, as it is called, consists of two parts: the posterior part, comprising a sac, called the utricle and three semicircular canals opening at each end into it, is the part concerned with the preservation of balance; the anterior part consists of another small pouch, the saccule, and of

Outline of the structure of the ear.

VetBooks.ir

a still more important part, the cochlea, and is the part concerned in hearing. In the cochlea there are three tubes, known as the scala tympani, scala media, and scala vestibuli, placed side by side (the middle one being part of the membranous labyrinth), which take 2½ spiral turns round a central stem, somewhat like snail's shell. In the central one (scala media) is the apparatus known as the organ of Corti, by which sound impulses are finally received, and by which they are communicated to the auditory nerve, which ends in filaments to the organ of Corti. The essential parts of the organ are a double row of rods and several rows of cells furnished with hairs of varying length.

The act of hearing The main function of the movement of the ears is that of efficiently collecting sound waves emanating from different directions, without the necessity of turning the whole head, although in some animals the ears may be flicked to dislodge flies.

When sound waves reach the ear-drum, the latter is alternately pressed in and pulled out; the movements being communicated to the auditory ossicles.

These movements are then transferred to the perilymph in the scala tympani, by which in turn the fluid in the scala media is set in motion. Finally these motions reach the delicate filaments placed in the organ of Corti, and so affect the nerve of hearing, which conveys the sensations to the auditory centre in the brain.

Ear, Diseases of

Diseases of the ears of animals should never be neglected, for although in the early stages most are amenable to treatment, in the later stages treatment is likely to be more difficult.

Inflammation of the outer ear (otitis externa) may be found in one or both ears. It is often due to the presence of a foreign body (frequently grass awns), parasites or bacterial infection. The signs include shaking the head, often persistently for a few moments at a time, scratching, rubbing, head rotation with the affected ear lowered, and a foul-smelling discharge. Rabbits with ear disease often do not show these clinical signs, but merely become quiet and lethargic.

Scratching the ears is also a sign of ear-mange mite (*Otodectes*) infection of the external ear canal in dogs and cats. (See MANGE - MANGE IN DOGS AND CATS, for first-aid and treatment of *Otodectes*.)

Other forms of mange may start at the ears and involve the pinna, e.g. psoroptic mange in rabbits which is seen as large amounts of dry flaky wax, notoedric mange in rodents characterised by crusty, hypertrophic lesions. Horses do not have ear mites and no ear drops should be put into horses' ears.

Discharge from the ear, or the presence of pus within, is a sequel to a neglected case of parasitic otitis in the dog and cat and due to secondary infection by bacteria and/or moulds.

Excessive wax in the ear often leads to disease later. It is especially common in dogs which have large pendulous ear flaps, when ventilation is poor, and in rabbits following AMPUTATION of the hind limb (normally used to clean the ear).

In some cases, dressing the inner parts of the ear is difficult or impossible because of the thickening and perhaps distortion. For these an operation, in which the cartilages at the lower parts are opened or resected, has been devised. Operation may also be needed where deep-seated ulceration of one or other of the aural cartilages has occurred, and even the mere initial cleaning of a very inflamed and painful ear must be done under an anaesthetic.

Foreign bodies, such as hay seeds, sand, pieces of glass, wood, peas, or parasites, may become lodged in the ears of animals, especially dogs, and give rise to irritation occurring very suddenly.

Haematoma of the pinna is common in dogs and in cats which are affected with ear mange, but it may occur in almost any animal except rabbits and other small animal species. A large fluctuating swelling appears upon the flap of the ear and causes the animal to hang its head towards the same side. In many cases little or no pain is experienced once the swelling has appeared, and, in fact, a small swelling becomes larger in many cases through the continued shaking of the head even after its original formation. The swelling is caused by bruising of the skin and the blood vessels which lie between it and the cartilage, with a consequent extravasation of blood or serum under the skin. The condition is treated by opening the haematoma under conditions of surgical cleanliness, evacuating the fluid contents, and suturing the skin in such a way that the collection of more fluid is prevented. LEECHES have been used to treat non-surgically.

Wounds of the flaps of the ears are usually caused by bites, or from barbed wire, etc., in the larger animals. The comparatively poor blood supply to the AURAL CARTILAGES means that, if torn or lacerated, necrosis may occur. In dogs with a fresh wound of the pinna, the animal's excessive head shaking may prevent blood clotting and a large amount of blood can be lost. Therefore it may be necessary to secure the ear-flaps by means

of surgical adhesive tape, or a head-cap improvised to give several 'tails' which can be tied.

Deafness (See DEAFNESS.)

Middle-ear infection (otitis media) is always serious as it may lead to MENINGITIS. It is often found on one side but both ears may be affected. Signs are similar to those of external ear inflammation but the balance can be affected; there is swaying of the hindquarters and the head is carried abnormally. It may be caused by spread of external ear infection or by an infection carried in the blood.

Inner-ear infection (otitis interna): signs are – the head is often rotated; the animal may walk in circles and show a stumbling, swaying gait.

Tumours are occasionally found. Warts are not uncommon in horses and cattle. In cats a polyp is occasionally found, and in white cats a squamous cell carcinoma may affect the tip of the pinna.

Mange Psoroptic and sarcoptic mange often begin on the pinna of the ear; auricular or otodectic mange involves the presence of mites (*Otodectes*) within the ear canal. (See MITES, PARASITIC.)

Fly strike This is occasionally seen, mainly in dogs.

Ear Cleaning
This is not required in healthy ears. In dogs it is beneficial in hairy ears, pendulous ears, SEBORRHOEIC ears, STENOTIC ears and discharges.

Ear Cropping
The removal of part or all the ear for aesthetic reasons. It is undertaken in some countries and mainly in some breeds such as the Dobermann Pinscher and Great Dane. In the United Kingdom it is considered a MUTILATION and undertaking the procedure is illegal.

Early Weaning
(See under WEANING.)

Ears as Food
Ears from beef cattle which had been receiving sex hormones as implants in the ear have been fed in breeding kennels with disastrous results.

Ear Tags
A permanent method of identifying animals. It is the main method of legal identification of cattle. Tags are also used in sheep, goats and pigs as well as other animals. They can incorporate an insecticide (see FLIES).

Earthing
Earthing of electrical apparatus on farms, and especially in the dairy, is occasionally faultily carried out in such a way that in the event of a short-circuit, the water-pipes supplying the cows' drinking-bowls become 'live' – leading to the electrocution of the cows. (See ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION.)

Earthworms
Earthworms are of veterinary interest in that they act as intermediate hosts to stages in the life-history of the gapeworm of poultry (see GAPES) and of lungworm in pigs. They may also harbour viruses which cause disease in pigs. Earthworms can live for as long as 10 years. They can often be found at night in drains outside piggeries, and in crevices and cracks in the cement inside piggeries. (See also INFLUENZA.) An ARC research team at the Rothamsted Experimental Station found that earthworms, bred in animal manure, can provide a high-quality protein supplement for pigs, poultry and, especially, fish. Several species of earthworm were used, of which *Lumbricus rubellus* was the one of choice. *Eisenia foetida* (the brandling worm) is easier to farm but contains a heat-labile toxin in its skin making it unsuitable as a raw food. Free range poultry feeding on E. foetida produce garlic-flavoured eggs, whilst outdoor pigs ingesting these worms may show intestinal bleeding. Ideally, earthworms should be heat processed into meal for use in animal diets. Fresh earthworms are often fed to captive amphibians and some reptiles, especially terrapins, taking advantage of their useful calcium:phosphorus ratio. Heavy metals in sewage and other manures are in sulphide compounds and are inert, but they are released by the digestion of earthworms. Heavy metal poisoning in horses has occurred on pastures eight years after sewage application.

Ear Tipping
Ear tipping of feral cats has been advocated by animal welfare organisations and practised in America and Denmark, for example. The idea is to identify those cats which have been spayed, and prevent any 'rescued' cat from being subjected to unnecessary anaesthesia and laparotomy. It is a permitted mutilation in Britain.

In Australia, ear tattooing is practised for the same purpose, but has the disadvantage that the spayed feral cat cannot be identified from a distance.

East Coast Fever, Theileriosis
An acute specific disease of cattle enzootic in certain parts of Africa, especially in the eastern provinces of South Africa, in Kenya and in Zimbabwe. In these areas the native cattle attain a certain amount of

natural immunity, and only imported animals are affected. Animals which recover are commonly known as 'salted', but the mortality is very high (up to 90 per cent) in new outbreaks of the disease. Buffaloes are also susceptible.

Cause *Theileria parva*, which spends part of its life-history in cattle and part in ticks (*Rhipicephalus appendiculatus*).

Signs After an incubation period of a fortnight or so, the animal becomes dull, listless, loses appetite and runs a high fever. Lymph nodes become enlarged. There may be a discharge from eyes and nose; laboured breathing and diarrhoea may be seen.

Prevention and treatment East Coast fever may be to a great extent prevented by systematic dipping of all newly purchased cattle, and quarantining them for at least five weeks before they are mixed with the rest of the stock.

Where the disease has broken out on a farm, the 'short-interval' dipping system first devised by Watkins-Pitchford has proved of immense benefit in eradicating it. (See under TICKS - CONTROL OF TICKS.)

Since ticks responsible for the spread of East Coast fever can live for some time on other domesticated animals, it is advisable to dip sheep, goats and horses at suitable intervals.

Clinically-ill cattle may be treated with Bupavaquone which has a greater than 90 per cent success rate, oxytetracycline has a 50 per cent success rate. There is a vaccine licensed in East Africa which is based on inoculating cattle and treating with oxytetracycline at the same time.

East Friesland Milk Sheep

A breed from NW Germany; in England it has been used to produce the COLBRED. East Friesland ewes average 545 litres (120 gallons) butterfat in a lactation, rearing their lambs, and a yield of 1,000 litres (220 gallons) is not unknown. The lambs have a high growth rate and early maturity.

'Eastrip Special Blend' Sheep

A cross between Bluefaced Leicester and Poll Dorset sheep. A high lambing percentage is claimed.

Easy Care Sheep

A breed developed in the 1960s predominantly from the WILTSHIRE HORN and WELSH MOUNTAIN breeds. Selection is on performance and not physical characteristics. They shed their fleece and are also said to be easy lambing.

EBL

Abbreviation of ENZOOTIC BOVINE LEUKOSIS. (See BOVINE LEUKOSIS.)

EBLEX

(See ENGLISH BEEF AND LAMB EXECUTIVE.)

EBLV

The European Bat Lyssa Virus. (See LYSSA VIRUS IN BATS.)

EBM

(See EVIDENCE-BASED MEDICINE.)

Ebola Virus

This, together with the Marburg virus, is a member of the Filoviridae.

It is, in appearance, indistinguishable from the Marburg virus, but antigenically distinct. Infection of humans is very often fatal; cases have occurred in laboratory workers handling infected monkeys. It was found in 1976 in Zaire and Sudan; 500 people became ill and 350 died. Although infection is thought to be transmitted by contact with primates, fruit bats are thought to be the natural host. It can kill gorillas and chimpanzees in Africa. Viral antibodies have been found in healthy orang-utans and they may be naturally resistant. (See under MONKEYS, DISEASES OF.)

An outbreak of disease caused by an Ebola-related filovirus, and by simian haemorrhagic fever, occurred in 1990 at an American quarantine station among cynomolgus monkeys imported from the Philippines. It was reported that this was the first case in which a filovirus had been isolated from non-human primates without deliberate infection. The virus has been isolated from diseased pigs in the Philippines and from healthy staff on the pig farms. In 2014 the largest outbreak of human disease known up until then occurred in Western Africa.

EBVM

(See EVIDENCE-BASED VETERINARY MEDICINE.)

EC

(See EUROPEAN UNION.)

Ecbolics

Ecbolics are drugs which cause contraction of the muscle fibres of the uterus, such as ergot, pituitrin, etc. They are used to induce labour.

Ecdysis

Ecdysis is the shedding or moulting of an exoskeleton in arthropods, and of the old skin in reptiles. Failure to shed completely can lead to problems; it may be a clinical sign of illness, including nutritional deficiencies.

ECG

Electrocardiogram.

VetBooks.ir

Echinococcosis
(See HYDATID DISEASE; TAPEWORMS.)

Echinococcus granulosus
The cause of HYDATID DISEASE.

Echinococcus multilocularis
One of the zoonotic tapeworms. The final host is the dog. It is present in many parts of Europe and the world, but not United Kingdom, Ireland, Finland and Malta. The administration of a suitable anthelmintic to a dog 24 to 120 hours (one to five days) before entry to a country free of disease from European member states and certified by a veterinarian is a method of maintaining freedom from this disease. (See HYDATID DISEASE; PET TRAVEL SCHEME (PETS); TAPEWORMS.)

Echium plantagineum
A poisonous plant, also known as Paterson's Curse, or Salvation Jane, which has caused the death of many sheep from copper poisoning in South Australia. In one outbreak, 1,259 sheep died out of a total of 29,715 at risk. On one farm, 500 of 3,000 ewes died. Merino × Border Leicester crosses appear to be especially susceptible. At autopsy, jaundice is evident; livers are friable and enlarged or, less frequently, shrunken and fibrotic. Kidneys are swollen, soft and blackish.

The plant contains up to 10 alkaloids, and is the first to show growth after a prolonged drought.

E-cigarettes
If these or their refills are consumed by dogs, they can cause NICOTINE POISONING.

Eclampsia
Eclampsia is a disease occurring during the later stages of pregnancy or after parturition, and characterised by loss of consciousness or convulsions, or both. It occurs in the bitch, cat and, occasionally, pigs. A preferable name is lactation tetany. It is associated with HYPOCALCAEMIA. (See also MILK FEVER; FITS.)

E. Coli
Escherichia coli, formerly known as *Bacillus coli,* is a normal inhabitant of the alimentary canal in most mammals. This bacterial family is a large one, comprising many differing serotypes which can be differentiated in the laboratory by means of the agglutination test. Only a few serotypes cause disease. However, *E. coli* infections can be severe and have become sufficiently prevalent for a range of vaccines to be developed for protection against the most common pathological strains in farm animals. (See also DIARRHOEA; JOINT-ILL; COLIFORM INFECTIONS.)

Sheep *E. coli* scours and septicaemia are common in newborn lambs and often fatal. Vaccines are available for protection and antisera may be used for treatment.

Pigs One serotype gives rise to oedema of the bowel; another to the death of piglets within a few days of birth.

Those strains of *E. coli* which cause diarrhoea in piglets only a few days old are able to do so because they are covered with an adhesive coat known as the K88 antigen. This enables them to adhere to the wall of the intestine where they induce disease by means of toxins, causing diarrhoea, dehydration and death.

E. coli toxins are classified as (a) heat labile (LT), which may cause severe diarrhoea, dehydration and death of piglets; and (b) heat stable (ST) associated with only a mild enteritis.

Scouring in older pigs may often be caused by strains of *E. coli* having no K88 antigen.

The K88 antigen and related antigens can be prepared in the form of a vaccine, formulated with *E. coli* toxoids. This is injected into pregnant sows and gilts to provide protection (passive immunity) to the piglets when they are suckled, via the colostrum, by preventing the K88-coated *E. coli* from adhering to the intestinal wall. Oral and parenteral vaccines are available.

Cattle *E. coli* is an important cause of calf enteritis, enterotoxaemia and septicaemia, and mastitis. Combined antiserum preparations, vaccines and antisera-vaccine combinations are available. There are commercial products available that bind Type 1 FIMBRIAE successfully in the intestine and so offer an alternative to antibiotics.

Poultry Coliform septicaemia is a frequent cause of loss, and one difficult to control since infected birds are disinclined to eat or drink, which hinders drug administration.

Dogs *E. coli* is perhaps the most important pathogen of the bladder and urethra; it also causes enteritis.

Horse (See FOALS, DISEASES OF.)

Public health A strain of *E. coli*, 0157, has been associated with outbreaks of disease in humans. Animals that carry this toxic strain do not usually show any signs of clinical disease and shedding of the organism by animals is erratic, making detection difficult. Infection has to be transferred to the mouth to cause illness. Most people do not develop signs, but young children and the elderly are most susceptible to the disease. In the mild

VetBooks.ir

form there is blood-tinged diarrhoea. Some of those cases will go on to develop haemorrhagic diarrhoea and a number develop neurological disease that is fatal. Following an outbreak involving more than 50 persons who had eaten contaminated meat, an investigation led by Professor Hugh Pennington of Aberdeen University resulted in a series of recommendations for good hygiene practices. Several *E. coli* O157 outbreaks occurred in the summer of 2009 in children and some adults visiting open and petting farms. All who go to farms should always thoroughly wash their hands with soap and ideally running water before eating, smoking, etc. Also after taking off footwear worn on the farm, the hands again must be washed. Combining chlorate and nitro compounds seem to reduce or eliminate the *E. coli* O157 and *Salmonella* spp. populations in piglets and calves. Work is being undertaken to produce an *E. coli* O157.H7 vaccine which is available in the USA. In 2012 a Canadian vaccine became available for UK open farms under the Special Treatment Certificate scheme. In 2009 there were 1,306 reported laboratory-confirmed human cases with a decrease of 18.1 per cent to 1,069 in 2010.

Ecraseur
A surgical instrument used for castration of the larger domestic animals. Haemorrhage is largely prevented by crushing of the blood vessels of the spermatic cord. It is occasionally used for ovarioectomy in large animals. It is rarely used these days except for ovariectomy in large animals.

Ecthyma
Ecthyma is a localised inflammation of the skin characterised by the formation of pustules. (See ACNE; IMPETIGO.)

Ecto-
Ecto- is a prefix meaning on the outside.

Ectoparasites
Ectoparasites live on the integument (skin or hair). (See FLEAS; FLIES; LICE; MANGE; MITES, PARASITIC; TICKS.)

Ectopia cordis
A congenital condition in which there is a malpositioning of the heart outside the thoracic cavity. It can often be seen in the lower neck region.

Ectopia cordis thoracoabdominalis A very rare congenital abnormality characterised by protrusion of the heart to the outside of the body through a ventral body-wall fissure.

Ectopic
Ectopic means out of the usual place. An ectopic pregnancy is one in which a fetus is present outside the uterus. (See PREGNANCY AND GESTATION, ECTOPIC.)

Ectopic Cilia These are short stubby eyelashes which emerge from the palpebral conjunctiva (inner lining of the eyelid) are directed against the eye's surface and can lead to CONJUNCTIVITIS and CORNEAL ULCERATION. They are best surgically removed. (See EYE; EYE, DISEASES AND INJURIES OF.)

Ectothermy
(adjective, Ectothermic)
This is the phenomenon of acquiring body temperature from the environment. Ectothermic animals (e.g. reptiles) are unable to maintain their own body temperature and so they thermoregulate by moving in and out of warm situations, by basking, by altering their shape and orientation – snakes coil to conserve heat and stretch out to lose it. Lizards lie facing the sun to cool down and they place their bodies perpendicular to the sun's rays to acquire radiant heat. GULAR FLUTTERING is a cooling mechanism used by some lizards. CHELONIA and crocodilians (crocodiles, alligators) immerse themselves in water to cool and bask in the sun to warm up. (See also ENDOTHERMY; POIKILOTHERMY.)

Ectrodactyly
The absence of one or more digits (phalanges).

Ectromelia
Ectromelia means literally absence of a limb or limbs. The word is also used to describe a contagious disease caused by a pox virus, which affects laboratory mice, and in the subacute form causes necrosis of a whole limb, toe, tail or ear. Outbreaks are usually very severe at the outset, killing many of the affected mice, but later on the mortality becomes less, and the outbreak gradually fades and disappears; though a latent infection may persist.

Ectropion
Ectropion is a condition of the eyelids, in which the skin and periorbital musculature are so flaccid as to turn the mucous membrane lining of the lid to the outside. This is usually accompanied by profuse tear production. It is quite a common condition in AMERICAN COCKER SPANIELS, BASSET HOUNDS, BLOODHOUNDS, COCKER SPANIELS and ST BERNARDS, and is considered practically normal in these breeds. It may be treated surgically; part of the conjunctiva from

within the edge of the lid is removed (instead of skin from the outside, as in ENTROPION).

Eczema

An inflammation of the skin (dermatitis), occurring in both farm and domestic animals. Intense irritation or itchiness may accompany the acute form and frantic licking of the affected area may exacerbate the condition. In chronic eczema there may be very little irritation.

VetBooks.ir

Cats Eczema is often referred to as feline miliary dermatitis. Signs include reddening of the skin, with the appearance of papules (small blister-like spots) and, later, scabs. These may be easier to feel than to see. The area of skin involved may be small or large. Neck, shoulders and back are common eczema sites. Occasionally a bacterial infection is a complication.

The most common cause is considered to be hypersensitivity to flea bites. Once a cat (seldom a young one) has become sensitised to flea saliva, the presence of only a single flea on the cat's body is sufficient to cause the allergic reaction.

Other allergies may produce eczema; for example, a 'hay-fever' type (see ATOPIC DISEASE), or a food allergy of some kind. Cat foods containing colouring agents or preservatives are sometimes involved. Skin contact with some chemicals should also be considered. It is likely that among some breeds or strains there is a family predisposition to eczema.

Treatment involves flea removal and control of further infestation and follows identification of the causes. The veterinarian may prescribe a change of diet, a vitamin supplement, MEGESTROL ACETATE, an ANTIHISTAMINE, etc.

Dogs The causes, signs and treatment of eczema are similar to those described above. The disease is more common in dogs, in which it is localised or generalised.

First-Aid Calamine lotion may be applied if precautions can be taken to prevent it being immediately licked off.

In a few cases what a dog-owner assumes to be eczema may prove to be mange; a professional diagnosis should always be obtained.

Horses A common cause of eczema is sensitisation to midge-bites. (See 'SWEET ITCH' for preventive measures.)

Cattle and sheep Some cases of eczema affecting white-haired areas of skin are the result of LIGHT SENSITISATION. Overseas this condition is often referred to as 'facial eczema' and follows sensitisation to sunlight following the eating of certain plants. (See ATOPIC DISEASE.)

Edema

Edema is another (American) spelling of OEDEMA.

Edta

Ethylenediamine tetra-acetic acid. Its salts (edetates) are chelating agents which are used to treat poisoning by heavy metals. For example, calcium edetate is used in cases of lead poisoning. Non-clinically, sodium edetate is used as an anticoagulant for blood samples.

EEHV

(See ELEPHANT ENDOTHELIOTROPHIC HERPESVIRUS.)

Efferent

Efferent is the term applied to vessels which convey away blood or a secretion from a part, or of nerves which carry nerve impulses outwards from the nerve-centres.

Effluent

Liquid waste from an abattoir or SLURRY. (See DAIRY HERD MANAGEMENT.)

Effusion

The escape of fluid into a space, or part, such as the pericardial cavity, pleural cavity or peritoneal cavity. The fluid can be an exudate or a transudate.

EFSA

(See EUROPEAN FOOD SAFETY AUTHORITY.)

Egg-Bound

(noun, Egg Binding)

A condition of birds and reptiles in which an egg (or eggs) is formed in the oviduct but not expelled. (See also DYSTOKIA; VITELLOGENESIS.) In many cases this is due to inadequate facilities being provided and the provision of adequate nesting materials and stress-free security may be adequate to overcome the condition. Adjustment of the ambient temperature and humidity in the immediate environment often resolves the difficulties. Nutritional deficiencies are frequently causative factors – injections of CALCIUM GLUCONATE are often effective in some cases the administration of medication is necessary. Liquid paraffin may be used to lubricate the oviduct to ease the passage of the egg.

In chickens, it may follow VENT GLEET.

The condition also occurs in cage birds in which it is physically more difficult to remove the egg manually. These birds require nursing in a warm, humid environment and medical treatment may

VetBooks.ir

be more appropriate. PROSTAGLANDINS are proving useful in cage birds and OXYTOCIN is also used in reptiles. However, ARGININE VASOTOCIN is the natural reptilian oxytocin, but is only available as a research drug. Dystokia is common in captive chelonian in which propanolol is used prior to oxytocin. A veterinarian may resort to SALPINGOTOMY in stubborn cases.

Egg Drop Syndrome

This is caused by an ADENOVIRUS and occurs in laying hens and breeding birds where egg production will drop to almost zero and then levels recover to where they should be at the stage of egg laying. If the problem occurs early in the laying period, peak production will be lost. There are no misshapen eggs.

Egg Eating

Among intensively housed poultry, this may be a vice or sign either of boredom or pain.

Egg Hygiene

Washing of eggs for human consumption is not permitted in some countries and dirty eggs represent a total loss. The percentage of dirty eggs can be reduced by providing acidified drinking water.

Eggs, 'Healthy'

Dietary adjustments can be made to increase the content of several ingredients in eggs. Supplementing the diet with 6mg/kg iodine increased the iodine content of eggs to 26 mcg; 150mg/kg copper in layer diets decreased yolk cholesterol by 22 per cent without any adverse effects on production. A higher cholesterol reduction was obtained by use of 125mg/kg copper and 1,600mcg/kg chromium in the diet.

Eggshell Apex Abnormalities

A disease, initially reported from the Netherlands, Italy and GB, in which there is a reduction in egg production with some eggs having a 'cap' or 'hat'; at their apex (pointed end). About 5 per cent of eggs show this abnormality, but another 10 per cent can show egg breakages and rejections. The cause appears to be the result of infection with INFECTIOUS BRONCHITIS virus and *Mycoplasma synoviae* infection of the bird's reproductive tract.

Eggshell Quality

It can be affected by feeding, management and disease. Infections can include INFECTIOUS BRONCHITIS and EGGSHELL APEX ABNORMALITIES. Shell quality has been improved by feeding acidifiers (organic acids) in the diet.

Egg Yield

In Britain, the average is approximately 130 eggs per bird per year. An annual yield of 200 is obtained in well-managed batteries; about 190 on deep litter; 170 in fold units. A Honegger has laid 305 in 350 days.

Ehlers-Danlos Syndrome

(See CUTANEOUS ASTHENIA.)

Ehrlichia canis

Ehrlichia canis, 'or a closely related species', has been identified in human patients who had recently been bitten by ticks. They were suffering from fever, rigors, myalgia, and gastroenteritis. Tests showed leukopenia and thrombocytopenia. (See CANINE EHRLICHIOSIS.)

Ehrlichiosis

Infection with species of *Ehrlichia*, a rickettsia. *E. risticii* is one cause of abortion in mares. *E. chaffeensis* is a cause of human ehrlichiosis.

Canine ehrlichiosis has as its vector the brown dog tick. (See TICK-BORNE FEVER OF CATTLE.)

Eicosanoids

Arachidonic acid, a polyunsaturated fatty acid present in most body cells of domestic animals, can be oxidised to the prostaglandins, prostacyclin, thromboxanes and leukotrienes. These compounds, collectively known as the eicosanoids, are involved in inflammatory and allergic conditions; in reproductive and perinatal processes; with platelet aggregation and vascular homeostasis, kidney function, fever, and certain tumours; and with other normal and disease conditions.

Eimeria

(See COCCIDIOSIS.)

Elaphastrongylus

A genus of nematode found in deer. *E. cervi* locates in the central nervous system; *E. panticole* in the brain; and *E. rangiferi* in the muscles and central nervous system.

Elastic Bands

(See RUBBER BANDS.)

Elastrator

An instrument used to stretch a strong rubber ring so that it may be placed over the neck of the scrotum for the purpose of castration. They should be used in the first week of life. The rings and instrument are also used to dock lambs' tails.

Elbow

Elbow is the joint formed between the lower end of the humerus and the upper ends of the radius and ulna.

VetBooks.ir

Elbow Dysplasia

A condition in which the ANCONEAL PROCESS is not fused (non-union) with the upper ulna bone. In several breeds of dog the elbow may not develop properly. These include BASSET HOUNDS, BLOODHOUNDS, BULL MASTIFFS, DACHSHUNDS, FRENCH BULLDOGS, GERMAN SHEPHERD DOGS, GREAT DANES, IRISH WOLFHOUNDS, LAKELAND TERRIERS, POINTERS, NEWFOUNDLANDS, WEIMARANERS. (See also ELBOW DYSPLASIA)

Electric Fences

(See under PASTURE MANAGEMENT.)

Electric Pulse Training Aids (EPTA)

A method used to control companion animals, especially dogs. There are various types and they can be used as disrupters, negative reinforcers or as a punishment. They can be used to prevent dogs straying. They can be of assistance in training dogs but they can also be abused. In Wales, the use of all electronic collars is banned, including those related to boundary fencing.

Electric Shock, 'Stray Voltage' and Electrocution

Faulty electrical wiring and earthing have led to drinking-bowls, water pipes, mangers, etc. becoming live. In some instances this has led to the death of cows from electrocution following a short circuit. Cattle are particularly susceptible to the effects of electricity and will react when there is no sensation to a human being.

'Stray voltage' In one incident, this led to cows refusing concentrates in the parlour – not because they were unpalatable, as at first thought, but because cows wanting to eat were deterred by a mild electric shock.

This 'stray voltage' has been associated with intermittent or unexplained periods of poor performance, increased milking time, and an increased prevalence of mastitis'. 'Stray voltag' was detected in 32 out of 59 dairy farms in Michigan, following investigations requested by dairymen or veterinarians.

Electrocution Deaths from electrocution may occur outside buildings. Cattle are very susceptible to electrical shock. Cattle can be found dead beneath electric pylons. It can occur following metal contacts with the high-voltage lines carried by pylons. A tragic case occurred when two horses died at Newbury Races in February 2011 due to shocks from a faulty underground cable.

Pigs Metal troughs becoming electrically live led to 20 pigs becoming paralysed after a severe thunderstorm in England. Injuries apparently resulted from panic and crushing. In another case 22 out of 32 pigs in one pen were found piled up around the trough, close to which was a burnt-out live wire. The carcases were bloated and the skin bluish. Additional post-mortem findings may include external burns, numerous haemorrhages affecting many internal organs, black unclotted blood, congestion/oedema of the nervous system, and fracture of lumbar vertebrae or of the pelvis. In pigs, rupture of the urinary bladder may occur.

Horses A New York insurance agency has stated that 0.96 per cent of its claims in respect of the death of horses were for lightning strike, and 0.27 per cent for electrocution.

In Canada a veterinarian was called to see a horse which appeared to be suffering from colic. On arrival at the farm the veterinarian was told that the animal had died minutes after he had been telephoned. Earlier the same day, the owner explained, a mare in foal had died instantly in the same spot in front of a small barn; and another had died there too. Suspecting electrocution, she had switched off the barn's power supply.

Subsequently an inspector found that the builder of the barn had made a serious mistake with the electrical wiring, so that the earth line was live. In a recent excavation in front of the barn the earthing plate had been accidentally dug up and replaced horizontally across the path to the barn. The horses had died on the first wet day after the work was completed; but their owner recalled that previous to that they had shied or tended to bolt when passing the spot.

Dogs and cats Electrocution is not uncommon, and almost invariably results from puppies or kittens chewing through the insulation of electric wiring (e.g. of vacuum-cleaner, table-lamp, etc.). Burns to the mouth and lips are seen; a tan to grey discoloration is noticeable. Oedema of the lungs may be caused, with dyspnoea. In a survey of 26 dogs treated for electrocution, 16 survived. Mortality rate for all the dogs in the survey was 38 per cent. (See EUTHANASIA.)

Lightning strike Cattle, sheep and horses are most often affected. Usually death occurs instantly, and the animal is often found with a bunch of grass between its teeth. Usually, but not invariably, there are external scorch marks, with subcutaneous lesions beneath. The other signs are as those given above under 'Electrocution'.

Static electricity can build up on equipment made from materials such as plastics. In one incident, turkeys refused to eat because of a build-up of static electricity on the chain feeders which

VetBooks.ir

gave the birds a shock when they attempted to feed. The situation was detected when it was noticed that wood shavings were attracted to the feeders where the chains were operated. Earthing the feeders removed the problem.

Electrocardiogram (ECG)

Electrocardiogram (ECG) is a record of the variations in electric potential which occur in the heart as it contracts and relaxes. This record is obtained by placing electrodes on either side of the chest wall or on the two forelegs, the skin being first wetted with salt solution. These are then connected to an electrocardiograph, which records the pattern of the heart's activity. The normal electrocardiogram of each heartbeat shows one wave corresponding to the activity of the auricle, and four waves corresponding to the phases of each ventricular beat. Various readily recognisable changes are seen in cases in which the heart is acting in an abnormal manner, or in which one or other side of the heart is hypertrophied. This record, therefore, forms a useful aid in many cases of cardiac disease.

Electrocardiography has been described as a useful aid to pregnancy diagnosis in the mare – 'where thoroughbred mares more than five months pregnant are presented for sale' (see under TWINS (FOALS)); and also for monitoring heart rate during anaesthesia.

Electrocautery

Electrocautery is useful for operations where space is restricted, such as removing small tumours, etc. in mouth, nose, or throat, and to check haemorrhage in the deeper parts of wounds. Also sometimes for disbudding. (See also CRYOSURGERY.)

Electrocution

(See under ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION.)

Electrolyte

Any compound which, in solution, conducts an electric current and is decomposed by it. (See under FLUID REPLACEMENT THERAPY; NORMAL SALINE; DEHYDRATION.)

Electrolyte Solutions

Electrolyte solutions contain sodium, potassium and other electrolytes in an ISOTONIC formulation. They are used, often with plasma substitutes or other additives, in restoring the body fluid volume in cases of shock, diarrhoea, injury and other conditions.

Electron

A sub-atomic particle with a negative charge. The antiparticle of an electron is a POSITRON.

Electronic Identification

A method of identifying animals by means of microchips, electronic tags of boluses. They require a reader and if in a national scheme, a national database. There are several types and, unless there is legislation, often several will be available and may require different types of readers. Microchips are used in many companion animals including dogs, cats, horses, tortoises, and other exotic pets. In Europe they are now compulsorily used in tags for identification of sheep and goats. In cattle they are used in for management purposes, but not in a national scheme. In New Zealand a national scheme for cattle identification began in 2012.

Electron Microscope

These instruments have made it possible to study and photograph viruses, bacteriophages, and the structure of bacteria. Instead of light, the electron microscope uses a beam of electrons to scan the specimen. This is prepared as an extremely thin film and subjected to a high degree of vacuum. The electron image is focused on a video screen and may be recorded photographically or electronically. Magnification may be up to ×300,000, and by means of photographic enlargement and the use of projection slides a total magnification approaching ×1,000,000 can be achieved.

Electrophoresis

The movement of particles in a fluid under the influence of an electric current. It is used, e.g., in the analysis of blood or serum constituents which form visibly identifiable patterns in a starch gel to which current is applied.

Electrostatic Dust Control

This has been used in the USA to reduce dust levels in broiler houses by 46 per cent and atmospheric ammonia by 12 per cent.

Electrotherapy

High-frequency currents are mainly used to produce muscular contractions as an aid to muscular re-education following injury or during transient paralysis. It can also be used for passive exercise when an animal is suffering from certain neurological conditions. The technique is painless and no control measures are necessary. Animals must not, however, be excited during periods of therapy, which vary between 5 and 20 minutes per day. Some chronic skin conditions may be controlled by this method. Where movement of painful joints or tendons is required, or where there is neuritis, administration of painkillers or use of nerve blocks by local anaesthetic may be considered.

VetBooks.ir

Diathermy is a modified form of high-frequency current therapy in which warmth is induced deep in the tissues.

Repetitive stimulation is produced by cardiac pacemakers; these have been used in small animals and in horses.

Faradism is the use of electric currents to treat certain muscle, tendon and joint conditions, mainly in horses. It has also been used in working elephants.

(See also X-RAYS; IONIC MEDICATION; CANCER.)

Electuary

Electuary is a soft paste made by compounding drugs with treacle, sugar, or honey. It is used as a convenient method of applying medication to the throat and pharynx of animals. To relieve sore throat in the horse, an electuary of extract of belladonna, potassium chlorate, and aniseed, made up into a paste with treacle, was formerly much used. The electuary is applied by means of a flat stick, and is smeared upon the back of the tongue and upon the teeth.

Elephant Endotheliotrophic Herpesvirus (EEHV)

The virus is an unusual type of herpesvirus known as elephant endotheliotrophic herpesvirus (EEHV) and causes acute haemorrhagic disease in elephants. At present there are eight different known types or species, all belonging to the Genus *Proboscivirus*. They appear to be unique and co-evolved with the ancestors of the Asian (*Elephas maximus*) and African elephant (*Loxodonta Africana*).

Elephants

Asian elephant: There are several substrains. A pachyderm. The height to the shoulder of the Indian and Sri Lankan Asian elephant (*Elephas maximus*) is about 3.4 m (11 ft) with the Sri Lankan strain being more heavily built; the Sumatran elephant is much smaller and the Borneo Pygmy slightly smaller.

The African elephant (*Loxodonta africana*): There are two substrains, the larger one is a savanna elephant with the male reaching up to 4 m (13 ft) and females 3 m (9 ft 8 in). The less common substrain is the African forest elephant which is typically just over 3 m (about 10 ft). (See MUSTH; SPEEDS OF ANIMALS.)

Some cases of so-called 'rogue' elephants can be due to non-shedding of teeth causing dental IMPACTION.

Elephants, Diseases of

These include ANTHRAX (sometimes brought on by the breaking of a tusk where the disease has lain dormant in the dental pulp), multiple ABSCESSES, BLACK-LEG, BOTULISM, elephant POX, enzootic PNEUMONIA, FOOT-AND-MOUTH DISEASE, INFLUENZA, MYIASIS, parasitic gastroenteritis, pasteurellosis, RABIES, SALMONELLOSIS, stephanofilarial DERMATITIS, SCHISTOSOMIASIS, SURRA, TETANUS, TRYPANOSOMIASIS, TUBERCULOSIS. Elephants imported into Great Britain may serve out their quarantine period for FOOT-AND-MOUTH DISEASE on board the ship transporting them. Since the INDEX CASE in 1995, up to 24 per cent of all Asian elephants born in captivity in North America and Europe have been affected with HERPESVIRUS and 60 per cent of all deaths in calves (eight months to 15 years old) have been due to acute haemorrhagic disease in elephants.

ELISA

ELISA is the abbreviation for the system of ENZYME-LINKED IMMUNOSORBENT ASSAY, developed by the Swedish scientists Engvall and Perlmann. ELISA tests are widely used in laboratories for the rapid detection of pathogens or antibodies to pathogens.

Elizabethan Collar

Made these days from plastic but can be improvised from cardboard, the shape of a lampshade, and designed to fit over the dog's head and to be attached to its collar, with the object of preventing the animal from interfering with wounds, skin lesions or dressings. The illustration shows a proprietary version.

This Elizabethan collar is a transparent version, easy to adjust to the dog's neck diameter. An excellent way of preventing the canine patient from interfering with wounds, skin lesions, or dressings.

Elk

A species of large deer also called the wapiti (*Cervis canadensis*); the European elk is *Alces alces*; the American moose *A. americana*. This farmed animal

VetBooks.ir

was found to be a source of tuberculosis in people in Alberta, Canada, in 1990. *Mycobacterium bovis* was isolated.

Elkhound
A medium-sized dog with thick grey-black coat, pointed ears and a bushy tail curled over the back; it originated in Scandinavia. Inherited traits include CLEFT PALATE, GONIODYSGENESIS, OSTEOGENESIS IMPERFECTA, both by unknown mechanisms; PROGRESSIVE RETINAL ATROPHY, renal cortical HYPOPLASIA as recessives and HIP DYSPLASIA appears multifactorial.

Eltenac
A potent non-steroidal anti-inflammatory, antipyretic and anti-oedematous drug used in horses.

Emaciation
A wasting condition of the body.

Emamectin
An avermectin-like anthelmintic used in the feed to treat and control all stages of sea lice (*Lepeophtheirus* and *Caligus spp.*) in salmonids. It is not for use in brood stock. It is essential to obtain a discharge consent from the local office of the Environmental Protection Agency or from the Scottish Environmental Protection Agency before use.

Emasculator
An instrument to remove the testicles in horses, cattle and sheep. Most crush the spermatic cord to prevent haemorrhage as well as severing the testicle from it.

Embolism
The plugging of a small blood vessel by blood-clot fragments originating from elsewhere in the body and carried along in the bloodstream. Bacteria, worm larvae, air-bubbles and fat are other causes of embolism. The importance of the embolism depends upon the situation. In the brain it may cause apoplexy; in other organs, the area that was supplied by the little vessel before it became blocked by the embolism ceases to function, and if the blood supply is totally cut off it dies, or degenerates, becoming an 'infarct'. (See also THROMBOSIS; CATHETERS - CATHETER EMBOLUS.)

Embrocations
(See LINIMENTS.)

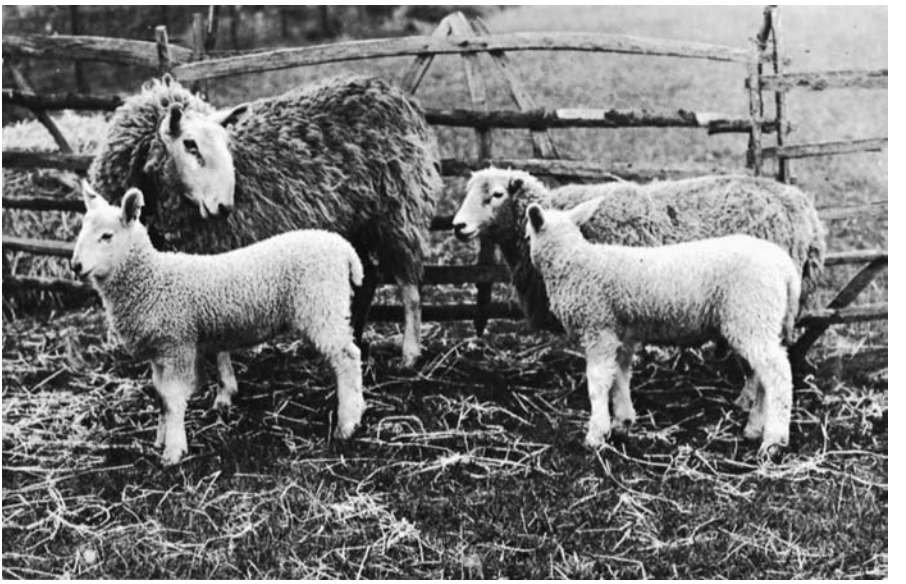
Embryo
The outcome of a successful conception following fusion of an avum and a spermatozoon. The term applies until the conceptus has developed its structures when it is called a fetus (See EMBRYO TRANSFER; EMBRYOLOGY; FETUS.)

Embryology
Embryology is the study of the development of the embryo from a fertilised egg within the body of the female or within an egg of a bird or reptile. Some development can now be undertaken within laboratories.

Embryotomy
The section and removal of a fetus still present in the uterus to facilitate manual removal at parturition; most commonly undertaken in cattle and sheep.

Embryo Transfer
The technique of transferring an embryo from one animal and implanting it in the uterus of another has become a widely used method, particularly in cattle, of improving breed quality and herd reproductivity. Basically, the technique involves the collection of embryos from one cow (the donor), seven to eight days after insemination, by flushing out the uterus with a special medium such as phosphate-buffered saline. The donor cow is prepared by administering gonadotrophins to cause superovulation, the production of multiple eggs and, therefore, multiple embryos. The embryos are collected and transferred surgically, or non-surgically by a method similar to artificial insemination, to the recipient cow which must be at exactly the same stage of oestrus as the donor. Embryos may be preserved by deep-freezing and thawed for use when required.

A number of firms operate commercial embryo transfer services; success rates of up to 70 per cent are achieved.



Embryo transfer is also used in sheep and goats; it is possible, but little used in practice, in mares and pigs.

The advantages of embryo transfer have been summarised as follows: (1) increased number of offspring from valuable females; (2) rapid progeny testing of females; (3) induction of twinning; (4) the investigation of causes of infertility; (5) transport of cattle ova from one state or country to another; and (6) an increased rate of genetic improvement.

Development The technique had, in the 1950s, already been successfully carried out in sheep – ewes having produced young of which they were not, in the full sense, the mothers; and it was extended to cattle later, by L. E. Rowson and colleagues at Cambridge, who were responsible for much of the research.

Development of a method of freezing the embryos greatly widened the scope of embryo transfer. Fertilised 10- to 13-day eggs (blastocysts) are treated with a protective agent (dimethylsulphoxide) to prevent damage by freezing and cooled to –196° C (-321° F); they are then stored in liquid nitrogen until required for implantation.

VetBooks.ir

Twins from different mothers. One of 2 eggs was removed from the Border Leicester ewe and transplanted into the Welsh ewe.

The technique Five days before oestrus is due, the donor animal is treated with pregnant mare's serum gonadotrophin (PMSG) or a similar gonadotrophin to produce superovulation. When oestrus occurs, insemination is carried out two or three times, using fresh rather than frozen semen.

Surgical transfer On day 6, when the eggs are at the morula stage, consisting of eight to 32 cells each, and looking under the microscope like blackberries, they are flushed out of the Fallopian tube. This may be done surgically or non-surgically. In the former, a fine catheter is inserted through a blunt needle after surgical exposure of the uterus by means of a flank incision, the cow being under local anaesthesia. It may be possible to recover eight to 12 ova, and an attempt is made to select the normal ones. (For example, by culturing

Transplantation. As a 7-day embryo, this calf was stored for a month at a temperature of –196° C (-321° F) before being transferred, non-surgically, to the recipient cow seen in the photograph. (ARC.)

VetBooks.ir

them for one or two days after recovery. In that time further development will have occurred; eggs which do not show this are discarded.) The transfer is made by puncturing one horn of the anaesthetised recipient's uterus with a small pipette containing one ovum in a synthetic medium. This liquid is forced out of the pipette, carrying the ovum with it.

Non-surgical transfer The eggs are collected by means of a two- or three-way catheter having an inflatable cuff. The catheter is passed through the cervix and into one of the horns of the uterus which is then sealed by inflating the cuff. Fluid is flushed into the horn and withdrawn through the catheter, with the eggs. The technique for transfer into the recipient cow is similar to artificial insemination. An egg is placed into a 'straw' and the embryo introduced into the uterine horn by means of an insemination 'gun'. With skilled operators, the results by this method are comparable with surgical collection and without the trauma of a surgical operation. This method is commonly used in the dairy industry.

The first inter-species transfer of embryos was carried out in 1979 at the Thoroughbred Breeders' Association's equine fertility unit at Cambridge. This resulted in a pony mare foaling a donkey (gestation period about 346 days or about 15 days longer than for a foal), and two donkeys giving birth to pony foals (born after 346 and 361 days' gestation period, respectively). (See PLACENTA.)

Emesis
Emesis means VOMITING.

Emetic
An agent that induces vomiting. In dogs the injection APOMORPHINE is commonly used. Home remedies include a strong salt solution or mustard water (one tablespoon of either to a cup of water). In emergency WASHING SODA can be used. Powdered IPECAC or ipecac syrup are also used.

Emetine
Emetine is one of the alkaloids of ipecacuanha.

Emodepside
An anthelmintic drug; applied to the skin, it is used with PRAZIQUANTEL to treat roundworms and tapeworms in cats.

Emphysema
An abnormal presence of air in some part of the body. The term is applied to the presence of air in the subcutaneous tissues following a wound but, more commonly, to two abnormal conditions of the lungs: destructive (vesicular) emphysema and interstitial emphysema.

Destructive (vesicular) emphysema is a condition of the lung characterised by an abnormal enlargement of the air spaces, accompanied by destructive changes in the alveolar wall. This condition occurs in dogs with chronic bronchitis and in horses with CHRONIC OBSTRUCTIVE PULMONARY DISEASE (see 'BROKEN WIND' RECURRENT AIRWAY OBSTRUCTION). Emphysema is irreversible and may progress to respiratory failure and death. The main sign is respiratory distress on exertion, with a marked expiratory effort.

Interstitial emphysema Air is present in the connective tissue of the lung – a state of inflation of the interstitial (interlobular) tissue. The air is found in the lymphatics, under the pleura in the interlobular septa, and around blood vessels, sometimes in the form of large bullae 10 cm or more in diameter. Air may track as far as the hilum of the lung and gain access to the mediastinum from where, in exceptional circumstances, it may even spread to subcutaneous connective tissue – usually in the shoulder region or over the upper part of the chest.

Interstitial emphysema is a common condition in cattle, especially in association with parasitic bronchitis (HUSK) or with FOG FEVER. Increased effort, in response to obstructed airways, overexertion and violent struggling, causes a marked increase in pressure within the alveoli. Rupture then occurs, allowing air to escape into the interstitial tissue on inspiration, but impeding its leaving on expiration. When the lung lobules become surrounded by interstitial emphysema their ability to inflate during inspiration is restricted, and this may lead to respiratory distress.

Empiric Medicine, Empiric Treatment
Treatment which from past experience has proved to be helpful in treating a condition. A more structured form might be EVIDENCE-BASED MEDICINE.

Empyema
A collection of purulent fluid within a body cavity, such as an accumulation of fluid in the pleural cavity. (See PYOTHORAX; PLEURISY.)

EMS
1. (See EQUINE METABOLIC SYNDROME.)
2. In veterinary schools this refers to Extra Mural Studies, where students have learning placements away from colleges, usually in veterinary practices or veterinary hospitals, but also at laboratories, slaughterhouses, etc.

Emu
A large flightless bird, *Dromaius novaehollandiae,* native to Australia. It is farmed in Britain but to a

VetBooks.ir

lesser extent than the ostrich. Severe enteritis resulting in death of up to 65 per cent of a flock has occurred in the USA from infection by eastern equine encephalitis virus. This is a NOTIFIABLE DISEASE throughout the EU.

Enalapril
A drug used to treat heart failure in dogs. Together with diuretics it is used in cases of heart failure caused by CANINE DILATED CARDIOMYOPATHY or MITRAL VALVE regurgitation.

Enamel
The very hard substance found on the external surface of the crowns of TEETH.

Enarthrodial Joints
Enarthrodial joints are those of the ball-and-socket type which allow movement in nearly any direction. Examples include the shoulder joint between the scapula and the humerus; and the hip joint in which the nearly spherical head of the femur fits into the cup-shaped cavity called the acetabulum on the pelvis.

Encephalitis
Encephalitis is inflammation of the brain. It may be brought about through the activity of bacteria, such as those of STRANGLES and LISTERIOSIS, but especially during infection with viruses, such as those of RABIES, CANINE DISTEMPER, FLAVIVIRUSES, etc.

Signs of encephalitis include fever, excitement, delirium, convulsions, paralysis, and loss of consciousness. Several signs are common to MENINGITIS. (See also 'SLEEPER' SYNDROME.)

First-Aid Keep the animal quiet – in a darkened room if showing excitement – and avoid noise or handling the patient.

Treatment It depends on the cause; antibiotics may be useful in bacterial infections. Often they are required for long periods, but the prognosis is usually poor. In some cases corticosteroids or NON-STEROIDAL ANTI-INFLAMMATION DRUGS can be helpful.

Encephalitozoon Cuniculi
An intracellular protozoal parasite. It develops in macrophages, brain, kidney and other tissues of rabbits, dogs, rodents and primates.

In carnivores, severe nephritis, encephalitis and a high mortality are associated with transplacental infection.

In a Norwegian outbreak, 1500 blue fox cubs died (33 per cent of the litters), although the parents showed no signs of infection.

In the UK, foxhound puppies have died, and in Tanzania 2 spaniel puppies died which had shown rabies-like signs.

Diagnosis An ELISA test. In one study, 51 positive samples were identified out of 248 sera from stray dogs.

Encephalitozoonosis
A disease of rabbits caused by the intracellular protozoal parasite *Encephalitozoon cuniculi*. This can develop in macrophages, brain, kidney and other tissues of rabbits, dogs, rodents and primates. It is commonly a serious problem in rabbits, but may be asymptomatic. It can cause chronic weight loss, ataxia, posterior paralysis ('floppy rabbit syndrome'), tremors and convulsions, usually with incontinence, POLYDIPSIA and POLYURIA with spores of the parasite in the urine. A severe sign is TORTICOLLIS so that affected animals cannot walk or feed properly.

Encephalocele
A hernia of the brain tissue.

Encephalomalacia
A group name for the degenerative diseases of the brain. Causes include the COPPER deficiency of SWAYBACK, HORSE-TAILS and BRACKEN POISONING, metallic poisoning, CEREBROCORTICAL NECROSIS and 'MULBERRY HEART' disease of pigs. Other examples of encephalomalacia are 'crazy chick' disease.

Encephalomyelitis
Inflammation of both the brain and the spinal cord.

Encephalomyelitis, Viral, of Pigs
This term covers Teschen disease, Talfan disease and *Poliomyelitis suum* – all caused by CORONAVIRUS. Teschen disease is NOTIFIABLE but Talfan, a milder disease, is not.

Believed to have originated in the former Czechoslovakia, viral encephalomyelitis of pigs is now encountered throughout most of Europe. In Britain and Denmark, only a small percentage of pigs become infected, and illness is far milder than in some other countries.

Signs include fever, stiffness, staggering gait, paralysis, and those of encephalitis.

Encephalomyocarditis Virus
Encephalomyocarditis virus is a picornavirus, antibodies to which have been found in the serum of more than 28 per cent of normal pigs in the UK. It is also a pathogen of rodents and human beings, and has caused outbreaks of illness in pigs in Australia, the USA and Panama.

VetBooks.ir

Enchondroma
A tumour formed of cartilage. (See TUMOURS.)

Encysted
Enclosed in a cyst.

Endangered Species Act 1985
Endangered Species Act 1985 lists measures for the protection of named animals.

Endarteritis
Inflammation of the inner coat of an artery. (See ARTERIES, DISEASES OF.)

Endectocides
Medicines that are able to kill both some ectoparasites and endoparasites. They include the AVERMECTINS and the MILBEMYCIN group.

Endemic
An endemic disease is one present in an animal population at all times.

Endo-
Endo- is a prefix meaning situated inside.

Endocardiosis
Any disorder of the smooth membrane that lines the inside of the heart, including thickening and inflammation, especially over the heart valves. (See HEART DISEASES; MYXOMATOSIS, INFECTIOUS; VALVULAR DISEASE).

Endocarditis
Inflammation of the smooth membrane that lines the inside of the heart. It occurs especially over the heart valves. (See HEART DISEASES.)

Endocardium
The internal lining membrane of all the HEART chambers.

Endocrine Glands
Endocrine glands are those which secrete hormones. (See HORMONES; also under the name of individual endocrine glands, e.g. ADRENAL, THYROID, PARATHYROID, PITUITARY, THYMUS, PANCREAS.)

Endometritis
Inflammation of the mucosal lining of the uterus (endometrium). This is a common cause of METRITIS in many species (see UTERUS, DISEASES OF).

Endorphins
Morphine-like, natural analgesics produced in the body. Acupuncture is said to stimulate their release into the bloodstream. (See also TWITCH.)

Endoscope, Endoscopy
An instrument used for visual examination of body cavities or hollow organs. Additional instruments are used to facilitate the extraction of a foreign body, e.g. from the oesophagus; and for assistance with other surgery, including taking tissue samples (BIOPSY) and embryo transfer. (See also LAPAROSCOPY.)

Endoskeleton
This is the bones and cartilage which provide the shape of the vertebrate inside the body. It does not apply to the skin, horns or hooves or other structures derived from the DERMIS.

Endothelium
Endothelium is the membrane lining various vessels and cavities of the body, such as the pleura, pericardium, peritoneum, lymphatic vessels, blood vessels, and joints. It consists of a fibrous layer covered with thin flat cells, which render the surface perfectly smooth and secrete the fluid for its lubrication.

Endothermy
The ability of an animal to maintain its body temperature without any dependence on the environment. (See also ECTOTHERMY and POIKILOTHERMY.)

Endotoxins
Endotoxins are those toxins which are retained within the bodies of bacteria until the latter die and disintegrate.

Endotracheal Anaesthesia
(See ANAESTHESIA, GENERAL.)

Endotracheal Tube
A tube introduced into the trachea to prevent its collapse; used in endotracheal anaesthesia.

Endrin
A highly toxic insecticide of the chlorinated hydrocarbon group. It has caused fatal poisoning in cattle, dogs, fish, and birds.

Enema
The introduction of fluid into the rectum to assist evacuation of faeces. It may also be used for diagnostic purposes, or because the large intestine is a good site for absorption, it can be used to deliver medications.

Energy
(See CALORIE; CARBOHYDRATES; METABOLISABLE ENERGY; JOULES.)

VetBooks.ir

English Beef and Lamb Executive (EBLEX)
A successor to the Meat and Livestock Commission which provides management and veterinary information to its subscribers (beef and sheep farmers). It is part of the AGRICULTURE AND HORTICULTURE DEVELOPMENT BOARD. Address: EBLEX, Agriculture and Horticulture Development Board, Stoneleigh Park, Kenilworth, Warwickshire CV8 2TL. Telephone: 024 7669 2051.

English Bulldog
(See BULLDOG.)

English Cocker Spaniel
A type of COCKER SPANIEL which more resembles the SPRINGER SPANIEL or FIELD SPANIEL than the AMERICAN COCKER SPANIEL. It is a gundog which is larger and with a shorter coat than the American Cocker Spaniel. It is prone to DEAFNESS.

English Goats
The aim of this breed is to develop a utility goat for smallholders. It is adapted to the English climate and vegetation and should be able to produce a moderate milk volume over a long period. They are of variable colour mainly brown and grey with a characteristic black line down the spine, hair length is variable, and usually there are dark markings on head, legs and flanks.

English Setter
A medium-sized working dog. Haemophilia A (Factor VIII deficiency) has been found as a sex-linked recessive trait. Atopic dermatitis is inherited by an unknown mechanism. CANINE LIPFUSCINOSIS (DNA test available) occurs.

English Spot
A medium-sized breed of rabbit with a white PELAGE and coloured markings on ears, muzzle and spots on the body.

English Springer Spaniel
Long-eared, medium-sized dog with silky coat, brown and white or black and white; originally bred as a gun dog. ACHALASIA, MULTIFOCAL RETINAL DYSPLASIA and RETINAL PIGMENT EPITHELIAL DYSTROPHY are inherited by unknown mechanisms and possibly GONIODYSGENESIS. Entropion, cutaneous asthenia and haemophilia (Factor XI deficiency) are autosomal dominant traits. There is an increased prevalence of CANINE CHRONIC HEPATITIS in the breed.

Enilconazole
A topical antimycotic which when diluted is used to treat ringworm in cattle, horses and dogs.

Enophthalmus
Displacement or sinking of the eyeball within the socket.

Enriched Cages
These are required (from 2012) for laying poultry within the EU. The cages provide nests and perches for the birds, also include litter and claw shortening devices. Minimum height is 45 cm (1½ ft) and area 750 cm^2 (116 in^2) per bird, with 600 cm^2 (93 in^2) usable area per bird and 1,502 (23 in^2) per bird nesting area. Compared with conventional cages, stocking density will be less and feed intake greater than earlier cages, the cost will be higher by about 12 per cent. The aim is to provide a better environment for the bird. By 1 January 2012 several EU countries had not met completely banning conventional battery cages including Spain and Portugal had not met the regulation completely banning conventional battery cages.

Enrofloxacin
Enrofloxacin is a quinolone antibacterial active against a wide range of GRAM-POSITIVE and GRAM-NEGATIVE organisms. As it may affect the development of load-bearing articular cartilage, it should not be administered to growing animals. Note: Hard water reduces its efficacy when the drug is given in the drinking water.

Ensilage
(See SILAGE.)

Entamoebiosis
Entamoeba invadens affects carnivorous and omnivorous reptiles; herbivorous species do not show clinical signs but are carriers of the organism. Signs can include inappetance, excessive drinking, foul-smelling diarrhoea, food regurgitation and sometimes death. Treatment is with metronidazole and, in snakes, raising the ambient temperature to 35–37°C.

Enteque Seco
A wasting disease of cattle, sheep and horses. It occurs mainly in Argentina, but also in Uruguay and possibly Brazil. It may be identical with Manchester wasting disease (Jamaica) and Naalehu disease (Hawaii).

Cause A plant, common on wet land, known as duraznillo blanco (*Solanum melacoxylon* or *glaucum*). Poisoning may arise from deliberate eating of the leaves or from the accidental consumption of dead, fallen leaves during grazing of the underlying pasture plants. It is particularly dangerous when growing in association with white clover.

VetBooks.ir

It produces an arteriosclerosis, with calcification in heart, aorta, lungs, etc. Blood levels of calcium and phosphorus tend to be high as *S. malacoxylon* contains a potent metabolite of vitamin D.

Signs Emaciation occurring over weeks or months, and an abnormal gait.

Enteralgia
Enteralgia (literally 'pain in the intestines') is another name for colic.

Enteric Redmouth Disease
A disease of trout. (See FISH, DISEASES OF.)

Enteritis
Inflammation of the intestines (see DIARRHOEA and INTESTINES, DISEASES OF).

Enterocele
(See HERNIA.)

Enterococcus
(plural, Enterococci)
These are Gram-positive bacteria which produce lactic acid. They form part of the normal intestinal flora of animals and man, and include *Enterococcus faecalis* (about 90 per cent) and *E. faecium*. They can be pathogenic in other areas but usually mainly in man, where they have intrinsic antibacterial resistance. They do indicate contamination when found on food, including meat and milk.

Enteroliths
Enteroliths are stones that develop in the intestines, being formed by deposition of salts round a hard metallic or other nucleus. (See CALCULI.)

Enterostomy
Enterostomy is an operation by which a temporary or permanent artificial opening is formed into the intestine.

Enterotomy
A surgical operation to incise the intestine. It is usually performed to remove an obstruction or foreign body.

Enterotoxaemia
An acute disease of calves, lambs, goats, and occasionally of piglets and foals.

Cause Toxins emanating from the intestines and present in the bloodstream. The toxins involved are from 4 strains of *Clostridium perfringens* and from some strains of *E. coli*.

Signs Severe enteritis, with dysentery in some cases, and sudden death in others.

Prevention A vaccine is available.

Calves seldom survive for more than a few hours.

Goats show a sudden drop in milk yield, dysentery, and death within 36 hours. There is also a subacute type of the disease lasting 7 to 10 days, and followed by recovery.

Sheep The disease affects both unweaned lambs and sheep one to two years old. There are few signs (diarrhoea, colic), but sudden death.

Enteroviruses
A group of smaller viruses pathogenic to animals and causing disease in cattle, pigs and ducks (duck hepatitis).

Entlebucher Mountain Dogs
Also called ENTLEBUCHER SENNEN HUND, it originates in Switzerland. It is a medium-sized dog breed (25.5 kg to 30 kg; 45 lb to 65 lb) and tricoloured (black, brown and white). Some have bobtails. The breed suffers from PROGRESSIVE RETINAL ATROPHY (DNA test available), and a HIP DYSPLASIA.

Entlebucher Sennen Hund
(See ENTLEBUCHER MOUNTAIN DOGS.)

Entropion
The turning in, or inversion, of an eyelid. It can be congenital or acquired and is inherited in some breeds of lambs and dogs. It results in the eyelashes irritating the cornea and EPIPHORA. The condition can be corrected surgically, although in lambs a subcutaneous injection of sterile liquid paraffin or long acting antibiotic is often effective. It is very common in 'mini-pigs'. In dogs it is seen in many breeds including AIREDALE TERRIERS, AMERICAN COCKER SPANIELS, BLOODHOUNDS, BULLDOGS, CHOW CHOWS, COCKER SPANIELS, ENGLISH SPRINGER SPANIELS, FLAT-COATED RETRIEVERS, GERMAN SHORT-HAIRED POINTERS, GOLDEN RETRIEVERS, SHAR-PEIS and ST BERNARDS. (See ECTROPION; EYE, DISEASES AND INJURIES OF - ENTROPION).

Enucleation
The term used to describe removal of the eyeball. The operation involves suturing the eyelids closed over the empty eye socket, giving a perfectly acceptable appearance once the hair or fur has grown back (it is shaved off before commencing the operation for reasons of hygiene).

Enuresis
(See INCONTINENCE.)

VetBooks.ir

Environment
(See HOUSING OF ANIMALS; PASTURE MANAGEMENT; EXPOSURE; RAINFALL; ALTITUDE; HEATSTROKE; ANHIDROSIS; TROPICS, LIVESTOCK PRODUCTION IN THE; VENTILATION; CALF HOUSING.)

Enzootic
Enzootic refers to a disease present (endemic) among animals in a particular region, country, or locality. For example, braxy and louping-ill are enzootic in the south and west of Scotland and the north of England. Compare EPIZOOTIC (epidemic), in which a disease spreads rapidly through large numbers of animals over a wide area.

For enzootic abortion of sheep, see under ABORTION, ENZOOTIC.

Enzootic Bovine Leukosis (EBL)
(See BOVINE LEUKOSIS.)

Enzootic Haematuria
A disease typically found in old suckler cows following the long-term ingestion of bracken. It results in various cancer problems of the bladder.

Enzootic Hepatitis
(See RIFT VALLEY FEVER.)

Enzootic Muscular Dystrophy
A disease in calves, lambs and foals caused by vitamin E and selenium deficiency. Acute cases may drop dead after exercise; mild cases are weak and breathe with difficulty.

Enzootic Nasal Granuloma
Obstruction of the nasal cavities of cattle by an eosinophilic granuloma. More common in Channel Island breeds.

Enzootic Ovine Abortion
Enzootic ovine abortion is caused by *Chlamydia ovis* (formerly *Chlamydia psittaci*). (See under ABORTION, ENZOOTIC.)

Enzootic Pneumonia of Calves
Acute pneumonia usually seen in calves between two and four months old; it is caused by environmental and management changes as well as viral, mycoplasmal and bacterial infections. (See BOVINE RESPIRATORY DISEASE COMPLEX; 'SHIPPING FEVER'.)

Enzootic Pneumonia of Pigs
This was formerly described as virus pneumonia of pigs (VPP), but the cause is now generally regarded as being strains of *Mycoplasma hyopneumoniae* of varying virulence. However, other organisms may be involved to a varying degree. Airborne infection can occur over many kilometres. (See RESPIRATORY DISEASE IN PIGS; SYNERGISM.)

Many pigs reaching the bacon factories are affected with some degree of pneumonia, so that the matter is of the very greatest economic importance.

Signs When the disease is first introduced into a herd, pigs of all ages (from 10 days upwards) go down with it, and many die. Where the disease is already present, deaths are few. Signs, which may easily be overlooked or ignored, then consist merely of a cough. There is, in addition, a certain degree of unthriftiness which in extreme cases may amount to stunted growth. In all cases one may expect the liveweight gain to be reduced. Sometimes pigs which contract the disease earlier in life quite suddenly develop acute pneumonia at 19 to 26 weeks of age, known as 'secondary breakdown'. Affected animals lose their appetite and often become prostrate, breathing rapidly with a temperature over 40.5° C (105° F). A number die if left untreated, but the majority have a fluctuating fever for a few days and then recover.

Prevention Vaccination at one to 10 weeks of age and management measures such as avoiding buying-in infected stock. Litters are best kept in arks on pasture, and any sows showing a cough eliminated. Weaned pigs should not be brought into a fattening house where pigs with pneumonia are present. (See DUSTY ATMOSPHERE; SWINE INFLUENZA.)

Diagnosis Confirmed by a complement fixation test.

Treatment Macrolide antibiotics, administered on a herd or individual basis, help to control the severity of outbreaks.

Enzootic Pneumonia of Sheep
(See PASTEURELLOSIS IN SHEEP; PNEUMONIA IN SHEEP.)

Enzyme-Linked Immunosorbent Assay
(See ELISA).

Enzymes
Enzymes are complex organic chemical compounds which facilitate or speed biochemical processes in the animal body, including those of digestion. Some enzymes are also produced by the normal bacterial inhabitants of the intestinal canal. Each has a specific use in splitting up proteins, carbohydrates, fats, or crude fibre. The best known are the ptyalin of saliva and diastase of

VetBooks.ir

the pancreatic juice, which break down starches into soluble sugars; pepsin from the gastric juice and trypsin from the pancreas, which break complex proteins into simple amino acids; and lipase in the intestines, which attacks fats. (See DIGESTION, ABSORPTION AND ASSIMILATION.) Enzymes are used in the cleaning of badly infected wounds. (See STREPTODORNASE.)

Some enzymes detoxify poisons, breaking them down into relatively harmless compounds. The differing susceptibility of cat and dog, for example, to phenol is due to the former animal lacking a particular enzyme which the dog has. (See TAURINE.) Enzymes are now added to some animal feeds to improve digestibility.

Some enzymes are injurious (see under THIAMIN).

(See also BLOOD ENZYMES, and CREATINE KINASE for enzymes used in diagnosis.)

Eosinophil

Eosinophil is the name given to white cells in the bloodstream containing granules which readily stain with eosin, a histological dye. The nucleus of this leukocyte is lobular. Eosinophils, basophils, and neutrophils are collectively known as polymorphonuclear leukocytes. As well as these circulating cells, eosinophils are found in the pituitary and pineal glands.

In a normal horse, 2.5 ml^3 (1 cu in) of blood contains between 5 and 8 million eosinophil white cells – compared with about 160 million other white cells, and 128,000 million red cells.

Eosinophils increase in numbers during certain chronic infections and infestations with parasites. They contain hydrolytic enzymes. 'Unlike neutrophils, eosinophils have low phagocytic capacity and are not good at killing microorganisms.' (*Lancet.*) (See BLOOD.)

Eosinophilia

Eosinophilia means that an abnormally large number of eosinophils are present in the bloodstream. This may occur during severe parasitic infestation in horses and dogs, in certain wasting conditions, and in disease of the lymph system.

Eosinophilic Granuloma

A complex in cats. The name covers at least three different lesions, of a chronic nature.

Eosinophilic ulcers in cats usually occur on the upper lip, or commissure of the lips, gums, palate, pharynx and tongue. Reddish-brown in colour, they have raised edges. They are reddish-brown in colour and not malignant (compare 'rodent ulcer' in man which is a basal cell carcinoma).

Eosinophilic plaques may occur anywhere on the body but are most common on the abdomen and inside of the thigh. The plaques are red, with raised edges, and ulcerate. They are extremely itchy.

Linear granulomas are seen mainly on the hind legs and in the mouth, and are yellowish-pink in colour. Itching is not usually present. As with the ulcers mentioned above, females seem more prone to this granuloma than are males. In the mouth, lesions are 'more nodular' and have to be differentiated from bacterial or mycotic infections and also carcinoma. In horses, they often occur in the saddle area as an overreaction to insect bites. These granulomas cause few problems and often resolve spontaneously. Occasionally local treatment with corticosteroid injections is helpful.

Eosinophilic Myositis

A disease of dogs, especially GERMAN SHEPHERD DOGS, in which there is hardening of the muscles of mastication and of the temporal muscles. The dog assumes a foxy appearance. (See under MUSCLES, DISEASES OF.)

Eperythrozoon felis

A blood parasite found in cats in Britain; it was first reported in 1959. (See FELINE INFECTIOUS ANAEMIA.)

Eperythrozoon Parvum

A blood parasite of the pig, which gives rise to fever, anaemia, and sometimes jaundice. It can be transmitted from pig to pig by lice. It occurs in Britain and the USA. Other species of this parasite affect sheep, and cattle in Africa. In the UK *E. wenyoni* has been isolated from anaemic cattle. (See also HAEMOBARTONELLA.)

Ephedrine

Ephedrine is an alkaloid derived from the Chinese plant *Ma Huang*, or prepared synthetically. It stimulates the heart and central nervous system, and relaxes the bronchioles. It has been used for asthma in dogs.

Ephemeral Fever, Three-Day Sickness

An acute, infectious and transient fever accompanied by muscular pains and lameness, which has a tendency to shift from limb to limb. The disease was first described in South Africa in 1867 and has been seen in Africa, Asia and Australia. Considerable economic loss has been caused among beef and dairy cattle in northern and eastern Australia. An outbreak began in Madeira in October 2012 with more than 1,000 cases.

Cause A rhabdovirus. The disease is sudden in onset and attacks a large percentage of the cattle in

VetBooks.ir

affected districts, taking the form of an acute epizootic; then, in a few weeks, it dies down again as quickly as it arose. The disease is transmitted by insects, including *Culicoides* midges. The incubation period is two to 10 days.

Signs The disease is ushered in by a suddenly occurring rise of temperature which may reach 41.6° C (107° F). This is accompanied by loss of appetite, cessation of rumination, rapid respirations, a quick and full pulse (which, however, may become very weak later) and a staring coat. The affected animal stands with head down. The attitude of the patient is rather characteristic, the four legs being placed far under the body and the back arched, suggestive of the position of a horse suffering from laminitis. There may be a discharge from eyes and nose.

In milking cows, the milk yield is much diminished. Many animals prefer to lie down rather than remain on their feet, and once down are most reluctant to get up again. The signs along with the elevated temperature continue like this for about three days – hence the name. There is usually a considerable loss of condition.

In Australia the mortality is seldom more than 0.5 per cent.

Prevention Vaccines may be available in some areas.

Epi-
Epi- is a prefix meaning situated on, or situated outside of.

Epicardial Haemorrhages
Haemorrhages on the outer wall of the heart, the epicardium. They may vary in size and can usually be obvious in problems such as 'MULBERRY HEART' disease.

Epidemic
A disease affecting a large number of individuals at the same time in the same area. The term is strictly applied to man, not animals.

'Epidemic Tremors'
'Epidemic tremors' is the colloquial name for a virus disease of poultry characterised by an unsteady gait. (See AVIAN INFECTIOUS ENCEPHALOMYELITIS.)

Epidemiology
The study of disease as it affects groups of humans. It can be used in predicting the pattern of an outbreak and in making plans to control the spread. International reporting services, as carried out by WHO and OIE, play their part; and the use of computers has greatly assisted the statistical analysis on which epidemiology relies. The term is also often used to refer to animals although the correct term is EPIZOOLOGY.

Epidermis
The outer layer of the SKIN.

Epididymis
Epididymis is a structure situated within the scrotum and in which the sperms mature after leaving the testicle. It has three parts: the head (caput epididymis), the body (corpus) and the tail (cauda). The epididymis has as its outlet the vas deferens. (See TESTICLE.)

Epididymitis
Inflammation of the epididymis. (See also under RAM EPIDIDYMITIS.)

Epididymitis and 'Epivag', Contagious Vaginitis
A venereal disease of cattle and sheep in Kenya and Southern Africa, and an important cause there of infertility and sterility. INFECTIOUS BOVINE RHINOTRACHEITIS virus can be the only agent found.

Cause Possibly a double infection with a virus and a mycoplasma; possibly a campylobacter. In sheep, *Brucella ovis* is responsible (not in the UK).

Signs There may be a yellowish discharge from the vagina, or merely a redness of the mucous membrane. In the bull, enlargement of the epididymis occurs over a period of months.

Control Slaughter of infected bulls and use of artificial insemination.

Epidural Anaesthesia
Epidural anaesthesia is a form of spinal anaesthesia induced by the injection of a local anaesthetic solution into the epidural space of the spinal canal. The technique is used, for example, in bovine obstetrics – the injection being made between the first and second coccygeal vertebrae. Occasionally it is used to provide regional analgesia in dogs, even when under general anaesthesia. (See also ANAESTHESIA, GENERAL; ANALGESICS.)

Epigastrium
Epigastrium is the region lying in the middle of the abdomen, immediately over the stomach. (See ABDOMEN.)

Epigenetics
The study of the activation or suppression of gene effects which can be the result of various stimuli.

VetBooks.ir

Epiglottis

Epiglottis is a leaf-like piece of elastic cartilage covered with mucous membrane, which stands upright between the back of the tongue and the entrance to the glottis, or larynx. It plays an important part in the act of swallowing, preventing solids and fluids from passing directly off the back of the tongue into the larynx.

Epiglottic entrapment in the horse is diagnosed more and more frequently due probably to the wider use of endoscopy and greater expertise in its use. Affected horses have a history of decreased exercise tolerance and they make abnormal inspiratory and expiratory noises.

Epilepsy

Epilepsy is a chronic nervous disorder characterised by a sudden and complete loss of consciousness, associated with muscular convulsions, often called SEIZURES. This is particularly a disease of the dog, although other domesticated animals may be affected. In dog breeds it would appear to be inherited in BEAGLES, BELGIAN SHEPHERD DOGS (Tervueren Form), BORDER TERRIERS, DACHSHUNDS, GERMAN SHEPHERD DOGS, GOLDEN RETRIEVERS, ITALIAN GREYHOUNDS, KEESHONDS, LAGOTTO ROMAGNOLOS and TERVUERENS. JUVENILE EPILEPSY occurs in dogs under one year old and can be IDIOPATHIC or symptomatic. The FLY CATCHING SYNDROME in CAVALIER KING CHARLES SPANIELS is thought to be a form of epilepsy. In idiopathic epilepsy lifelong medication may be necessary. Anti-epileptic drugs include PHENOBARBITONE SODIUM and POTASSIUM BROMIDE. Epileptic fits in the horse were formerly called megrims.

Cause The cause of primary or idiopathic epilepsy is a genetic one, whereas secondary epilepsy may be caused by trauma, neoplasia, infections, cardiovascular disease or metabolic conditions.

The disease can be controlled completely in about one-third of affected dogs, and considerably improved in another third.

Secondary epilepsy may be the result of a head injury, and can occur whenever scar tissue is formed in the brain.

(See also FITS; HYSTERIA, CANINE; ENCEPHALITIS; POISONING; HEART DISEASES.)

Signs Attacks usually commence without any warning. The limbs are sometimes held out rigidly, and sometimes moved as if the animal were running or galloping. The animal champs its jaws; the eyes are fixed and staring, or the eyeballs may roll, and the pupils are dilated. There is usually a good deal of salivation from the mouth. The rectum and the bladder are usually evacuated involuntarily. The dog regains consciousness in one or two minutes; in a few cases consciousness may not be completely lost. The first fit often occurs between the age of one and three.

Treatment Barbiturates, diazepam, gabapentin, levetiracetam (these last three are unlicensed for animal treatment) and potassium bromide are among drugs used for treatment. After consciousness returns, the dog should be placed in a quiet room away from other dogs or human beings. Treatment should be left to a veterinary surgeon. Anti-epileptic drugs include PHENOBARBITONE SODIUM, POTASSIUM BROMIDE, and can include use of IMEPITOIN.

Epileptiform

Resembling EPILEPSY or its manifestations; occurring in severe or sudden paroxysms.

Epinephrine

(See ADRENALIN.)

Epiphora

Epiphora is a condition in which the tears that bathe the eye, instead of passing down the tearduct to the inside of the nose, run over the eyelid edge on to the cheek. It may be due to a blocking of the tearduct, or irritation of the cornea or conjunctiva generally from inflammation of its lining membrane or ENTROPION or by a foreign body such as a grass seed. (See EYE.) Bilateral epiphora is a sign of naphthalene poisoning in cattle, as well as respiratory diseases.

Epiphyseal Dysplasia

This is also called chondrodystrophia fetalis or pseudochondroplastic dysplasia in miniature POODLES. It is an inherited condition seen as short legs and early degenerative arthropathy. In BEAGLES there is a multiple epiphyseal dysplasia which is histologically identical.

Epiphyseal Fracture

Epiphyseal fracture is one which occurs along the line of the epiphyseal cartilage, and results in the epiphysis of a bone becoming separated from the shaft or diaphysis. These fractures may occur in any young animals before complete ossification has occurred. (See FRACTURES; BONE, DISEASES OF.)

Epiphysis

(plural, Epiphyses; adjective, Epiphyseal)

The end of a long bone, separated from the rest of the bone (the DIAPHYSIS) by a cartilage (see BONE, DISEASES OF).

VetBooks.ir

Epiphysitis, Physitis

Epiphysitis (physitis) may occur in young calves affected with joint-ill, and has been reported in adult cattle housed on slatted floors. The cattle were lame, and inflammation and necrosis were found involving the distal epiphysis of the large metatarsal bones. It also occurs in horses.

Epiplomphalocele

An alternative term for an umbilical hernia that contains omentum.

Episode

Something of note happening in a continuous series of events.

Episodic

Occurs as EPISODES.

Episomes

(See PLASMIDS.)

Epispastics

Epispastics are substances which produce blistering on the skin.

Epistaxis

Bleeding from the nose. (See GUTTURAL POUCH DISEASE; HAEMORRHAGE.)

Epitheliocystis

A disease of over 50 wild and farmed fish species in the sea and fresh water (including species of salmon, trout and carp) and caused by *Chlamydia*. Low infection levels may be undetected but with heavy infection there is excessive mucus production and possible respiratory distress. It is also known as mucophilosis. Transparent or white cysts on the gill lamellae normally indicate infection.

Epitheliogenesis Imperfecta

An inherited condition in which there is a gap in the epithelium which readily bleeds and then heals by scar tissue. It has been seen in foals, calves, piglets, lambs, and kittens, and can occur in all tissues that possess an epithelial layer, especially the skin, oral and gut mucosa and reproductive tract.

Epithelioma

Epithelioma is a type of malignant tumour. (See CANCER.)

Epithelium

Epithelium is the layer or layers of cells of which skin and mucous membranes are formed. The epithelial tissues take many forms. (See SKIN and MUCOUS MEMBRANE.)

Epivag

(See EPIDIDYMITIS; VAGINITIS.)

Epizoology

The study of disease within a group of animals. The term for the study in humans is EPIDEMIOLOGY, although this term is also often used for animals and veterinary disease studies.

Epizootic

Epizootic is a term applied to a disease which affects a large number of animals in a large area of land at the same time and spreads with great rapidity, e.g. FOOT-AND-MOUTH DISEASE and CATTLE PLAGUE. It is the equivalent term to epidemic in humans. Certain of these epizootic diseases are monitored by OIE.

Epizootic Catarrhal Enteritis, Green Slime Disease

A coronavirus infection of ferrets causing bright green diarrhoea (the colour can vary). It is self limiting and rarely fatal. Treatment with bismuth is of benefit as are diets to assist with malabsorption. Antibiotics are unnecessary unless there is a secondary infection.

Epizootic Cerebrospinal Nematodiasis

A disease of horses in Asia, caused by the migrating larvae of the roundworm *Setaria equina*. (See ROUNDWORMS.)

Epizootic Haemorrhagic Disease

An infection of deer but also cattle and sheep caused by an ORBIVIRUS and transmitted by arthopods (see MIDGES, BITING) probably mainly *Culicoides* spp. The virus is closely related to BLUETONGUE virus. Animals become weak, recumbent, sometimes with bloody diarrhoea, and die.

Epizootic Lymphangitis

A chronic contagious NOTIFIABLE DISEASE disease of the horse family (Equidae). The cause is a fungus, *Histoplasma farciminosum*, formerly called Cryptococcus farciminosum. Rare cases have been recorded in cattle, and also in man.

Distribution It occurs widely in Asia, in Africa, and has also been described in America.

Cause A fungus, *Histoplasma* (*Cryptococcus*) *farciminosum*, which gains entry into the body through a wound, either on the skin or on a mucous surface. The disease is spread by flies, grooming tools, or by any materials which have come into contact with diseased animals or their infective discharges, such as cloths, sponges, and even pails of antiseptic solution.

VetBooks.ir

Incubation period Under natural conditions at least one month, but more commonly three or more, may elapse from the time of contamination of a wound till the onset of the signs.

Signs Initial signs of the disease are often thickenings or 'cording' of a lymphatic vessel and the enlargement of the adjacent lymph nodes. A fore-limb is usually the site of the lesions, which include granulomas, nodules which discharge a creamy pus and ulcerate. Ulcers may form on the mucous membrane of the nose; occasionally on vulva or scrotum.

The disease, which runs a slow course lasting weeks or months, has to be differentiated from GLANDERS. A few horses recover.

Treatment In the UK this is not allowed.

Epizootic Pulmonary Adenomatosis

(See under JAAGSIEKTE.)

Epizootic Rabbit Enteritis

A disease of commercial rabbiteries in which affected animals show distension of the gastro-intestinal tract and profuse watery diarrhoea.

Eprinomectin

An avermectin anthelmintic administered as a pour-on treatment, primarily for endoparasites in cattle. It does not have a milk or meat withdrawal period after use.

Epsom Salts

(See LAXATIVES.) Epsom salts (magnesium sulphate) are also useful as a first-aid treatment of lead and carbolic acid poisoning.

EPTA

(See ELECTRIC PULSE TRAINING AIDS.)

Epulis

Epulis is a tumour of the gum; it often has a bony centre.

Equid

(See under EQUINE.)

Equine

Pertaining to the horse.

Equine Back Lesions

(See HORSES, BACK TROUBLES IN.)

Equine Biliary Fever

This disease is caused by two distinct parasites: *Babesia caballi* and *B. equi*. The former species resembles *B. bigemina* in size and morphology, and causes a disease similar to Texas fever but which is milder and more amenable to treatment than that caused by *B. equi*. This is a smaller species than *B. caballi* and causes a disease which is highly virulent for adult horses and other species of the horse family, but is mild in young animals. Recovered animals are in a state of premunition, and inoculation of colts as a means of protection later in life is commonly practised.

Distribution The disease occurs in Russia and various parts of Europe, India, Africa, South America and South Africa.

Signs At the beginning of the disease there is a sharp rise in temperature to about 41.5° C (107° F). During this period the parasites are multiplying in the blood. In a few days the temperature falls and anaemia sets in. In the horse this is usually masked by an intense icterus, though not in the donkey and mule. Haemoglobinuria and constipation followed by diarrhoea, are frequent signs, and are succeeded by rapid emaciation. The animal may die during the initial fever (two to five days) or from anaemia and emaciation about the eleventh day or later. Complications are frequent.

Treatment Complete rest; an injection of a broad-spectrum antibiotic. IMIDOCARB DIPROPIONATE can be used.

Transmission In Southern Europe, *B. caballi* is transmitted by *Dermacentor reticulatus* and *D. silvarum*; in South Africa *B. equi* is transmitted by *Rhipicephalus evertsi* and *R. bursa*. Other species and genera of ticks probably act as vectors of *B. equi* in other countries.

Equine Blood Typing

Seven main blood groups are recognised in horses: A, C, D, K, P, Q and U. A further group, T, is listed by some authorities. There are numerous subgroups, or subtypes, some of which are important. For example, a mare which is Aa- must not be given blood that is Aa+ as this can lead to fetal haemocytolysis in subsequent pregnancies. For a first transfusion, blood need not be typed in an emergency as the horse rarely has natural isoantibodies. However, blood will have to be typed for any subsequent infusions; typing is also recommended if blood from a different breed is to be used. In theory, the Shetland pony is the best donor as it has the lowest level of alloantibodies Aa and Qa (which are the most antigenic) but because of its small size the blood volume that can be withdrawn is limited.

Accurate blood typing can be used to identify parentage but DNA 'fingerprinting' is more accurate.

VetBooks.ir

Equine Canker

A debilitating condition affecting the frog (where it usually starts), the bars and the surrounding hoof of horses with soft moist material. It is a chronic moist HYPERTROPHIC PODODERMATITIS. It results from bacterial or fungal infection in feet which are not kept properly cleaned and are kept on moist bedding or ground. The area tends to smell and causes discomfort and pain to the animal. Removal of all affected material is required to allow recovery (which is slow), together with localised routine use of ANTISEPTICS and ANTIBIOTICS.

Equine Coital Exanthema

A venereal disease of horses caused by a herpesvirus. (See table under HERPESVIRUSES.)

Equine Contagious Metritis

(See CONTAGIOUS EQUINE METRITIS.)

Equine Cushing's Disease

Now usually called PITUITARY PARS INTERMEDIA DYSFUNCTION (PPID). (See CUSHING'S SYNDROME.)

Equine Dysautonomia

(See GRASS SICKNESS.)

Equine Ehrlichiosis

(See POTOMAC HORSE FEVER.) The tentative name given to a transmissible disease of horses first recognised in California. The causal agent (*Neorickettsia risticii*) resembles that of tick-borne fever of cattle. Oedema of the extremities is a sign.

Equine Encephalitis

A virus disease occurring in North, Central and South America, Russia, the Far and Middle East. It affects horses, but chickens, pheasants, etc. act as a reservoir of infection. Man can be infected. Paralysis of the head and neck muscles is a feature. Mosquitoes transmit this disease, or group of diseases; the horse is an 'accidental' host. (See also BORNA DISEASE; NEAR EAST ENCEPHALITIS; VENEZUELAN EQUINE ENCEPHALOMYELITIS.) The viruses mainly responsible are the alphaviruses St Louis encephalitis (SLE), western equine encephalitis (WEE), and eastern equine encephalitis (EEE). In the Far East, the flavivirus Japanese encephalitis (JE) is the most important cause. Outbreaks usually follow a bird-mosquito cycle, with an occasional spill-over to mammalian hosts. SLE appears in humans, and WEE/EEE appear in both humans and horses. Rodents may be affected, too. The infections cannot be differentiated on clinical grounds; laboratory tests are essential. (For signs, see under ENCEPHALITIS.)

Control Mosquito control measures reduce transmission of the disease; stabling horses during outbreaks and applying insecticides can help prevent mosquito attacks. Vaccines are available for use in areas where the disease is prevalent.

Public health In man, the disease takes the form of an aseptic meningitis; outbreaks can be very serious, and mortality can be high. In one outbreak in Canada, 509 human cases were reported, with 78 deaths; 12 of them among children. Of 27 infants, many suffered brain damage, resulting in convulsions, spasticity, and hemiplegia.

Equine Filariasis

Infestation of horses with the filarid worm, *Setaria equina*, the larvae being carried by mosquitoes and biting flies. It occurs in South and Central Europe, and Asia.

Signs Malaise and anaemia, or fever, conjunctivitis, and dropsical swellings.

Equine Gait Analysis

A combination of photographic recording and computer analysis is used to study the motion of the horse's limbs as it trots or gallops on a treadmill. The system was originally devised by a Swiss, Bruno Kaegi. It helps to provide an objective measurement of the degree of lameness affecting a horse, and also a comparison between the limbs.

Equine Genital Infections in the Mare

A wide range of organisms may be found on taking cervical swabs. Some may be harmless, but others may cause abortion or disease in the mare or transmit infection to the stallion.

CONTAGIOUS EQUINE METRITIS (CEM), a NOTIFIABLE DISEASE, is an important uterine infection described in a separate entry. It is caused by *Taylorella equigenitalis*.

Other infections include beta haemolytic streptococci, *Klebsiella aerogenes*, *Pseudomonas* species (see also LISTERIOSIS; LEPTOSPIROSIS; BRUCELLOSIS). Fungal infections have rarely been reported, and include *Aspergillus fumigatus* and *Candida albicans*.

Abortion caused by the virus of equine rhinopneumonitis has also occurred in the UK for several years, most outbreaks being associated with imported or visiting mares.

Equine Herpesviruses

These include EHV1, the equine rhinopneumonitis or 'equine abortion' virus which has also caused ataxia and paresis. The one affecting the respiratory system is EHV4. EHV2 and EHV5 have both been implicated in keratoconjunctivitis.

Equine Hydatid Disease

(See HYDATID DISEASE.)

Equine Hyperlipaemia

A very serious disease of small ponies and donkeys with a high mortality if not treated early enough. The predisposing factors are an obese animal that stops eating initiating a mobilisation of body fat which damages the liver. Blood testing for triglyceride levels will give an estimate of the seriousness of the condition. Fat in serious cases can be seen in the blood with the naked eye. Every effort must be made to start the animal eating. Severe cases require intravenous glucose.

Equine Infectious Anaemia

A NOTIFIABLE DISEASE. Synonyms include: pernicious equine anaemia, swamp fever, horse malaria.

A contagious disease of horses and mules during the course of which changes occur in the blood, and rapid emaciation with debility and prostration are evident. It occurs chiefly in the Western States of America and the North-Western Provinces of Canada, as well as in most countries of Europe, and in Asia and Africa. The first case in the UK was reported from Newmarket in 1975.

Cause A virus. The horse is commonly infected by biting insects, e.g. horse flies, stable flies, mosquitoes. Infected grooming tools if they cause an abrasion, syringes, hypodermic needles (or even contaminated vaccines) are other means of transmission. The virus may be present in urine, faeces, saliva, nasal secretions, semen and milk.

The disease is prevalent in low-lying, swampy areas, especially during spring and summer months.

The virus may cause illness in man (who may infect a horse); also in pigs.

Signs After an incubation period of two to four weeks, equine infectious anaemia gives rise to intermittent fever (with a temperature of up to 41° C [106° F]), depression and weakness. Often there are tiny haemorrhages on the lining of the eyelids and under the tongue. Jaundice, swelling of the legs and lower part of the abdomen, and anaemia may follow. In acute cases, death is common. In chronic cases there may be a recurrence of fever, loss of appetite and emaciation.

About 50 per cent of horses in a stud or stable may become ill with this disease, and the mortality rate can vary between 30 and 70 per cent.

Some horses do not show signs but become latent carriers of the infection, passing it on to others.

No treatment has so far been proved to be effective, and recovered animals become carriers. Vaccines are ineffective.

Diagnosis may be confirmed by the agar gel immunodiffusion precipitation (Coggins) test. Horses imported into the UK from the USA must have passed this test with a negative result. Equine infectious anaemia may be confused with other infections including trypanosomiasis, anthrax, equine rhinopneumonitis abortion, African horse sickness, the equine encephalitides, leptospirosis and piroplasmosis.

Control Where possible, test the animals and slaughter reactors in order to eradicate the disease.

Equine Influenza

A common and highly infectious disease of horses. Provided that the animals have not been worked while ill, mortality from influenza is usually nil, except in foals infected during the first few days of life. There is a danger in referring to equine influenza as 'The Cough' or 'Newmarket Cough' if those colloquialisms give rise to the idea that it is only a cough and not an illness. Owners should appreciate that influenza viruses need to be treated with respect; also that there are many other causes of coughing in horses. (See COUGHING.)

Cause Viruses of the family Orthomyxoviridiae type A. A virus was first isolated in Prague in 1957; one of a similar type was isolated in the 1963 outbreak in Britain, and is now known as A/Equi/l. Also referred to as the 'Cambridge strain', it was found as well in the USA. In the 1963 outbreak in the USA another virus, believed to have come from South America, was isolated. This is called A/Equi/2 or the 'Miami strain'. This virus appeared in Britain for the first time in the 1965 outbreak.

A strain of equine influenza virus – influenza/A/equine/Jilin (China) 1/89 – identified in the USA caused up to 20 per cent mortality in some herds. (See EQUINE RESPIRATORY VIRUSES.)

Signs The temperature rises to a degree or two above normal, or even as high as 41° C (106° F). Often the first sign observed by the owner is the cough, initially of a dry type but later becoming moist. Coughing may last for one week, or persist for three weeks. In mild cases there may be virtually no other signs and – if rested – the horse makes an uneventful recovery.

In less mild cases the animal has a dejected appearance and very little appetite. Sometimes there is probably pain in the muscles, for the horse may show difficulty or clumsiness in lying down and getting up, or may appear stiff.

A foal born to a mare during an attack of influenza, or as the first signs are beginning to appear, will appear normal for four or five days; but then the temperature rises to 40.5° C (105° F)

VetBooks.ir

VetBooks.ir

or more, the foal ceases to feed, and within a couple of days its breathing becomes very laboured. Death can be expected when the foal is about nine or 10 days old.

Treatment First-aid measures call for rest, warmth and, if appetite fails, several small feeds a day. Professional advice should always be obtained. Antibiotics may be used in order to prevent any complications caused by bacteria.

When the disease has already appeared in a stable, it is wise to rely upon the thermometer rather than the cough as the first sign of infection in a horse. The temperature may occur up to 12 hours before coughing starts, and if the fever is detected early the animal can be rested with all the greater chances of the influenza remaining mild.

Prevention Vaccines prepared from a mixture of virus strains are available. It is recommended that foals born to vaccinated mares are vaccinated after five months of age. In-foal mares should be vaccinated at least three weeks before they foal. Horses should be vaccinated three weeks before they go to sales, etc., where they are likely to be exposed to infection. Horses entering a property or competing under the rules of the Jockey Club or Fédération Equine International must be vaccinated according to the manufacturer's instructions, certificated by a veterinarian and identified by a 'passport'. Newcomers to a stable, especially two- or three-year-olds, should also be vaccinated. Immunity is developed in 98 per cent of vaccinated animals within two to three weeks, and should last for about a year. Regular booster doses are essential.

Some apparent 'breakdowns' in horses vaccinated against equine influenza may be due to the fact that some outbreaks of coughing are due to other infections, e.g. rhinopneumonitis.

Equine Lymphosarcoma

In cases involving the thoracic cavity, clinical signs may include dysphagia, inappetence, weight loss, pectoral oedema, dyspnoea, pleural effusion and distension of the jugular veins and chronic diarrhoea is seen in the alimentary form. Post-mortem examination may disclose MILIARY lesions in the chest and throughout the intestines.

Equine Metabolic Syndrome (EMS)

A concept developed in 21st century concerning horses and ponies becoming overweight and more susceptible to other problems such as LAMINITIS. The animals have HYPERINSULINAEMIA and are insulin resistant. Diets with restricted calories, low non-structural carbohydrates, high fibre, adequate proteins and micronutrients will reduce weight, and can be used with regular weighing. Collapsible, portable weighbridges can be used and some fit in vans, estate cars, etc. (See also HORSES, FEEDING OF; OBESITY, OVERWEIGHT ANIMALS.)

Equine Motor Neuron Disease (EMND)

This was first recognised in 1990. A suspected case was seen in the UK in 1993. Of 45 confirmed cases of the disease, none had previously been reported outside North America.

Signs Weight loss over a six-week period, trembling, muscle atrophy, generalised weakness, head carried downwards and a short-strided gait.

Equine Myoglobinuria

(See EQUINE RHABDOMYOLYSIS.)

Equine Piroplasmosis

The virus is transmissible by both the respiratory and the venereal routes. (See EQUINE BILIARY FEVER.)

Equine Protozoal Myeloencephalitis

Caused by *Sarcocystis neurona* parasite, the life cycle has a final host of horses or opossum. Seen in North America, intermediate hosts include cats, raccoons, skunks and armadillos. It results in ataxia, weakness and spasticity. Treatment is by potentiated sulphonamides, and a vaccine has been used for prevention.

Equine Purpura Haemorrhagica (EPH)

(See PURPURA HAEMORRHAGICA.)

Equine Recurrent Uveitis (ERU)

(See PERIODIC OPHTHALMIA.)

Equine Respiratory Viruses

The table on page 287 shows the viruses known to cause disease of the horse's respiratory system.

Equine Rhabdomyolysis, Equine Myoglobinuria, Azoturia

Equine rhabdomyolysis (also previously called equine myoglobinuria or azoturia) is seldom seen in horses under four years old.

Cause When horses that have been in continuous work are suddenly rested for a few days, fed very well meanwhile, and then returned to work or exercise, there is a risk of azoturia.

It has been suggested that the cause is an accumulation of glycogen in muscle, liberating excessive amounts of lactic acid during exercise.

Equine respiratory viruses

Virus Classification	Virus	Disease produced
Myxovirus	Myxovirus influenzae A/equi 1 Myxovirus influenzae A/equi 2	Equine influenza
Picornavirus	Rhinovirus 1 Rhinovirus 2	Rhinitis; pharyngitis
Herpesvirus	Equine herpesvirus 1 and 4	Rhinopneumonitis; viral abortion
	Equine herpesviruses 2, 3, etc. ("Slow growing herpesviruses"; "Cytomegaloviruses")	Pathogenicity uncertain; often present in the respiratory tract
Adenovirus	Adenovirus	Pneumonia and acute respiratory illness; enteritis
Paramyxovirus	Parainfluenza virus; Morbillivirus; Pneumovirus	Acute upper respiratory infection; canine distemper; rinderpest; respiratory disease
Coronavirus	Infectious bronchitis-like agent	Acute upper respiratory infection, enteritis, etc.
Orbivirus	African horse sickness virus	African horse sickness; bluetongue
Pestivirus	Equine arteritis virus; BVD virus; Border disease virus	Equine viral arteritis; bovine viral diarrhoea/ mucosal disease; border disease

VetBooks.ir

Signs The hind-limbs suddenly become stiff and weak or staggering, and there is a tendency to 'knuckle-over' at the fetlocks. The muscles of the hindquarters become tense, hard, and often painful. They feel like wood to the hand. Colicky signs are observed in some cases, but these pass off after a short time. The urine is a wine-red or coffee colour. In some cases the urine is retained, and it is necessary to relieve the bladder by the passage of a catheter. The temperature is generally elevated in severe cases, but seldom reaches more than 40° C (104° F).

The horse should be rested at once when the stiffness is noticed and placed in a loose-box for preference with plenty of bedding, and kept warm.

If the horse has to be taken home, this should be done by horse box. **If the horse is walked for any distance, a fatal outcome is likely.**

Treatment An antihistamine or cortisone may be used in treatment; the application of hot packs, etc., to the loins and over the hard muscles, gives relief. A well bedded and ideally padded box should be used; isotonic fluids reduce kidney problems. An analgesic (NSAID; OPIOIDS); VITAMIN E; METRONIDAZOLE all may be used in treatment. Carbohydrate-based feeds, GLUCOSE orally or by injection and OXYGEN can all help.

Prevention When horses are not working they should be exercised and have their concentrate diet restricted.

Atypical equine myoglobinuria This syndrome affects mostly horses at grass. (Compare above.) There is a sudden onset of stiffness unrelated to exercise. Affected horses or ponies are reluctant to move, and many become recumbent; some die. Consumption of red maple leaves (North America) or sycamore leaves (UK) is a cause of death. Appetite is not lost and water is drunk. Pulse and respiration rates also remain normal as a rule. Dark chocolate-coloured or red urine is passed.

Equine Sarcoid

(See 'SARCOID'.)

Equine Verminous Arteritis

This is a swelling of the cranial mesenteric artery, commonly encountered in horses, and resulting from thickening and fibrosis of the arterial wall due to the effects of migrating strongyle worm larvae. Thrombosis and embolism may follow the stenosis, or reduced lumen, of the artery. Infarction and ischaemia of the bowel may result. Rupture of the artery at this site is very rare indeed. (The term 'verminous aneurysm', which persisted in the veterinary literature until the late 1970s, or beyond, is a misnomer.)

Signs often occur during or shortly after work and include the sudden onset of abdominal pain, fever, flaring of the nostrils, a pulse rate of 70–80, and turning the head towards the right flank. Following recovery from one attack, abdominal pain may return at frequent intervals over weeks or months. The horse may become bad-tempered, be unwilling to back or turn in a small circle, may remain recumbent for long periods, and may hesitate before jumping.

Prevention Dosing with a suitable anthelmintic, such as ivermectin paste, kills the larvae responsible for the condition.

Equine Viral Arteritis (EVA)

This is a highly contagious NOTIFIABLE DISEASE caused by an RNA virus, in which damage is caused to the arteries, especially the smaller ones. The disease may be transmitted from acutely

infected animals through the breath, or venereally in the semen of chronically infected stallions.

Signs include fever, conjunctivitis, oedema of the lungs and also affecting the legs and other parts of the body. Haemorrhagic enteritis, with abdominal pain and diarrhoea, may occur. Over 50 per cent of pregnant mares abort. Horses which recover are likely to become carriers. A vaccine is available. (See HORSES, IMPORT CONTROLS.)

VetBooks.ir

Equine Viral Enteritis

This is an acute contagious disease caused by the virus responsible for EQUINE VIRAL ARTERITIS.

Equine Viral Rhinopneumonitis

A disease caused by the equine herpesviruses 1 and 4. (See EQUINE RESPIRATORY VIRUSES.)

Signs include slight fever, cough and nasal discharge. These are seen in weaned foals and yearlings, though some infections are subclinical. In the mare, abortion, often after the gestation period has passed the 8th month, may sometimes result – hence its alternative name of 'equine virus abortion'. Indeed the term 'abortion storms' has been used, since 40 to 60 per cent (or even more) of the mares in a stud may abort. Usually such an occurrence is a sequel to an outbreak of severe and extensive nasal catarrh when the in-foal mares were between 0.5 and seven months pregnant. It must be emphasised, however, that these 'abortion storms' are exceptional, and have become more so, in recent years.

When abortion has occurred, subsequent foaling is nearly always normal.

The virus is present in the aborted fetus, fluids and membranes. It cannot survive more than a fortnight in the absence of horse tissue. On straw, concrete floors, etc. it dies within a week, but when dried on to horse hairs it has been shown to be infective for up to 6 weeks. The stallion is not, it is believed, involved in the spread of the disease, which was first reported in the UK in 1961.

Cases of acute paresis and paralysis in horses have been attributed to this virus.

Equisetum Poisoning

(See HORSE-TAILS, POISONING BY.)

Ergometrine

Ergometrine is the most powerful of the active constituents of ergot in producing muscular contractions of the uterus. It is used to stimulate a sluggish uterus during parturition and to control uterine haemorrhage following parturition.

Ergot

Ergot is the small mass of horn which is found amongst the tuft of hair which grows from the back of the fetlocks of horses. It is produced by cells which are similar to those which form the horn of the hoof.

Ergot, Fungal

There are several species of ergot, including *Claviceps fusiformis*, which infests the bulrush millet, and *C. purpurea*, which is a parasite of rye and other cereals such as maize.

Ergot of Munga

Ergot of munga, the bulrush millet, is in southern Africa an important cause of loss to the pig industry. The sow's udder fails to enlarge and does not become functional; piglet mortality is heavy as a result of the absence of milk (agalactia). Sows show no other signs of ill health. The alkaloidal composition of this ergot, *Claviceps fusiformis*, is believed to differ from that of *Claviceps purpurea*.

Ergot of Rye

Ergot of rye is a fungus which attacks the seed of rye or other cereal, subsists upon it, and finally replaces it. The fungus is called *Claviceps purpurea*, and is artificially cultivated on account of its medicinal properties. Its medicinal preparations are used to stimulate the wall of the uterus during parturition when there is inertia (in both humans and animals), and are also useful for checking haemorrhage by causing constriction of the arterioles. The crude ergot is unsafe to use.

Ergot Poisoning

Ergot poisoning occurs through eating cereals upon which the fungus is parasitic, such as rye and various kinds of maize, etc., and through taking foods made from affected plants (e.g. maize meals). Extensive outbreaks have occurred in various parts of the USA, in Germany, Austria and other parts of Europe. Abortion and gangrene of the extremities in cattle have been seen in Britain.

Signs The characteristic feature of poisoning due to *Claviceps purpurea* is that there is irritation and pain in the extremities of the body. Later, areas of the skin of these parts become gangrenous, and may slough off.

Two forms are recognised: in the first, convulsive signs due to stimulation of the nervous system are seen; and in the second, gangrene occurs.

Horses that have eaten large amounts of ergotised hay develop signs during the first 24 hours after feeding. The animal becomes dull and listless, a cold sweat breaks out on the neck and flanks, the breathing is slow and deep, the temperature is below normal, the pulse is weak and finally imperceptible, and death occurs during deep coma. When lesser amounts have been taken

over a longer period there may be diarrhoea, colic, vomiting and signs of abdominal pain. Pregnant animals may abort and lose condition.

Trembling, general muscular spasms, loss of sensation of the extremities, convulsions and delirium may be seen.

In the gangrenous form there is coldness of the feet, ears, lips, tail, combs and wattles of birds, and other extremities, a loss of sensation in these parts, and eventually dry gangrene sets in. After a day or two the hair falls out, teeth drop out, the tips of the ears and tail may slough off, and the skin of the limbs, or even the whole of the feet, may be cast off. Death occurs from exhaustion or septicaemia.

Ergot-contaminated feed may result in reduced fertility and agalactia in the sow. (See also under ERGOT OF MUNGA.)

Eriskay Ponies

These ponies originate in the Hebrides in North Scotland. They are now a rare breed, but a few enthusiasts are trying to keep the breed surviving. They are usually grey in colour.

'Eroded Mouth Syndrome'

(See FLEXIBACTERIOSIS IN FISH.)

ERV

Abbreviation of EQUINE RECURRENT UVEITIS. (See PERIODIC OPHTHALMIA.)

Erysipelas, Swine

(See SWINE ERYSIPELAS.)

Erysipeloid

Human infection with *Erysipelothrix rhusiopathiae*, the cause of swine erysipelas.

Erythema

Erythema is a redness of the skin, the surface blood vessels of which become gorged with blood.

Erythroblast

(See NORMOBLAST.)

Erythrocyte

An erythrocyte is a red blood cell. Their shape differs in different species. In mammals, erythrocytes are devoid of a nucleus; their role is simply the transportation of oxygen and carbon dioxide. In birds and reptiles the erythrocyte is larger, contains a nucleus and, in severe infections, it is capable of PHAGOCYTOSIS.

Erythrocyte Mosaicism

The mixture of two blood types in each of non-identical twins.

Erythroleucosis

This is a transmissible virus-associated type of cancer occurring in poultry. It is associated with the fowl paralysis group of diseases. It was described and named in 1908, three years before the Rous sarcoma made history. (See under LEUKOSIS COMPLEX.)

Erythromycin

An antibiotic which has a bacteriostatic action against Gram-positive organisms. It is used when penicillin-susceptible strains have developed resistance. It is administered by mouth, in drinking water or feed to poultry and farm animals, and by tablets to dogs, cats and foals.

Erythropoiesis

The formation of red blood cells in the bone marrow, stimulated by the hormone erythropoietin secreted by the kidneys.

ESBL

(See EXTENDED-SPECTRUM BETA-LACTAMASE.)

Eschar

Eschar is an area of body tissue that has been killed by heat or by caustics.

Escherichia coli

This is the modern name for *Bacillus coli*. (See *E. Coli*.)

Escutcheon

The anal region of an ox, with special reference to the direction of growth of hair.

Essex Saddleback Pigs

The old breed with a black skin except for clear band of white over the shoulders and forelegs with white feet and a tip of the tail. It is now combined with the WESSEX SADDLEBACK to form the BRITISH SADDLEBACK.

Ester

A compound formed from an alcohol and an acid by elimination of water, e.g. ethyl acetate.

Estradiol and Estrone

Estradiol and estrone (oestradiol and oestrone) are hormones secreted by the ovary (interstitial cells and Graafian follicles) which bring about oestrus and, in late pregnancy, stimulate development of the mammary gland.

Estrela Mountain Dogs

Originating in Portugal, these dogs are showing increased registrations in Britain. They have a thick slightly coarse straight or wavy fawn, grey or yellow coat resembling goat hair with a dense undercoat. They are 60 cm to 72.5 cm (24 in to 29

VetBooks.ir

in) to the shoulder and males weigh 40 kg to 50 kg (88 lb to 110 lb) and females 30 kg to 40 kg (66 lb to 88 lb).

Estrin
American spelling of OESTRIN.

Estriol
American spelling of OESTRIOL.

Estrogens
American spelling of OESTROGENS.

Estrumate
A proprietary name for the prostaglandin analogue cloprostenol. (See CLOPROSTENOL; CONTROLLED BREEDING.)

Estrus
American spelling of OESTRUS.

Etamiphylline Camsylate
Etamiphylline camsylate is a smooth-muscle relaxant and cardiac and respiratory stimulant. It is used in the treatment of neonatal weakness in calves and lambs when this is associated with cardiac and respiratory distress after dystocia or caesarian section. In dogs, cats and horses it is also used as an aid in the management of coughing.

Ethanol
(See ETHYL ALCOHOL.)

Ether
A volatile liquid formerly widely used as an anaesthetic. It forms an explosive mixture with oxygen, and precautions to avoid electrical or other sparks must be strictly adhered to.

Ethidium Bromide
A trypanocide given by intra-muscular injection. This drug is also used in the treatment of 'heather blindness' (contagious ophthalmia) in sheep, and of bovine keratitis.

Ethmoid
Ethmoid is a bone which separates the nasal cavity from that of the brain. It is spongy in nature and contains numerous cavities, some of which communicate with the nose and serve to carry the nerves of the sense of smell.

Ethology
The study of the behaviour of animals in their normal environment. Applied ethology is an important aspect of animal welfare, and includes experiments to determine animals' preferences and also their reactions to farming practices.

Ethyl Alcohol, Ethanol
The name given to alcohol, a volatile, inflammable liquid. Poisoning can occur in dogs, cats and birds. (See ALCOHOL POISONING.)

Ethyl Chloride
Ethyl chloride is a clear, colourless liquid, produced by the action of hydrochloric acid upon alcohol. Extremely volatile, it rapidly produces freezing of the surface of the skin when sprayed upon it. It is used to produce insensibility for short surface operations, such as the removal of warts or small tumours, the lancing of painful abscesses, the removal of thorns or foreign bodies, etc. It is packaged in a glass or metal tube provided with a fine nozzle.

Ethylene
Ethylene is a colourless inflammable gas which is sometimes used as an anaesthetic in small animals. Ethylene glycol, the antifreeze used for cars, is highly poisonous for dogs and cats. (See ANTIFREEZE.)

Ethylstrenol
This is derived from testosterone and is used in dogs and cats as a supportive treatment in chronic renal failure, where response maybe variable. It must not be given to pregnant animals.

Etiology
Etiology is the American spelling of AETIOLOGY, the study of the cause(s) of disease.

Etorphine
(See IMMOBILON.)

EU
(See EUROPEAN UNION.)

Eubacterium suis
Also known as *Corynebacterium suis,* it is a cause of cystitis and pyelonephritis in pigs.

European Bat Lyssa Virus (EBLV)
(See LYSSA VIRUS IN BATS.)

European Brown Hare Syndrome
This has been reported from several EU countries including the UK. It has been suggested that affected hares could be carriers of GRASS SICKNESS.

Cause Picorna-like virus particles have been isolated in the UK.

Signs Dullness, loss of fear of people, and nervous disorders such as ataxia. The death rate has been high.

VetBooks.ir

European Food Safety Authority (EFSA)

The European authority concerned with risk assessment on food and feed safety. It provides independent scientific advice on existing and emerging risks. It was set up in January 2002. Address: European Food Safety Authority, Largo N. Palli 5/A, 43121, Palma, Italy. Telephone: 0039 0521 036111; website: www.efsa.europa.eu.

European Union (EU)

Originally called the European Economic Community (EEC), created by the Treaty of Rome in 1957, with six Member States, it subsequently became known as the European Community (EC). The UK became a member in 1973. In 1992, in Maastricht, the Member States signed the Treaty on European Union. By 2014, the number of Member States was 28 with 17 adopting the single European common currency, the Euro. The aim has been to allow the free movement of animals, animal products and other goods between Member States.

EU legislation is mainly in the form of Directives or Regulations. A Directive requires each Member State to introduce a law that will meet the requirements of the Directive. A Regulation becomes legally binding without further action. Laws are mainly produced by the Council of Ministers and the European Parliament. The Ministers are the appropriate government ministers in matters concerning animals and food. In the UK it is the Secretary of State of the Department for Environment, Food and Rural Affairs (DEFRA); for laboratory animal use it is the Home Secretary.

EU legislation on animal medicines, intended primarily to minimise drug residues in food animals, has created some problems, for example, when a veterinarian needs to prescribe a medicine authorised only for humans for treatment of small animals or equines.

It is sometimes possible to obtain derogations from some legislation. For example, EU regulations treat the horse as a food animal, whereas in the UK the horse is not primarily considered a food animal.

Other legislation enables the European Commission to ban exports from a Member State where a significant NOTIFIABLE DISEASE (e.g. foot-and-mouth disease) occurs. The 28 EU Member States in 2014 were: Austria, Belgium, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden and the United Kingdom.

Euryblepharon

A large slit in the eyelid (palpebral fissure) seen mostly in BRACHYCEPHALIC dogs and also in the CLUMBER SPANIEL, NEOPOLITAN MASTIFF.

Eurytrema

A fluke. (See PANCREAS, DISEASES OF.)

Eustachian Tubes

Eustachian tubes are the passages, one on each side, which lead from the throat to the middle ear, and serve to maintain an even atmospheric pressure upon the inner surface of the 'ear-drum' or tympanum. They open widely in the act of swallowing, and during a yawn. Each has a sac or diverticulum connected with it in the horse, and in certain conditions these become filled with pus from a strangles abscess or from some other suppurating source near, when an operation becomes necessary to evacuate the pus and prevent it doing damage by burrowing into the middle ear or surrounding parts. (See EAR.)

Euthanasia

As applied to animals, this is a means of producing death free from ante-mortem fear or suffering. The term mainly applies to dogs and cats and other pets which must be put to death because of an incurable or painful condition, or because of severe persistent behavioural problems. The decision to euthanase an animal is not to be taken lightly and the informed consent of the owner should be obtained in writing wherever possible.

Strictly speaking, the humane slaughtering of animals for food purposes, and the humane destruction of horses or other animals kept for working purposes, should also fall within the meaning of the word.

Small animals An injection of an overdose of a barbiturate, usually pentobarbitone given by rapid intravenous injection, is the method preferred by most veterinarians. The method is painless; the animal quickly loses consciousness and death occurs by depression of the respiratory and vasomotor centres of the brain. Sometimes sedatives are administered first, especially in pet rabbits.

Minimising stress for the animal and owner is an important part of satisfactory euthanasia.

Horses and cattle are sometimes killed by barbiturate injection where other means are unavailable or inappropriate. A combination of quinalbarbitone and cinchocaine (Somulose; Arnolds) is said to produce rapid heart arrest thus avoiding the gasping which barbiturates alone may produce. The carcases should not be used for food. Hunting dogs and carnivores in zoos fed on meat from animals killed by barbiturate have been poisoned as a result.

Captive-bolt pistol Correctly used, this type of 'humane killer' can be a valuable means of

VetBooks.ir

euthanasia for farm animals. Generally it should not be used in lambs, kids or piglets under eight weeks old as the bolt penetrates the soft skull bruising, but not necessarily stunning or killing, the animal.

The following advice may be useful for animal-owners or others in remote places where no veterinarian is available and who have to shoot an animal.

For cattle, the point aimed at is **not** in the middle of the forehead, between the eyes; a shot so placed passes into the nasal chambers or air sinuses, down into the mouth and throat, and misses the important vital centres. The correct spot is higher up than this. Two imaginary lines should be drawn, each running from one eye to the opposite ear across the front of the forehead, and the point of their intersection is the most vital spot. A shot aimed about parallel with the ground and directed at this spot enters the brain cavity, destroys the brain and the beginning of the spinal cord, and passes on into the neck, where its energy is expended. Otherwise, if for some reason this part is not accessible, the next best place to aim at is the base of one ear, the direction being again parallel with the ground. In the case of horned cattle, the presence of the horn may deflect the shot, and it is better to shoot into the base of the brain from behind, directing the charge downwards and forwards. When pigs have to be shot, the middle line of the head is not altogether the best place, because there is a strong crest of bone running downwards in this position; the shot should be placed a little above and a little nearer the centre of the skull than the eye. For dogs and cats the centre of the forehead should be aimed at, for in these animals the brain is of relatively larger size, and more easily accessible. Horses should only be destroyed with a captive-bolt pistol if they are already on the ground. If they are standing there is a danger of damage to the wrist of the veterinarian if the horse falls suddenly.

Humane Pistol Horses should be destroyed with a humane pistol with a free-bullet to avoid problems with a captive-bolt. Such a firearm requires the owner to have a firearms certificate. If such a weapon is used in a public place, great care must be taken to avoid injury to bystanders and the weapon must have a silencer.

Horses with Tetanus Veterinarians should avoid standing directly in front of a horse with tetanus. Such horses will not drop straight down as normal but they will lurch forward dying in tetanic spasm.

Shotgun May be used to kill animals humanely if the gun is held within 1 m (3 ft) of the head and no closer than 3 inch (7.5 cm) to avoid damage to the gun barrel and pointed as for a captive-bolt pistol. The shot will emerge from the gun in a tight cluster, penetrate the skull and disperse within the cranial cavity, destroying the brain in the process. Veterinarians can use a shotgun belonging to another party provided the other party has a valid shotgun licence and gives their permission. Veterinarians are *not* allowed to use a firearm unless they personally have a valid firearms licence for that firearm.

Electrocution is used to stun or kill poultry, pigs and sheep in abattoirs.

Cervical dislocation by a sharp blow to the back of the neck is, **in expert hands**, the quickest way of stopping brain function in small animals that are easily handled, such as rabbits and poultry.

A number of other methods, including gassing by carbon dioxide, are used on occasion. For further information about euthanasia, particularly of fish and of exotic species, the *Humane Killing of Animals*, published by the Universities Federation for Animal Welfare is very useful.

EVA

(See EQUINE VIRAL ARTERITIS.)

Evening Primrose

The oil derived from this plant is a source of gamma-linoleic acid, an essential fatty acid. Administered orally, it is used, alone or in combination with fish oils or sunflower oil, in treating allergic skin conditions in dogs and cats and improving coat condition. Tablets, capsules, powder or liquid preparations are available

Evidence-Based Medicine (EBM)

This is the conscientious, explicit and judicious use of current best evidence from research for the care of an animal. It was introduced as a concept in human medicine in the 1990s and in veterinary medicine in the 2000s.

Evidence-Based Veterinary Medicine (EBVM)

A method of using clinical evidence and reporting to amass information concerning disease and its treatment.

Exanthemata

(See under VESICULAR EXANTHEMA; EQUINE COITAL EXANTHEMA.)

Exchange Transfusion

(See BLOOD TRANSFUSIONS.)

Excipient

Excipient means any more or less inert substance added to a prescription in order to make the remedy more suitable in bulk, consistency, or form for administration.

VetBooks.ir

Exencephaly
An absence of a cranium, partial or complete, with exposure of membranes and brain substance.

Exercise
Exercise is a matter of great importance in the preservation of health. It is obvious that the methods of domestication, which have made such enormous modifications in the characteristics of horses, cattle, sheep, pigs and dogs, have also so altered their modes of life that exercise is a matter over which they themselves often have no control. Lack of sufficient exercise is most serious in young animals, especially calves, pigs and puppies. They do not grow and develop as they should.

Females of all species must have regular exercise during pregnancy otherwise the tone of the uterine wall and other muscles of the body is lost, and there is a risk of trouble occurring at parturition.

Over-exercise, especially if an animal is not in a fit condition, is, on the other hand, equally bad. Efforts beyond the animal's strength are apt to bring about dilatation of the heart, or lead to exhaustion; even, rarely, to death if a horse is taken out hunting when unfit.

Heavy draught horses should get a short walk for 10 to 15 minutes twice daily when standing idle, or they may be turned out into a paddock or yard for the greater part of the day. Cattle tied up in stalls should receive a minimum of 10 to 20 minutes' exercise out of doors twice daily. Breeding sows and boars kept in pig-houses where space is limited always thrive better when allowed into a yard for some part of the day, or when allowed into a paddock to graze. House-dogs need different amounts of exercise according to their breeds and ages. Young dogs of the sporting breeds never do well unless they receive at least one hour's sharp walk morning and night when on the leash, or about half this period when allowed to range at liberty. Older dogs and those of pet breeds need less, but generally speaking, the more exercise the dog gets the better health it will enjoy. (See also SHEEPDOGS; MUSCLE — Condition.)

Exercise-Induced Collapse
An inherited sign seen in some breeds of dog which collapse during hard exercise (after five to 20 minutes) usually from seven months to two years, but are otherwise well. Very occasionally dogs die during or soon after an episode. It occurs in RETRIEVERS (CHESAPEAKE BAY, curly coated LABRADOR) (DNA tests available).

Exercising Horses
Horses must be gradually introduced to exercise or work, because over-exertion of an unfit or of a partly fit horse may have serious and permanent consequences. To get a riding horse fit it is usual to begin with daily walking exercise, with only an occasional trot for the first month or so. As the horse becomes fitter the duration of the exercise is lengthened, and the animal is made to walk, then given a sharp trot or a short gallop, and finally another walk home each day for a further 2 to 4 weeks. From this stage it proceeds to one when the gallop is of longer duration on alternate days, and then, later, the horse gets a stiff gallop every day for perhaps half an hour or so. In some stables there is a system of morning and afternoon exercise for each horse, but much must be left to the individual requirement of each animal, and to the judgement of the trainer. After a time, varying up to 4 months or more in some cases, the horse arrives at its maximum pitch of perfection, and then begins to 'go stale'. The art of the race-horse trainer enables him to judge the length of time it takes for each individual horse to arrive at his best at such a time as will allow him to enter for the race for which he is being trained. Every horse-trainer has his own individual methods, and as these are by no means hard-and-fast rules, nothing more than the merest outline can be given here.

The 'condition' of a horse, by which is meant its capacity for doing work, cannot be retained indefinitely; there comes a time when it begins to perform less and less well, and is said to have 'gone stale'. This is an indication that a rest is required.

Overtraining in the racehorse This, and stress, are a common cause of poor performance, and could be regarded as a clinical entity. Affected horses appear to 'fade' at the end of a race. They also show signs of stress before racing. Once identified, such a horse should be exercised more slowly and gradually worked up to previous levels. (See also RACEHORSES.)

Exertional Rhabdomyolysis
(See EQUINE RHABDOMYOLYSIS; RHABDOMYOLYSIS.)

Exfoliation
The separation in layers or scales of dead bone or of skin.

Exmoor Horn Sheep
A breed of sheep whose predecessors roamed Exmoor in Devon, England for many centuries before being developed in the 19th century. It is a white-faced horned sheep well-suited to the hardy terrain of Exmoor and makes up about 10 per cent of the sheep population on the moor. The breed is used for wool and meat as well as being good mothers and relatively prolific.

VetBooks.ir

Exmoor Ponies
These are a distinct breed from the DARTMOOR but both breeds originate in Devon, England. They are semi-feral and are between 11 and 12.2 HANDS (1.1 m to 1.22 m) and are of any colour except PIEBALD or SKEWBALD.

Exocordia
A congenital abnormal positioning of the heart.

Exocrine
(See GLANDS.)

Exocrine Pancreatic Deficiency
A disease of dogs in which there is a reduced secretion of digestive enzymes from the pancreas. Affected animas show severe hunger, the passage of bulky, pasty faeces and COPROPHAGIA.

Exomphalos
An alternative term for an UMBILICAL HERNIA.

Exophthalmos, Exophthalmia (adjective, Exophthalmic)
An abnormal bulging of the eyeballs. In America it has been observed as a hereditary defect in certain Jersey cattle; and in Britain in certain Shorthorn herds – the condition being preceded by a squint. It is also seen in certain breeds of toy dogs. (See EYE, DISEASES AND INJURIES OF.)

Exoskeleton
An external hard framework which shapes the body of most invertebrates. These include the shells of crustaceans and the outside body of insects and arthropods. Occasionally it is used to describe the hair, hooves, teeth and claws of vertebrates.

Exostosis (plural, Exostoses)
An outgrowth from a bone. (See BONE, DISEASES OF.)

Exotoxins
Toxins which diffuse readily from the bodies of bacteria during their lifetime.

Expectant Medicine, Expectant Treatment
Treatment designed to alleviate untoward signs and then allowing 'nature to take its course'.

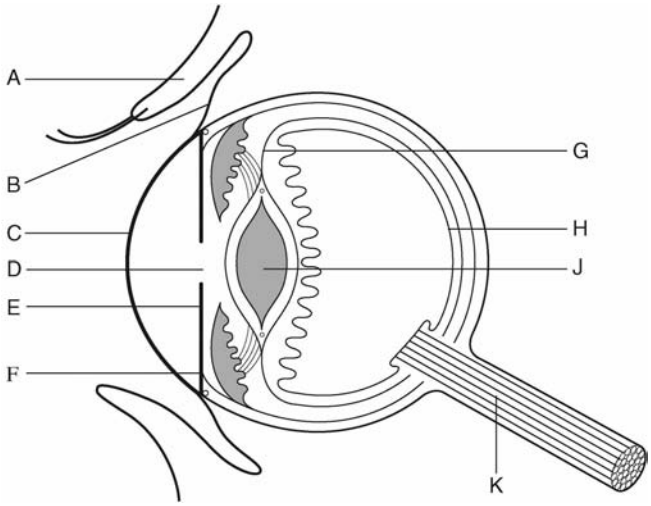
Expectorant
This promotes or is an agent promoting the coughing up and swallowing of mucus or other materials from the TRACHEA, BRONCHI and LUNGS. Agents include creosote, IPECAC and potassium iodide.

Expectoration
The coughing up and swallowing of mucus and other material from the TRACHEA, BRONCHI, and LUNGS.

Exploratory Laparotomy
A surgical opening of the abdomen to investigate a possible problem or examine one or more organs.

Explosive, Plastic (PE4) Poisoning
(See CYCLONITE POISONING; also DYNAMITE.)

Exporting Animals
(See IMPORTING/EXPORTING ANIMALS; BORDER INSPECTION POSTS; HORSES, IMPORT CONTROLS; BIRD IMPORT CONTROLS; LAWS; RABIES; QUARANTINE.)



Exposure
Exposure to intense cold can usually be well tolerated by the animal which is well fed. More food is required during very cold weather in order to maintain the body temperature. Windbreaks are important, but the tendency is for their number to decline in the interests of larger fields and units more suited to mechanisation. Animals denied shelter from very cold winds, and at the same time inadequately fed, are most liable to disease of one kind or another. (See also SHEARING; FROSTBITE; FEED BLOCKS; SHEEP BREEDING AND MANAGEMENT.)

Exsanguination
The loss of blood sufficient to cause death.

Extended-Spectrum Beta-Lactamase (ESBL)
These are enzymes produced by some bacteria which make them resistant to CEPHALOSPORIN ANTIBIOTICS. Whilst the bacteria are mainly seen in humans particularly in hospitals, they have been found in animals. They were originally found in KLEBSIELLA species, but now are common in some *E. Coli* (mainly CTX-M enzymes) and these can resist PENICILLIN and CEPHALOSPORIN ANTIBIOTICS. They are most common in human urinary infections, especially in CYSTITIS.

External Skeletal Fixators
External fixators are a system of metal rods, clamps, screws, etc., used to create a frame to keep fractured bones rigid while they heal. Their advantages over conventional splinting materials are their adaptability to bone shape and fragment size, as well as owner-acceptance. They also maintain limb length and allow access to open wounds. (See also BONE-PINNING and BONE PLATING.)

VetBooks.ir

The eye: a sectional view. A, indicates the eyelid; B, conjunctiva; C, cornea; D, pupil; E, iris; F, ligament of the iris; G, ligament of the lens; H, retina; J, lens; K, optic nerve. Next to the retina (H) comes the hyaloid membrane, then the choroid coat and (the outermost) the sclerotic coat.

Extracellular
The part of animal tissue outside cells. (See also INTRACELLULAR.)

Extracellular Fluid
The fluid outside the cells. It includes the blood plasma (intravascular fluid) and interstitial fluid. It contains the CATIONS mainly sodium, potassium and calcium and the ANIONS chloride and hydrogen carbonate. (See also INTRACELLULAR FLUID.)

Extramedullary
Situated outside any of the medullas. These include the MEDULLARY CAVITY of the bone and the MEDULLA OBLONGATA.

Extravasation
An escape of blood or lymph from the vessels which ought to contain it.

Extrinsic Allergic Alveolitis
(See 'FARMER'S LUNG'; 'BROKEN WIND'; ALLERGY.)

Exuberant
Excessive production of a material, and usually refers to excessive multiplication of cells.

Exudate
A fluid which seeps into a body cavity or the tissues, often as a result of disease and often due to inflammation. It arises by escape from blood vessels and contains much protein and cellular debris. It can be non-septic or septic.

Eye
The eyes are set in deep cavities known as 'bony orbits', whose edges are prominent and form a protection to the eyeball. In the pig, dog and cat the edge of the bony orbit is not complete posteriorly, but in the other domesticated animals it forms a complete circle. The two orbits are separated from each other in the middle line of the skull by only a very small space, and posteriorly the nerves leaving each eye (optic nerves) converge and meet each other on the floor of the brain cavity. Around the eyeball there is 'periorbital fat' upon which the eye rests. It is protected by two main eyelids and in many cases by a small rudimentary 'third eyelid', 'haw', or NICTITATING

A senior ophthalmologist at the Animal Health Trust, Newmarket, examines a patient's eyes. She is using a slit lamp ophthalmoscope, a vital tool for identifying problems in the cornea and the front of the eye.

VetBooks.ir

MEMBRANE, which is found at the inner corner. The eyelids meet at the outer and inner 'canthi'. Within the inner canthus and attached to the nictitating membrane is a small rounded pigmented prominence known as the 'lacrimal caruncle', which is formed of modified skin, and which often bears one or two tiny hairs. (See also HARDERIAN GLAND.)

Eyelids Each of the two main eyelids consists of four layers: on the surface there is skin similar to that which covers the adjacent part of the face, but thin, loose, pliant, and bearing extremely fine hairs; below this is a layer of thin subcutaneous tissue, and then comes the second or muscular layer which is instrumental in opening and shutting the eyelids; the third layer is fibrous, and along the free edge of the lid this layer is denser and forms the 'tarsus' of the eyelid, in the substance of which is embedded a row of glands, called the 'tarsal glands', numbering 45 to 50 in the upper and 30 to 35 in the lower lid of the horse (small cysts are occasionally formed in connection with these glands, which appear as rounded swellings upon the surface of the lid); the fourth layer consists of the delicate mucous membrane called the 'conjunctiva'. This inner lining of the eyelid, which runs from the free edges of the eyelids, partly bend the eyeball, folds over and returns to the point at which the sclera is attached to the cornea. By rubbing over the surface of the eyeball this tends to remove any dust, particles of debris, etc. that may collect on the moist surface. There are thus two layers of conjunctiva contiguous with each other, being reflected off the eyelid on to the anterior surface of the eyeball, and forming little pockets (upper and lower) (see FORNIX) all round the eye in which foreign bodies sometimes lodge which are difficult to remove; normally these pockets should contain small amounts of fluid, forming tears. These tears cover the eyeball surface (also called the conjunctiva) and tend to remove any dust, particles of debris, etc. that may collect on the moist surface. Any excess secretion of tears reaches the nasal cavity by the 'lacrimal duct', the two openings of which can be seen towards the inner canthus along the free margins of each of the lids. In the rabbit, there is only one opening on the lower eyelid and it is lower down the conjunctiva than in other species. The third eyelid is situated at the inner angle of the eye, consisting of a semilunar fold of the conjunctiva, which is supported and strengthened by a small roughly crescentic plate of cartilage. Ordinarily this eyelid covers only a very small part of the surface of the eye, but in certain diseases, such as tetanus, the pressure by the muscles of the eyeball upon the orbital fat displaces the third eyelid, and it may reach across the eye to the extent of almost 1 inch.

In the cat, the appearance of the third eyelid (nictitating membrane), like a curtain partly drawn across a window, is a common sign of general ill health and is due to absorption of fat in the vicinity. It is not usually a disease of the eye. (See also EYE, DISEASES AND INJURIES OF - 'DRY EYE'.) In birds the NICTITATING MEMBRANE makes a greater contribution to blinking than its mammalian counterpart and it is transparent in diurnal species so that it does not interfere with sight. Geckos and snakes do not possess eyelids, the cornea being protected by transparent skin instead. (See RETAINED SPECTACLES.)

Front of the eye The 'white' of the eye is called the SCLERA. In most mammals it is easily seen, but in the horse the eyelids have to be separated widely before the 'white' of the eye comes into view. The white appearance is due to the sclerotic coat, composed of dense white fibrous tissue, shining through the translucent conjunctival covering. In the centre of the white is set the transparent oval 'cornea', through which the rays of light pass on their way to the inner parts of the eye. (In the pig, dog and cat the cornea is practically circular in outline.) In birds, lizards and chelonians the shape is maintained by a ring of tiny bones called 'ossicles', which lie along the junction of the cornea and sclera. The cornea is far smaller relative to the size of the globe in birds than in mammals and far more conical in shape. Behind the cornea lies the beautifully coloured 'iris', with a hole in its centre, the pupil, black against the dark interior of the eye. The edge of the horse's pupil is often irregular in outline, owing to the presence of 'nigroid bodies'. The shape of the pupil and the colour of the iris vary in each of the domesticated animals and in individuals of the same or different breeds. In the horse and ox the pupil is roughly oval, or even egg-shaped, with the larger end inwards. In some horses, rarely in cattle, and in some breeds of dog (especially Collies and other sheepdogs) there may be an absence of pigment matter in the iris, and the animal is then said to be 'wall-eyed' or 'ring-eyed'. In birds, pigs, dogs and cats the pupils are rounded when fully dilated, but in the cat the contracted pupil (e.g. during the day or in a strong light) contracts into a vertical slit; the contracted pupil of the dog and pig is round. The aperture of the iris is controlled by involuntary muscles in mammals, but by voluntary muscles in birds, which therefore have more conscious control of their vision than mammals can. Lying between the posterior surface of the cornea, and the iris, in a space known as the 'anterior chamber' of the eye, a clear lymph-like fluid – the 'aqueous humour'.

Coats of the eyeball The eyeball, as already mentioned, rests upon a pad of fat within the

VetBooks.ir

cavity of the orbit, where it is held in position through the agency of seven ocular muscles and the optic nerve around which they are arranged. There are three layers forming the eyeball:

a. The Sclerotic Coat which is outermost, is composed of dense white fibrous tissue, which gives its appearance to the white of the eye in front. This coat completely encloses the ball, except for a small area through which emerges the optic nerve, while in front it is modified so as to form the transparent cornea. It maintains the shape of, and gives strength to, the ball of the eye. The cornea, which has a greater curvature than the rest of the ball, especially in birds bulges out in front. The whole cornea is somewhat like a window let into the front of the sclerotic coat.

b. The Choroid or vascular coat, lies within the sclerotic, and consists of three parts. The choroid membrane, lining more than two-thirds of a lining to the sclerotic, consists mainly of a network of vessels which nourish the sclerotic coat and the interior of the eyeball. In general, the colour is bluish-black, but in non-primate mammals an area a little above the level of the end of the optic nerve has a remarkable metallic lustre and is known as the TAPETUM LUCIDUM. The colour of the tapetum is variable, but generally it has a brilliant iridescent bluish-green colour shading imperceptibly into yellow. The choroid membrane is prolonged forwards into the 'ciliary body', a very complex structure which runs from the ciliary body to the lens capsule and forms a thickened ring opposite the line where the sclera merges into the cornea. To this line of junction the ciliary body is firmly attached by the ciliary muscle, which by its contraction and relaxation moves the ciliary body to and fro over the sclerotic, so as to allow the lens of the eye which is suspended from, or rather 'set into', the ciliary body, to alter its shape in such a way that it is able accurately to focus rays of light, coming from an object before the eye, on to the retina. The farthest forward part of the choroid coat is the 'iris', lying in front of the lens and behind the cornea.

The iris consists partly of fibrous tissue and partly of muscle fibres, arranged radially and circularly, with pigment cells interspaced throughout. These fibres by their contraction serve to narrow or dilate the pupil, according to whether the light entering the eye is strong or weak, and whether the animal looks at a near or distant object.

c. The Retina or nervous coat, is the innermost of the three coats of eyeball. After the optic nerve has pierced the sclerotic and choroid coats and the OPTIC DISC, it ends by a sudden spreading out of its fibres in all directions to form the retina, which also contains some blood vessels and pigment cells. The retina, when examined microscopically, is seen to consist of no less than 10 layers.

Parts of the segments of the retina are seen to be formed into cylindrical areas called rods and conical areas called cones. Both of these are the light sensitive areas of the retina and convert light waves into nerve impulses which eventually reach the optic nerve. The rods are very sensitive under night vision and near darkness. The cones achieve (under good light) detailed vision and differentiate between colours.

The 'visual purple' is a pigment called rhodopsin, synthesised from retinene (a pigment related to carotene) and a protein. Under bright light, the fading of the visual purple involves a conversion of rhodopsin into vitamin A plus protein by means of an enzyme.

Contents of the eyeball, viz. aqueous humour, vitreous humour and crystalline lens. The AQUEOUS HUMOUR, a clear watery, lymph-like fluid, occupies the space between the iris and the cornea, i.e. the anterior chamber of the eye. It is being constantly secreted and drained away, and eventually reaches the veins of the eye. Behind the iris lies the 'crystalline LENS', which acts in a similar way to the lens of a camera, with the exception that it can alter the curves of its surfaces and therefore is able to change its refractive powers. It is composed of concentric layers arranged like the leaves of an onion. The lens is held suspended in its capsule by a ligament, which is attached to the ciliary body already mentioned. Behind the lens the cavity of the ball of the eye is filled with the vitreous humour viscid, a jelly-like, tenacious fluid that maintains the intra-ocular pressure by which the eyeball retains its shape.

The lacrimal system provides a means whereby the eye surface is maintained free from dust and other foreign material by means of lacrimal secretion or 'tears'. It consists of one or more lacrimal glands (the number varies between species) which secrete the clear fluid popularly known as 'tears'; excretory ducts, from 12 to 16 in number; and the two lacrimal ducts which open into a lacrimal sac from which begins the naso-lacrimal duct which carries the secretion down into the nose. The gland lies towards the upper outer aspect of the orbit; secretes the clear salty, watery fluid which flows out through the excretory ducts to reach the conjunctival sac and bathe the surface of the eye. The secretion is finally received by the two lacrimal ducts, the openings of which lie one in each eyelid about a third of an inch (about 0.8 cm) from the inner canthus. These open into the lacrimal sac, from which takes origin the long naso-lacrimal duct which conveys the

VetBooks.ir

secretion down into the lower part of the corresponding nasal passage, just within the nostril. There is only one lacrimal duct in the rabbit. It runs from the lower conjunctival fornix (not the edge of the eyelid as in other species) via an extremely tortuous course to the nostril.

Accommodation All the rays of light proceeding from a distant object may be looked upon as being practically parallel, while those coming from a near object are divergent. The difference between distant and near in this connection can be taken as about 5 m (20 ft) from the animal. A 'near' object can be seen anywhere between 5 m (20 ft) and 10 cm to 12 cm (4 in to 5 in) from the eye, but nearer than this it loses its distinction. Parallel rays of light do not require any focusing on the retina other than is provided by the surface of the cornea; when an animal looks at a distant object, the lens capsule (which is attached to the ciliary process) retains the lens in a temporarily flattened condition and the ciliary muscle is relaxed, so that no great strain is put upon the eye. Rays of light from an object near at hand, however, which are divergent, require to be brought to a point of focus upon the retina, and as they pass through the lens their direction is changed on account of the convexity of the lens. The appropriate convexity is determined by the divergency of the rays, and is automatically provided through the pull of the ciliary muscle upon the ciliary body. As the function of the muscle is to pull the ciliary body forwards, the tension upon the ligament of the lens is lessened and the capsule of the lens slackens, so that the lens, by its inherent elasticity, bulges with a greater convexity upon its anterior surface. The greater the convexity, the more are the rays of light refracted, and the more the rays passing through the lens converge. (See also VISION.)

Lens (See illustration on page 295.)

Eye, Diseases and Injuries of

All such diseases and injuries can be of economic importance to farmers, since the productive efficiency of affected animals is likely to be reduced, owing to stress, pain or infection – or all of these. Milk yield may decline in the dairy cow. If the animal's sight is seriously impaired, feeding may become difficult, with consequent loss of bodily condition. Due to the prominence of the eyes and to their sensitivity, pet-owners attach a lot of importance to ocular health. Birds of prey require particularly acute vision to be able to hunt efficiently.

Blepharitis Inflammation of the edges of the eyelids; it usually accompanies conjunctivitis. Its causes, signs, and treatment are similar (see below).

Blindness There are many causes, including disease of the retina, of the optic nerve, and of the brain. Blindness may be congenital or acquired, temporary or permanent. VITAMIN A deficiency may be responsible, and also poisoning by rape and other plants, and by substances such as lead. Blindness in the dog and cat may result from, e.g. metaldehyde poisoning, and persist for some time. (See also under CARBON MONOXIDE poisoning; METALDEHYDE POISONING QUININE; MALE FERN; BRIGHT BLINDNESS.)

'Day blindness' (HEMERALOPIA) is stated to be due to an autosomal recessive gene.

Horses The sudden onset of blindness in one or both eyes has been reported as a result of optic

VetBooks.ir

nerve atrophy, following trauma. Signs are dilated, fixed pupils, and a lack of the menace reflex. Within three to four weeks the optic disc becomes paler, and the retina's blood vessels markedly decreased. There is a rupture of the nerve axons.

'Night blindness' (NYCTALOPIA) is a condition that sometimes affects horses and mules in very sunny countries and at night such animals are quite unable to see.

Camels are seldom affected by night blindness owing to the effective protection afforded to the retina by the overhanging eyelids and deeply placed eyeballs.

Opacity of the cornea will, of course, prevent light rays from reaching the retina, as happens in corneal opacity (KERATITIS), so that partial or complete blindness results. Similarly, partial or complete blindness may result from a cataract. Other causes are mentioned below, e.g. dislocation of the lens, glaucoma, etc.

Cattle and sheep Cerebrocortical necrosis (polioencephalomalacia), resulting from a thiamine deficiency, is a cause of blindness in ruminants. In sheep, other causes of blindness include: infectious keratitis or contagious ophthalmia ('heather blindness'); pregnancy toxaemia; and the effects of eating bracken, as described under BRIGHT BLINDNESS of sheep.

Poultry Blindness may be the result of excessive ammonia fumes from deep litter, or it may be associated with MAREK'S DISEASE, SALMONELLOSIS, ASPERGILLOSIS, etc. Cataract, followed in some cases by liquefaction of the lens, occurs during outbreaks of avian infectious encephalomyelitis. (See also under LIGHTING OF ANIMAL HOUSING.) Housed poultry must have a period of darkness each day otherwise BLINDNESS will result.

'Blue eye' (See CANINE VIRAL HEPATITIS.)

Cancer Both sarcomas and carcinomas can arise in the conjunctiva. Tumours appear as red hard swellings, painless when small, but not when large. They often grow rapidly, and may infiltrate the surrounding tissues, sometimes affecting the bones of the ORBIT. Cancer (squamous cell carcinoma) of the eye is a common condition in Hereford cattle. It has been suggested that several factors may contribute to the development of eye cancer in cattle. These include age, irritation of the eyes by dust, sand, insects or chemicals, sunlight, lack of eyelid pigmentation and viral infection. Some authorities believe that cattle may be genetically prone to the condition, while others feel that poor nutrition is another factor as the condition appears to occur more frequently following a drought. Squamous cell carcinoma of the third eyelid occurs in horses and ruminants. (See TUMOURS.)

The beginning of 'cancer eye', as it is sometimes colloquially known, may be a raised area of skin or a wart. Either may become malignant, developing into a typical carcinoma – the type of cancer occurring in this eye disease of Herefords. Many Herefords with 'cancer eye' tumours can resolve without treatment over a period of about two years.

Cryosurgery has been used to treat cancer of the eye. The technique is a highly skilled one and requires special thermocouples to monitor the very low temperatures.

Cure rates after treatment by a rapid freeze to –25° C (-13° F), a natural thaw, and then a re-freeze, can be 97 per cent.

Uveal MELANOMAS are the most common intraocular neoplasm in the dog.

Cataract The condition is by far the most common in the dog in old age, but rarer in the horse, although it is also encountered in other animals, and it may occur at almost any time of life. It consists of a coagulation of the plasma of the cells in the lens with loss of transparency. A bluish, cloudy appearance of the eye results and vision becomes blurred. Animals of most species can be born with congenital cataracts which can have various causes, including hereditary.

Causes Cataract is primarily a change characteristic of old age. Other causes include diabetes. Cataracts have also resulted from naphthalene and other forms of poisoning, and from exposure to X-rays.

Treatment As in human patients, cataracts may be removed successfully in animals. In one study, cataracts were removed by phacofragmentation and aspiration from one or both eyes of 56 dogs. Vision improved immediately in 53 of the dogs: after two years, 25 of 29 dogs still had vision, and after four years, five of seven dogs. The surgery was unsuccessful in dogs with severe anterior uveitis with secondary glaucoma, retinal detachments, and fibropupillary membrane formation.

'Collie eye anomaly' is a recessive inherited condition in which there is underdevelopment of the choroid membrane of the eye, especially in Smooth and Rough Collies, Shetland Sheepdogs, also in AUSTRALIAN SHEPHERD DOGS and NOVA SCOTIA DUCK TOLLING RETRIEVERS. The condition varies in severity from mild to blindness. Sometimes a COLOBOMA develops near the OPTIC DISC. Diagnosis is by OPHTHALMOSCOPY. Incidence can be controlled by selective breeding; a genetic test to detect carriers is available.

VetBooks.ir

Coloboma is a congenital and hereditary defect – a notch, gap, hole, or fissure in any of the structures of the eye. In other words, at birth a part of the eye is missing. Bilateral coloboma is common in Charolais cattle, often involving the optic disc. The condition can be recognised only with an ophthalmoscope, and does not deteriorate with the passage of time. Effect on vision varies from very slight to (rarely) blindness.

Conjunctivitis, or inflammation of the conjunctival membranes, is an extremely common condition among animals, and probably constitutes the commonest trouble to which the eyes are subject. In cattle, conjunctivitis is often the first sign of cattle plague (RINDERPEST), EPHEMERAL FEVER and Ondiri disease (BOVINE INFECTIOUS PETECHIAL FEVER).

Conjunctivitis is one sign associated with many specific infections, such as distemper in the dog (*and see* EYEWORMS).

Causes The presence of dust, sand, pollen, seeds, lime and pieces of chaff, in the atmosphere of a stable or field, is probably one of the commonest causes in the larger farm animals, but such agents as flies, worms, and ticks must also be noted in addition to the above. In the cat, two infections which cause conjunctivitis – *Haemophilus parainfluenzae* and *Moraxella lacunata* – are transmissible to man, in which illness may also be caused. (See FELINE EYE INFECTIONS. CONJUNCTIVITIS.)

In a study, *Chlamydophila psittaci* was isolated from 30 per cent of swabs from cats suffering from conjunctivitis.

Signs The first signs of conjunctivitis are redness and swelling of the lining membranes of the eyelids, excessive discharge of tears, and a tendency for the animal to keep its eyelids shut.

First-Aid Clean away the discharges by bathing with a warmed eye lotion. (If only one eye is affected, the cause may be a foreign body that has lodged there.) The best way to apply lotions, whether to the horse, dog, or other animal, is to use a perfectly clean piece of cotton-wool soaked in the solution and squeezed above the eye so that the drops trickle into it – never rub the cotton wool on the eye and eyelids. If a proprietary eye lotion is not available, cold tea or milk are acceptable substitutes but cool, boiled water is best. Cases of conjunctivitis should never be neglected, for the inflammation may spread to the cornea, resulting in keratitis (see below). Professional attention should be sought as soon as possible, especially if the presence of a foreign body is suspected.

'Dry eye' (keratoconjunctivitis sicca) is a condition in the dog arising from a partial failure of tear production and leading to roughening of the corneal surface with a consequent lack of lustre. 'Artificial tears' may have to be provided, or a surgical operation performed involving parotid duct transplantation. The condition has been linked to the use of sulfasalazine for the treatment of idiopathic colitis in dogs.

Ectropion means a turning-out of one or both eyelids, so that the conjunctiva is exposed. (See ENTROPION.)

Entropion Turning-in of the eyelid, often the lower one, so that it rubs upon the cornea, causing inflammation. The condition is common in dogs – often an inherited defect – occurring in many breeds. It is also seen in 'mini-pigs'.

In newborn lambs entropion is occasionally seen and, if bilateral, can lead to eventual blindness and starvation. It can be corrected by Michel clips (metal sutures) or with a small injection of liquid paraffin under the eyelid. It is treated by a plastic operation such as is performed for trichiasis (see below).

Epiphora is another name for what is commonly called 'watery eye' or 'overflow of tears'. It is generally due to some obstruction to the drainage of tears through the lacrimal duct to the nose, but it is also an accompanying sign of most forms of mild inflammation of the conjunctiva or cornea, of naphthalene poisoning in cattle, and of atopic disease in the dog.

Foreign bodies in the eye have already been referred to under 'Conjunctivitis' above. Severe irritation may be caused by a piece of grit or a grass seed or husk. Pain and irritation may be shown by the dog pawing its face.

Treatment This should be begun as soon as possible. If a hair, bristle or tip of an awn, for instance, can be seen on folding back the eyelid, or if a white spot (sometimes indicating the site of a thorn's penetration) or what appears to be 'a white film' is visible on the surface of the eye, the best first-aid treatment is a drop of olive oil. (Cod-liver oil will do, but not any oil!) The oil acts as a lubricant to reduce the harmful friction. Removal of a foreign body is best accomplished with the aid of a local anaesthetic, and professional help should be obtained.

Occasionally the object may be removed by taking the corner of a clean handkerchief, winding it into a point, and lifting the offending body out with it. The use of a proprietary eye lotion will be helpful afterwards.

VetBooks.ir

Glaucoma is a condition in which the pressure exerted by the fluid contents of the eyeball is too great. It is associated with obstruction to the eye's drainage system, in which fluid continues to be secreted but the excess is not removed. It may follow cases of progressive retinal atrophy. It eventually results in swelling and bulging of one or both of the eyes, and blindness. Secondary glaucoma is more common; this is caused by an eye disease, of which the most frequent is lens dislocation. (See also under EXOPHTHALMOS.)

Harderian gland, displaced In the dog this gland sometimes becomes enlarged and displaced, owing to blockage of its ducts or to a nearby swelling, when it becomes visible at the corner of the eye as a reddish lump. It may then require surgical removal.

'Heather blindness' is a colloquial name for the equivalent of infectious bovine keratoconjunctivitis (IBK) or contagious ophthalmia in sheep. *Rickettsia conjunctivae* is a common cause.

Treatment Shade and fly-control aid recovery, but veterinary treatment of IBK is necessary.

Boracic and similar eye lotions are useless in treating IBK or 'heather blindness'. Chloramphenicol eye drops or cloxacillin may be effective in treatment.

Horner's syndrome The pupil of one eye appears smaller than normal, the upper eyelid may droop, the lower lid may be raised, and the nictitating membrane ('third eyelid') protruded across part of the eye.

The cause is some lesion affecting the sympathetic nerves of the eye, e.g. a tumour of the spinal cord, chronic otitis, bite wounds, bee stings. Some cases are transient, as with wounds and bee stings.

Infectious bovine keratoconjunctivitis (IBK, IBKC)

is a convenient name for a group of eye diseases with a worldwide distribution, and includes New Forest disease (see below). What they have in common is conjunctivitis and keratitis.

Causes Bacteria, viruses, mycoplasmas, rickettsiae, fungi, and *Thelazia* worms – any of these alone or in combination may produce IBK. In addition, the sun's rays, dust particles, and chemical irritants may all predispose to, or exacerbate, the condition. IBK is commonly transmitted by flies and, in Africa, by two species of moth which feed on secretions and exudate from the eye. Some infective agents are present on the healthy eye, and become active only when the eye is damaged or irritated in some way.

Moraxella (Haemophilus) bovis is a common bacterial cause of IBK. Some American research has suggested that *Moraxella* may not cause keratitis unless the virus of bovine rhinotracheitis is present also. Cefalonium applied as an eye ointment is an antibiotic treatment.

Iritis means inflammation of the iris, a condition which is very often associated with inflammation of the ciliary body, when the term 'iridocyclitis' is used. The chief signs are dullness of the iris, congestion of the blood vessels around its margin, a lessened response to varying intensities of light and, usually, a firmly contracted pupil. Occasionally, especially during inflammation of the cornea, the iris adheres to this structure – a condition known as 'anterior synechia'; while more frequently the iris adheres to the lens, which lies behind it, and the condition is spoken of as 'posterior synechia'. The aqueous humour is often cloudy and may appear purulent, little flocculi of lymph being seen floating in the anterior chamber or sticking to the posterior surface of the cornea. There is always great pain, fear of light (photophobia), and the animal hangs its head and is dull and listless.

Iritis is a common condition in cattle, usually caused by eating poor-quality big-bale silage.

Keratitis Inflammation of the cornea may follow conjunctivitis, or it may arise from an injury to, or infection of, the cornea itself. A thorn, for example, may pierce the surface layers of the cornea and remain invisible until a faint whitish ring appears around its protruding part. Should a larger area of the cornea be involved, opacity becomes obvious. (Animal-owners often refer to it as 'a film over the eye'; but in fact the opacity stems from inflammation below the surface.) Keratitis may be caused by trauma of various kinds, e.g. a whip lash, a kick or blow; or by irritant skin dressings which are not prevented from running into the eyes, or by lime, sparks, or by continuous irritation by a foreign body such as a grass awn, piece of glass or grit. It may arise during the course of certain diseases, such as distemper in dogs and influenza in horses; it can be produced by the presence of *Thelazia* worms, or by fly-borne infections; frost-bite is said to be the cause of it in ewes on hills during severe weather, when it is called 'snow blindness'; turning-in of the eyelids (entropion) may give rise to it in the dog.

Keratoconjunctivitis sicca is a condition seen mostly in small animals; it is caused by the inadequate production of tears. There is a tacky mucoid discharge round the eyes; the cornea appears dry and may be ulcerated. If untreated, corneal opacity vascularisation and pigmentation

VetBooks.ir

may result. Topical application of antibiotics is indicated; 'artificial tears', formulated for use in human medicine, are useful.

Keratomycosis is keratitis due to a fungus, and is uncommon. If, however, tissue resistance is reduced by treatment with corticosteroids (which are immunosuppressive), any fungi present on the cornea may become pathogenic. It may be only when corneal ulcers fail to respond to conventional treatment that keratomycosis is suspected. Natamycin may prove helpful. *Fusarium solani* is implicated in most equine cases, sometimes *Candida* species; but several other fungi may be involved. (See also HYPERKERATOSIS.)

In the early stages, inflammation of the cornea results in signs very similar to those seen in conjunctivitis; the production of tears, closing of the eyelids, pain and swelling being noticed. When the eye is examined, however, the surface of the cornea is found to have lost its lustre. There may be a bluish haze, and an opacity, varying from pin-head size to the whole of the cornea – when the animal becomes completely blind in that eye, for the time being, anyway. The appearance of blood vessels where none is normally seen is another feature of keratitis and occurs before opacity becomes complete. There may be ulceration of the cornea, and even penetration. If the latter should occur, a keratocoele (hernia) may form endangering the whole eye, since infection, or escape of the aqueous humour, may sometimes occur.

Luxation (Dislocation) of the lens is a condition in which the crystalline lens becomes displaced into one of the chambers of the eye. It occurs in dogs, especially terriers and at first is very hard to recognise. Technically, lens dislocation may be classified as inherited, congenital, primary, secondary, or traumatic. The dog may run into stationary objects without any obvious reason. Casual examination of the eyes reveals no change and the condition may not be suspected for many months. Later, the owner becomes aware that sight is failing in the dog and careful examination reveals the problem. An operation may do much to restore some degree of vision and save the eye, but neglect almost invariably results in the development of glaucoma (see above) and the affected eye may have to be surgically removed.

Microphthalmos is an abnormally small eye; it is seen in vitamin A deficiency.

Myiasis (See UITPEULOOG.)

New Forest disease (infectious bovine keratitis). Success has been claimed for treatment involving the injection of 2 ml to 5 ml of an antibiotic preparation into the subconjunctival tissues of the upper eyelid. Antibiotics, parenterally, by subcutaneous injection or by long-acting antibiotic ophthalmic ointment are used in treatment; cortisone is contraindicated. Penicillin, oxytetracycline and chloramphenicol have been reported to give equally good results. A single treatment is usually sufficient.

Opacity of the cornea may result from oedema of the cornea following infection with CANINE VIRAL HEPATITIS; *see* 'Keratitis' above.

Ovine infectious keratoconjunctivitis This occurs worldwide. In a field survey carried out by the University of Liverpool's veterinary staff, the microflora of 240 clinically unaffected eyes from sheep in 10 flocks were compared with those of 240 clinically affected eyes from 12 natural outbreaks. Totals of 16 and 17 genera of bacteria were recovered, including *Branhamella ovis*, *E. coli* and *Staphylococcus aureus*. Mycoplasma and acholeplasma were isolated from both groups. *Chlamydia psittaci* can also be a cause.

Pannus is a complication of keratitis in which blood vessels bud out from the margins of the cornea and run in towards the centre of the eye, stopping at the edges of an ulcer if such exists. Pannus is a condition which always takes a long time to clear up, and even months after there may be seen a dullness of the cornea, due to the tiny vessels that still exist but are invisible to the naked eye.

Partial displacement Pekingese and other dogs with prominent eyes sometimes suffer a traumatic partial displacement of the eye from the orbit, as a result of being struck by a car or of some other accident. The globe may become trapped by the eyelids which become located behind it.

First-Aid The owner should bandage the eye with bandage moistened in saline solution (a teaspoonful of ordinary salt to a pint of water). Professional aid is urgently required.

Treatment This requires a general anaesthetic and re-positioning of the eye where possible. If the cornea, etc., has been badly damaged, the only course is enucleation of the eye. After suturing of the eyelids over the vacant socket, the result will not appear unsightly to the owner.

Periodic ophthalmia (see under this heading). (See also OPHTHALMIA.)

Progressive retinal atrophy is a hereditary condition common in many breeds of dog

VetBooks.ir

(especially IRISH SETTERS, MINIATURE POODLES and LABRADOR RETRIEVERS. The blood vessels of the retina undergo progressive atrophy and the animal suffers from impaired vision in consequence. To endeavour to correct this the pupil dilates widely, even in daylight, and the dog's expression becomes staring. At night or at dusk, the dog is unable to avoid objects and blunders into them, but during full daylight it appears to see quite well.

No treatment can arrest the progressive degeneration and the dog gradually becomes blind. In severe cases puppies may show first signs soon after weaning.

Neither dogs nor bitches which show the condition should be used for breeding. Breeds affected include COLLIES, GRIFFONS, POODLES, RETRIEVERS, SEALYHAMS, COCKER and ENGLISH SPRINGER SPANIEL.

The disease also occurs in cats, e.g. ABYSSINIAN and SIAMESE; 25 per cent of Abyssinian cats were found to be affected in a recent study. The earliest signs may not be seen until the cat is 18 months old or more; and the advanced form takes another 18 months to develop. (See also TAURINE.)

Prolapse of the Eyeball is common in dogs with protuberant eyes, e.g. Pekinese, pugs.

Ptosis is an inability to raise the upper eyelid, usually associated with some general disease, such as distemper in dogs or 'grass sickness' in horses. It may also arise after injuries when the nerve supplying the muscles of the upper lid (third cranial nerve) is paralysed.

Retention cysts are produced in the thickness of the eyelid owing to blockage of a tarsal gland.

Sclerotitis (scleritis), or 'blood-shot eye', is inflammation of the sclerotic coat of the eyeball. It often accompanies conjunctivitis when the latter is at all severe. It is treated as for conjunctivitis.

Stye, or hordeolum, is a condition in which a small amount of pus collects in the follicle around the root of one of the eyelashes. One after another may form in succession, owing to the spread of infective material from follicle to follicle.

Third Eyelids Squamous cell carcinoma occurs in cattle and horses. Prolapse of the third eyelid is seen in horses.

Trachoma A term used in human medicine for a granular conjunctivitis, often followed by keratitis and pannus.

Trichiasis Turning-in of the eyelashes so that they irritate and inflame the conditions. The condition is common in dogs and is sometimes a hereditary defect. It is treated surgically, by means of an operation in which an elliptical piece of skin is removed from the outer surface of the eyelid, and the edges sutured together. This causes the lashes to turn outwards, where they will not irritate or inflame the cornea.

Warts occur in connection with the eyelids comparatively frequently in horses, cattle, and dogs, and sometimes become malignant, spreading at a rapid rate and causing interference with sight or the movement of the eyelids. Owing to the malformation which they may cause when numerous, warts should always be removed before they attain a large size or before they have time to spread.

Eye Diseases, Hereditary

The British Veterinary Association, the Kennel Club and the International Sheep Dog Society operate a joint scheme to identify the presence or absence of inherited eye disease in a number of breeds of dog to help ensure that only disease-free animals are used for breeding. The main conditions covered are CENTRAL PROGRESSIVE RETINAL ATROPHY, COLLIE EYE ANOMALY, generalised PROGRESSIVE RETINAL ATROPHY, GONIODYSGENESIS, primary GLAUCOMA, hereditary CATARACT, persistent hypoplastic primary vitreous and persistent pupillary membrane.

Eye Fluke

(See DIPLOSTOMUM.)

Eyelids

(See under EYE.)

Eyeworms

In cattle, *Thelazia* worms are one cause of infectious bovine keratoconjunctivitis. Species include *T. skrjabini* and *T. gulosa*, found behind the third eyelid and in the ducts of associated glands. Up to 67 worms were found in eyes examined at a UK abattoir in 36.9 per cent of 287 cattle heads examined. Other species of *Thelazia* infest dogs, cats and man. *T. lacrymalis* was found in 28 per cent of horses whose eyes were examined at an abattoir.

F

FAB
(See FELINE ADVISORY BUREAU.)

Fabella Tie Back, Fabellar Tie Back
An operation in which a prosthetic ligament is inserted around the patellar ligament and the fabella to restabilise a stifle in which the cruciate ligament has been ruptured. (See CRUCIATE LIGAMENTS.)

Face Flies
(See under FLIES.)

Facial Deformity
(See HOLOPROSENCEPHALY.)

Facial Dermatitis
A condition in the gerbil due to excessive secretion from the HARDERIAN GLAND. There is erythema, scabs and sometimes moist dermatitis around the nostrils that may become infected, leading to sinusitis.

Treatment: reduce humidity, provide a sand bath and, where groups are kept, reduce numbers. Topical treatment of the bacterial infection can be used, but systemic antibiotics may be required.

'Facial Eczema'
'Facial eczema' is a synonym for a form of dermatitis caused by light sensitisation in cattle and sheep. (See LIGHT SENSITISATION.)

Facial Nerve
The facial nerve is the seventh of the cranial nerves, a motor nerve that supplies the muscles of expression of the face.

Facial Paralysis
In the case of unilateral 'facial paralysis', which very often follows accidents in which the side of the face has been badly bruised. The muscles on one side become paralysed but those on the opposite side are unaffected. This absence of antagonism between the two sides results in the upper and lower lips, and the muscles around the nostrils, becoming drawn over towards the unaffected side, and the animal presents an altered facial expression. The ear on the injured side of the head very often hangs loosely and flaps back and forward with every movement of the head, and the eyelids on the same side are held half-shut. MRI can be used to detect facial nerve abnormalities in dogs. (See also under GUTTURAL POUCH DISEASE; LISTERIOSIS.)

Factitious Urticaria
This is more correctly termed DERMATOGRAPHISM.

Factory Chimneys
Smoke from these may contaminate pastures and cause disease in grazing animals. (See FLUOROSIS; MOLYBDENUM.)

'Fading' Puppy Syndrome
'Fading' is the colloquial name for an illness of puppies, leading usually to their death within a few days of birth. Signs include: progressive weakness which soon makes sucking impossible; a falling body temperature; and 'paddling' movements. Affected puppies may be killed by their dams. Possible causes include canine viral hepatitis; another is a canine herpesvirus; a third may be a blood incompatibility; a fourth Bordetella; a fifth is hypothermia or 'chilling', in which the puppy's body temperature falls. Another possible cause may be *Clostridium perfringens* infection.

Kittens A similar syndrome may be caused by the feline leukaemia virus.

Faecal Egg Count Reduction Test
A test used to detect ANTHELMINTIC RESISTANCE. It involves taking a faecal sample and counting the worm eggs, giving a dose of the anthelmintic and then taking a second faecal sample after a certain number of days depending on the anthelmintic used. The egg count remaining is counted.

Faeces, Feces (US) (singular, Faex)
Excreta, excrement or the body waste removed from the ALIMENTARY CANAL via the RECTUM, moved by PERISTALSIS after its formation in the COLON. As the faeces build up in the rectum they stretch the rectal wall and stimulate nerves to signal the need to evacuate the contents. DEFAECATION occurs by relaxation of the sphincter muscles of the ANUS. In dogs, cats, some other animals and humans faeces are called STOOLS.

Faeces, Eating of
(See COPROPHAGY.)

Faex
The singular of FAECES.

Fainting Fits, Syncope
Fainting fits (syncope) are generally due to cerebral anoxaemia occurring through compromised blood circulation, sudden shock, or severe injury. It is

most commonly seen in dogs and cats, especially when old, but cases have been seen in all animals.

Falabella Horses

These are the smallest breed of horse. They must not be higher than 8.2 HANDS (82 cm) high, but they are usually between 7 hands (70 cms) and 8 hands (80 cms). They are mainly bay and black but spotted greys occur. They originate from Crillo stock from Argentina, with some SHETLAND PONY and WELSH PONY. There has been considerable INBREEDING to maintain the small size.

Falcons

Falcons are the genus of birds *Falco*, a collective containing 37 species of wild bird. In Britain, the peregrine falcon (*Falco peregrinus*) is the fastest bird on earth at 20 miles (320 km) an hour. Male falcons are called tercel (American tiercel) and the chicks, whilst in down, are called eyas. The female is larger than the male. In Britain, many falcons are kept for displays but they may be used for hunting, especially abroad. The red-tailed hawk (*Bueo jamaicensis*) or the Harris hawk (*Parabuteo unicinctus*) are popular.

Falcons, Diseases of

Avian pox has been found in imported peregrine falcons, giving rise to scab formation on feet and face and leading sometimes to blindness. Tuberculosis is not uncommon, and may be suspected when the bird loses weight. 'FROUNCE' and 'inflammation of the crop' are old names for a condition, caused by infestation with protozoan parasites (*Tritrichomonas*), which can be successfully treated. Frounce causes a bird to refuse food, or to pick up pieces of meat and flick them away again, swallowing apparently being too painful; there is also a sticky, white discharge at the corners of the beak and in the mouth. CAPILLARIA are found in the oropharynx or intestines of infected birds and can be treated with FENBENDAZOLE, 'sour crop' results in a swollen crop with foul smell containing meat and due to delay in emptying. Unless rapidly treated surgically under ANAESTHESIA there is rapid COLLAPSE, TOXAEMIA and death. ENTERITIS can be due to bacteria, viruses, fungi, endoparasites or toxins, COCCIDIOSIS (due to *Caryospora* spp.) occurs. TICKS feed on the birds.

ASPERGILLOSIS is a common cause of weight loss and even death in captive falcons. Bone fractures may arise as a result of calcium deficiency through birds being fed a bone-free all-meat diet. This may be prevented by sprinkling sterilised bone meal or oyster shell on the meat, or feeding the bird with small rodents. BATING, while tethered, can also cause leg fractures. BUMBLE-FOOT is another cause of lameness.

In the Middle East, dosing falcons with ammonium chloride – a common, if misguided, practice believed to enhance their hunting qualities – has caused sickness and fatalities.

Hawks experience similar problems but BUMBLE-FOOT is a more serious problem.

Fallopian Tubes

These, one on each side, run from the extremity of the horns of the uterus to the region of the ovary.

Falls from High Buildings

Cats fall from windows of high-rise buildings when chasing birds, insects, etc. and sustain fractures of the mandible and hard palate as the chin hits the ground.

Dogs fall less commonly, but when they do, they sustain injuries to face, chest and extremities, with spinal injuries occurring when they fall from over two storeys high.

False Pregnancy

(See under PSEUDO-PREGNANCY.)

Familial Nephropathy

A condition which can cover many types of kidney problems which have a familial basis. It occurs in FINNISH LANDRACE SHEEP and in some breeds of dogs such as COCKER SPANIELS.

Fanconi Syndrome

A group of diseases that cause dysfunction in the proximal renal tubules and then affect fluid reabsorption. The affected animal's urine contains glucose, amino acids, sodium, phosphorus and uric acid. There is also metabolic acidosis. It is seen as an inherited form in BASENJIS.

Fan Failure

In buildings that are ventilated artificially, it is mandatory under the Welfare of Farmed Animals Regulations 2007 (England and Wales) to have an alarm and stand-by system in order to prevent heat-stroke or anoxia. (See CONTROLLED ENVIRONMENT HOUSING.)

FAO

(See FOOD AND AGRICULTURE ORGANIZATION.)

Faradism

Local application of an electric current as a passive exercise which stimulates muscles and nerves.

Farcy

The form of GLANDERS affecting the body and limb surfaces. It is usually chronic in horses.

VetBooks.ir

Farm, Operations on the

In the UK it is illegal for the castration of horses, donkeys, mules, dogs or cats to be carried out without an anaesthetic. (See ANAESTHETICS, LEGAL REQUIREMENTS; CASTRATION.) Only a veterinary surgeon is permitted to castrate any farm animal more than two months old, with the exception of rams, for which the maximum age is three months.

Only veterinary surgeons are permitted to carry out a vasectomy or electro-ejaculation of any farm animal; likewise the de-snooding of turkeys over 21 days old, de-combing of domestic fowls over 72 hours old, and de-toeing of fowls and turkeys over 72 hours old. Nor can anyone but a veterinary surgeon remove supernumerary teats of calves over three months old, or disbud or dishorn sheep or goats.

Certain procedures legal overseas are prohibited in the UK, namely freeze-dagging of sheep, penis amputation and other operations on the penis, tongue amputation in calves, hot branding of cattle and the de-voicing of cockerels. Very short DOCKING of sheep is also prohibited in the UK.

Farm, Veterinary Facilities on the

(See VETERINARY FACILITIES ON THE FARM.)

Farm Animal Welfare Committee (FAWC)

This committee took over from the FARM ANIMAL WELFARE COUNCIL on 1 April 2011. It is an expert committee of the DEPARTMENT FOR ENVIRONMENT, FOOD AND RURAL AFFAIRS and the devolved administrations of Scotland and Wales. Address: FAWC Secretariat, Area 8B, 9 Millbank, c/o 17 Smith Square, London SW1P 3JR. Telephone: 0207 238 5124/ 6340/ 5016; email: fawcsecretariat@defra.gsi.gov.uk.

Farm Animal Welfare Council (FAWC)

An independent body set up by the government in 1979 to keep under review the welfare of farmed animals. Farms, markets, abattoirs and vehicles were inspected and, where appropriate, recommendations made to government. Reports were issued from time to time on the welfare of particular species or aspects (transport, slaughter, etc.) of the use of farm animals. This Council closed in March 2011 and was superseded by the Farm Animal Welfare Committee.

Farm Assurance Schemes

A scheme undertaken by one of several independent organisations which periodically visit farms and provides an overview of the farm, its management, and welfare and disease standards. It is undertaken in the United Kingdom, Ireland, Australia, some parts of the USA and other countries. It can in some ways be considered an extension of the HACCP principle onto farms. It involves areas of BIOSECURITY, and TRACEABILITY. Most responsible traders including supermarkets will usually only purchase food from farms and processors where there is farm assurance.

Farm Chemicals

(See SPRAYS USED ON CROPS; FERTILISERS; METALDEHYDE POISONING.)

'Farmer's Lung'

A disease caused by the inhalation of dust, from mouldy hay, etc., containing spores of e.g. *Thermopolyspora polyspora* or *Micropolyspora faeni*. Localised histamine release in the lung produces oedema, resulting in poor oxygen uptake. It is classed as an acute extrinsic allergic alveolitis. Repeated exposure causes respiratory distress, even when the interval between exposures is several years. The condition has been recognised in humans, cattle, horses and turkeys. In chickens, a similar condition has been caused by inhalation of dust from dead mites in sugar cane bagasse (fibrous residues).

Farm Treatment Against Worms

(See WORMS.)

Farrier

A person who shoes horses. Farriery is a craft of great antiquity and the farrier has been described as the ancestor of the veterinarian. In the UK, farriery training is strictly controlled. Intending farriers must undergo a five-year apprenticeship, including a period at an authorised college, then take an examination for the diploma of the Worshipful Company of Farriers before they can practise independently. The training is controlled by the Farriers Training Council and a register of farriers kept by the Farriers Registration Council.

Farriers Registration Council

Address: Sefton House, Adam Court, Newark Road, Peterborough PE1 5PP; Telephone: 01733 319911; email: frc@farrier-reg.gov.uk; website: www.farrier-reg.gov.uk.

Farrowing

The act of parturition in the sow.

Farrowing Crates

A rectangular box in which the sow gives birth. Their use is helpful in preventing overlying of piglets by the sow, and so in obviating one cause of piglet mortality; however, they are far from ideal. Farrowing rails serve the same purpose but perhaps the best arrangement is the circular one which originated in New Zealand. (See ROUNDHOUSE.)

VetBooks.ir

Work at the University of Nebraska suggests that a round stall is better, because the conventional rectangular one does not allow the sow to obey her natural nesting instincts, and may give rise to stress, more stillbirths and agalactia.

Farrowing Fever
(See MASTITIS METRITIS AGALACTIA SYNDROME.)

Farrowing Rates
In the sow, the farrowing rate after one natural service appears to be in the region of 86 per cent. Following a first artificial insemination, the farrowing rate appears to be appreciably lower, but at the Lyndhurst, Hants AI Centre, a farrowing rate of about 83 per cent was obtained when only females which stood firmly to be mounted at insemination time were used. The national (British) average farrowing rate has been estimated at 65 per cent for a first insemination. Australian research has shown that the quality of feed given to gilts from about 10 weeks will affect the number of eggs shed as an adult. In the USA feeding more energy and less protein has increased the chances of a sow having more than four pregnancies.

Fascia
Sheets or bands of fibrous tissue which enclose and connect the muscles.

Fascioliosis, Fascioliasis
Infestation with liver flukes.

Fat
Normal body fat is, chemically, an ester of three molecules of 1, 2 or 3 fatty acids, with 1 molecule of glycerol. Such fats are known as glycerides, to distinguish them from other fats and waxes in which an alcohol other than glycerol has formed the ester. (See also LIPIDS [which include fat]; FATTY ACIDS. For fat as a tissue, see ADIPOSE TISSUE). There are two types of fat – brown fat and white fat. Brown fat is seen particularly in young animals and is used to provide body heat on exposure to cold. White fat is metabolised following SYMPATHETIC NERVOUS SYSTEM stimulation releasing NORADRENALIN and is used for movement. White beige fat is an intermediate fat type derived from white fat with the properties of white and brown fat but is used less efficiently than either. A LIPOMA is a benign fatty tumour. For other diseases associated with fat see STEATITIS; FATTY LIVER/KIDNEY SYNDROME OF CHICKENS AND TURKEYS; OBESITY, DIET AND DIETETICS.

Fat Bodies
These accumulations of fat in the caudal COELOM of reptiles constitute their normal fat stores. Reptiles do not have subcutaneous fat deposits or an OMENTUM. Fat bodies should not be confused with fatty tumours (See LIPOMA).

Fat Cells
Found in fat and also called ADIPOCYTES.

Fat Chin Syndrome
Seen in cats. (See EOSINOPHILIC GRANULOMA.)

Fatigue
(See EXERCISE; MUSCLE; NERVES.)

Fat, Rumen Protected
Fats protected from rumen degradation are digested lower in the gut and serve as a concentrated energy source. They can also improve milk and meat production and increase conjugated linoleic acid.

Fat Supplements
In poultry rations these can lead to 'TOXIC FAT SYNDROME'. (See LIPIDS for cattle supplement; also ECZEMA in cats.)

Fatty Acids
These, with an alcohol, form FAT. Saturated fatty acids have twice as many hydrogen atoms as carbon atoms, and each molecule of fatty acid contains two atoms of oxygen. Unsaturated fatty acids contain less than twice as many hydrogen atoms as carbon items, and one or more pairs of adjacent atoms are connected by double bonds. Polyunsaturated fatty acids are those in which several pairs of adjacent carbon atoms contain double bonds. Certain fatty acids, e.g. linoleic acid, are known as 'essential' and are necessary for coat health. There may be species differences; for example, skin ulceration can be presented by fatty acid supplementation in the black rhinoceros, but they are not required in the white rhinoceros.

Omega-3 fatty acids appear to have a beneficial effect on heart muscle, but need to be balanced with omega-6 fatty acids as the latter can have a deleterious effect. In humans, conjugated linoleic acid has anti-carcinogennic effects, improves food digestibility and reduces body fat deposition.

Butyric acid can help inhibit infection of the mucous membranes by *Salmonella* and *Campylobacter* spp. and so reduce human food-borne illness.

Fatty Degeneration
A condition in which there is an excess of fat in the parenchyma cells of organs such as the liver, heart and kidneys.

VetBooks.ir

Fatty Liver Haemorrhagic Syndrome (FLHS)

This is a condition in laying hens which has to be differentiated from FLKS (see next entry) of high-carbohydrate broiler-chicks. Factors involved include high carbohydrate diets, high environmental temperatures, high oestrogen levels, and the particular strain of bird. FLHS in hens is improved by diets based on wheat as compared with maize; whereas FLKS is aggravated by diets based on wheat. Death is due to haemorrhage from the enlarged liver.

Fatty Liver/Kidney Syndrome of Chickens and Turkeys (FLKS)

A condition in which excessive amounts of fat are present in the liver, kidneys and myocardium. The liver is pale and swollen, with haemorrhages sometimes present, and the kidneys vary from being slightly swollen and pale pink to being excessively enlarged and white. Morbidity is usually between 5 per cent and 30 per cent. It can be caused by many factors, including genetics, diet, management, hormones, environment and toxic substances. A similar condition is seen in cage birds that receive diets high in fats and carbohydrates and do not exercise.

Prevention FLKS has been shown to respond to biotin (see VITAMINS), and accordingly can be prevented by suitable modification of the diet.

Signs A number of the more forward birds (usually two to three weeks old) suddenly show signs of paralysis. They lie down on their breasts with their heads stretched forward; others lie on their sides with their heads bent over their backs. Death may occur within a few hours. Mortality seldom exceeds 1 per cent.

Fatty Liver Syndrome of Cattle

A 'production disease' which may occur in high-yielding dairy cows immediately after calving. It is then that they are subjected to 'energy deficit' and mobilise body reserves for milk production. This mobilisation results in the accumulation of fat in the liver, and also in muscle and kidney. In some cases the liver cells become so engorged with fat that they actually rupture.

An important consequence of this syndrome may be an adverse effect on fertility. Cows with a severe fatty liver syndrome were reported to have had a calving interval of 443 days, as compared with 376 days for those with a mild fatty liver syndrome.

Complications such as chronic ketosis, parturient paresis (recumbency after calving), and a greater susceptibility to infection have been also been reported.

Fatty Liver Syndrome of Turkeys

The only sign may be wattles paler than normal; the birds remain apparently in good condition. The cause may be varied – genetic, nutritional, management, environmental, and presence of toxic substances. Adding choline, vitamins E and B_{12}, and inositol to the diet can remedy the condition. Reducing the metabolisable energy level in the diet by about 14 per cent usually prevents it.

Fauces

Fauces is the narrow opening which connects the mouth with the throat. It is bounded above by the soft palate, below by the base of the tongue, and the openings of the tonsils lies at either side. Faucitis is inflammation of the tissues around the opening and may occur in isolation or form part of a more generalised stomatitis.

Faulty Nutrition

(See ACETONAEMIA; ACIDOSIS; KETOSIS; NUTRITION, FAULTY; FEED BLOCKS; DIET AND DIETETICS; LAMENESS in cattle; BLINDNESS.)

Faulty Wiring of Farm Equipment

Faulty wiring of farm equipment has led to cows refusing concentrates in the parlour, not because they were unpalatable (as at first thought), but because the container was live so that cows wanting to feed were deterred by a mild electric shock. (See also EARTHING; ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION.)

Faverole Chickens

A dual-purpose breed originating from France. They are large birds, good layers, and were considered as possibly contributing to broiler breeder genes. Cocks weigh 3.5 kg (8 lb) and hens 3 kg (6.5 lb). They have five toes and feathered shanks. The plumage of hens is mainly brown and creamy-white and cocks have black, brown and straw-coloured feathers. Their eggs are brown.

Favus

Favus is another name for 'honeycomb ringworm'. (See RINGWORM.)

FAWC

Abbreviation of FARM ANIMAL WELFARE COUNCIL. (See FARM ANIMAL WELFARE COMMITTEE.)

Feather

(Feathering; adjective, Feathered)

Long hairs on the fetlocks of draught horses and some ponies. In dogs, feathering is seen on the ventral surface of the body, the caudal aspect of the legs and the ventral tail of spaniels and setters.

VetBooks.ir

'Feather Duster' Disease

An inherited problem particularly of budgerigars and parrots thought to be due to a single recessive gene. Abnormal feathering is seen as soon as they start to feather up and the flight, tail and contour feathers continue to grow. Most birds die at 10 to 12 weeks but they can survive two or more years. Affected birds should not be bred from. It is also known as 'Chrysanthemum disease'.

Feather Picking, Feather Pulling

Feather picking (feather pulling) in poultry and in cage birds, particularly parrots, may be due to boredom or insecurity.

Poultry In many cases it is due to the irritation caused by lice or to the ravages of the depluming mite. In such cases the necessary anti-parasitic measures must be taken. Insufficient animal protein in the diet of young growing chicks, especially when kept under intensive conditions, may cause the vice. Once the birds start pulling the feather they sooner or later draw blood, and an outbreak of cannibalism results. Treatment consists of isolating the culprit, if it can be found at the beginning, and of feeding the birds a balanced diet containing green food. The addition of blood meal in the mash is effective in many cases. The use of blue glass in intensive houses has stopped the habit in some cases. Use of trees in free-range pens reduces feather-pecking.

Parrots In parrots the syndrome is much more complex and triggered by many factors. Feather pecking is never seen in birds in the wild. The condition is diagnosed by the fact that the affected bird has a fully-feathered head and the wings, legs and body are deplumed as only they can be reached by the beak. The condition has to be thoroughly investigated: often there is an underlying disease, and response to appropriate treatment resolves the feather picking. Specific treatment varies from the application of an ELIZABETHAN COLLAR to the administration of psychotic drugs, but sometimes environmental changes have been effective – e.g. the transference of a caged bird to an aviary or the provision of a CONSPECIFIC individual for company.

Febantel

An anthelmintic used for the treatment of parasitic gastroenteritis and parasitic bronchitis in cattle, sheep, pigs and horses and in combination with PYRANTEL and PRAZIQUANTEL for the control of intestinal worms in dogs. Chemically, febantel is a pro-benzimidazole which is converted in the body to benzimidazole.

Federation of Veterinarians of Europe (FVE)

An organisation representing veterinary organisations in 38 European countries and with four sections representing practitioners, hygienists, veterinary state officers and veterinarians in education, research and industry. Address: Avenue de Tervuren 12, B-1040 Brussels, Telephone: (00) 32 2533 70 20; E-mail: info@fve.org

Fedesa

The European Federation of Animal Health, an association of veterinary medicine manufacturers.

F

Feed Additives

(See ADDITIVES.)

Feed Blocks

These 'self-help' lick blocks, placed out on pasture, are useful especially on hill farms for preventing loss of condition and even semi-starvation in the ewe.

Most feed blocks contain cereals as a source of carbohydrate, protein from natural sources supplemented by urea, minerals, trace elements and vitamins. In some blocks glucose or molasses is substituted for the cereals as the chief source of carbohydrate. A third type contains no protein or urea but provides glucose, minerals, trace elements, and vitamins; being especially useful in the context of hypomagnesaemia (and other metabolic ills) in ewes shortly before and after lambing.

Their effectiveness for providing specific ingredients is variable as animals differ in the extent to which they use feed blocks.

Feed Conversion Efficiency (FCE)

The gain in weight, in kg or lb, produced by 1 kg or 1 lb of feed; it is the reciprocal of the feed conversion ratio.

If FCRs are to be used as a basis of comparison as between one litter and another, or one farm's pigs and another's, it is essential that the same meal or other foods be used; otherwise the figures become meaningless.

Feed Conversion Ratio (FCR)

The amount of feed in kg or lb necessary to produce 1 kg or 1 lb of weight gain.

Feeding

(See DIET AND DIETETICS; FAULTY NUTRITION.)

Feeding-Stuffs, Storage of

Feed must be stored separately from fertilisers, or contamination and subsequent poisoning may occur.

The safe storage period on the farm of certain feeds is given under DIET AND DIETETICS.

VetBooks.ir

Poultry and rats and mice must not be allowed to contaminate feeding-stuffs, or SALMONELLOSIS may result. If warfarin has been used, this may be contained in rodents' urine and lead to poisoning of stock through contamination of feeding-stuffs. (See also TOXOPLASMOSIS.)

Unsterilised bone-meal is a potential source of salmonellosis and anthrax infections.

(See also ADDITIVES; CONCENTRATES; DIET AND DIETETICS; MITES, PARASITIC - OTHER MITES - FORAGE MITES; MOULDY FOOD; MYCOTOXICOSIS; CUBES AND PELLETS; SACKS; LUBRICANTS.)

Feeding-Stuffs Regulations 2000

Feeding-Stuffs Regulations 2000 control the constituents of animal feed including pet food. They specify, among other items, permitted additives, colourants, emulsifiers, stabilisers, maximum amounts of vitamins and trace elements, and permitted preservatives.

Feedlots

Feedlots involve the ZERO-GRAZING of beef cattle on a very large scale. In the USA there are some feedlots of 100,000 head each, and many more containing tens of thousands of cattle. Veterinary problems arise when these cattle are brought to the feedlot from range or pasture, and fed on grain. Shipping fever is a common ailment; likewise liver abscesses.

Feline

Related to, or of, the Family *Felidae* including the domestic cat (*Felis catus*).

Feline Advisory Bureau (FAB)

A charity in the UK dedicated to promoting the health and welfare of cats through improved knowledge. It provides information for those involved in veterinary care, rescue work and boarding establishments as well as the general cat-owning public. After 55 years the name was changed in 2013 to INTERNATIONAL CAT CARE. (See also INTERNATIONAL SOCIETY OF FELINE MEDICINE.)

Feline Anaemia

(See ANAEMIA; TOXOPLASMOSIS; HAEMOBARTONELLA; FELINE LEUKAEMIA; FELINE BABESIOSIS.)

Feline Autonomic Polygangliopathy

(See FELINE DYSAUTONOMIA (KEY-GASKELL SYNDROME).)

Feline Babesiosis

An uncommon parasitic disease of cats due to infestation of erythrocytes with *Babesia felis* causing anaemia, lethargy and sometimes jaundice. Young cats may develop immunity to *Babesia felis* without prior signs of illness; older cats often have recurrent illness. Subclinical infections occur. The disease can prove fatal. (See also BABESIOSIS.)

Feline Bordetellosis

A disease of the upper respiratory tract of cats involving *Bordetella bronchiseptica*. Clinical signs can be mild, but fatal pneumonia can develop especially in kittens. Some animals may become symptomless carriers of the organism (which is also responsible for respiratory disease in other species, including kennel cough in dogs). Treatment is by antibiotics.

Feline Calicivirus

Infection with calicivirus (of which there are several strains) is an important cause of FELINE INFLUENZA ('CAT FLU'). Signs include fever, discharge from the eyes and nose and ulcers of the mouth and tongue. The virus is disseminated by sneezing cats, through contact with nasal secretions picked up on the hands and clothing of attendants, etc. Calicivirus is also associated with chronic stomatitis, a limping syndrome and a virulent systemic form associated with high mortality.

Feline Cancer

Cancer is an important disease of cats. Cancer of the lymph nodes is common, as is that of the bone marrow. Skin cancer and mammary gland cancers also occur. (See also under CANCER.)

Feline Cardiomyopathy

Clinical signs of this heart condition include dyspnoea, weight loss and lethargy. Diagnosis is by radiography. Beta blockers, digitalis and diltiazem have been used in treatment. The cause is unknown.

Feline Chlamydial Infection

An acute upper respiratory disease caused by *Chlamydiophila felis*; also known as feline pneumonitis.

Signs Severe swelling and redness, nasal discharge, sneezing and coughing. It commonly affects groups of animals, rarely single cats. Treatment includes topical and/or systemic antibiotics. Chlamydiosis vaccine (available as a combination product) protects against clinical disease but not infection.

Feline Conjunctivitis

It is seen as ocular hyperaemia and/or CHEMOSIS. Causative agents are feline herpes virus-1 (FHV-1), *Chlamydophila felis*, *Mycoplasma felis* or Gram-negative bacteria. Diagnosis is best confirmed by PCR. Treatment of FHV-1 involves the use of topical anti-viral agents such as acyclovir,

VetBooks.ir

or famciclovir given orally – these products are not licensed for cats in the UK. Treatment of *Chlamydophila* and *Mycoplasma* is best achieved with a tetracycline such as doxycycline.

Feline Coronavirus

This is a common infection in cats that usually causes mild, often asymptomatic, infections, but it may progress to FELINE INFECTIOUS PERITONITIS (FIP).

Feline Dental/Mouth/Tooth Problems

Gum and tooth diseases are quite common in cats. (See MOUTH, DISEASES OF; TEETH.)

Feline Dental Resorptions

Resorption of the teeth by the body is common in domestic cats. This may occur as (usually) painful cavities at the gum line (often hidden by a flap of gum) or painless root resorption. (See MOUTH, DISEASES OF.)

Feline Diabetes

(See under DIABETES MELLITUS.)

Feline Dysautonomia, Key-Gaskell Syndrome

A condition in cats first recognised at Bristol University's department of veterinary medicine in 1981–2. It is also called feline autonomic polyganglionopathy.

Signs include depression, loss of appetite, prominent nictitating membranes, dry and encrusted nostrils – suggesting a respiratory disease. Constipation and a transient diarrhoea have both been reported; also incontinence in some cases. The pupils are dilated and unresponsive to light and tear production is diminished. There may be difficulty in swallowing and food may be regurgitated. A common finding is enlargement of the oesophagus (MEGAOESOPHAGUS). Lesions include loss of nerve cells, and their replacement by fibrous tissue, in certain ganglia. The disease is similar to GRASS SICKNESS in horses. The cause is still unknown.

Treatment involves countering dehydration, maintaining nutritional status through assisted feeding, use of eye drops to encourage nasal and tear secretions and using laxatives to encourage bowel movements.

Prognosis The recovery rate is stated to be about 25 per cent, but recuperation may take weeks or months. Cats with a greatly enlarged oesophagus, persistent loss of appetite, or bladder paralysis are the least likely to survive.

(See also CANINE DYSAUTONOMIA.)

Feline Ehrlichiosis

An uncommon infection affecting the blood cells of cats that is likely to be spread by ticks. Several *Ehrlichia* species have been implicated. The commonest findings are fever, malaise and gastroenteritis, but the respiratory system and joints may also be affected. Tick repellents help prevent infection; treatment is usually with TETRACYCLINES.

Feline Encephalomyelitis

This has been reported in Sydney, Australia, and is characterised by non-fatal cases of hind-leg ataxia, and sometimes by side-to-side movements of head and neck. On post-mortem examination, demyelinating lesions and perivascular cuffing involving the brain and spinal cord were found. The cause is thought to be a virus, but efforts to transmit the disease have failed.

Feline Endocrine Alopecia

Hair loss that usually occurs on the posterior aspects of the hind-limbs and along the belly and back. Often associated with flea infestation (see ECZEMA), it may respond to control of the parasite and administration of steroids.

Feline Eye Infections

Conjunctival swabs from cats with conjunctivitis and from clinically normal cats were examined microbiologically. Non-haemolytic streptococci and *Staphylococcus epidermis* were isolated from both groups while beta-haemolytic streptococci, rhinotracheitis (feline herpes 1) virus, *Mycoplasma felis* and *Chlamydophilia felis* were isolated from cases with conjunctivitis.

Feline Gingivitis

This can be mild and transient. Sometimes the term is applied not to an inflammation of the gums but merely to a hyperaemia – an increased blood flow – which 'may alarm the owner but does not hurt the (young) cat'.

Gingivitis can also be acute or chronic, easily treatable, or highly intractable.

One of the commonest causes of gingivitis in middle-aged or elderly cats is the accumulation of tartar on the surface of the teeth. If neglected, the tartar will gradually encroach on to the gums, causing these to become inflamed. Unless the tartar is removed, a shrinkage of the gums is likely to follow. As the gum recedes from the teeth it leaves pockets or spaces into which food particles and bacteria can lodge, exacerbating the inflammation, causing halitosis and leading to the roots of some teeth becoming infected.

The yellowish tartar deposits can become so thick and extensive that eventually they completely mask the teeth. A cat in this condition undoubtedly suffers much discomfort, finds eating a little

VetBooks.ir

difficult, and may have toothache. Health is further impaired by the persistent infection. The cat becomes dejected.

Even in such advanced cases, removal of the tartar (and of any loose teeth) can bring about almost a rejuvenation of the animal.

This form of chronic gingivitis can be successfully overcome by treatment and, indeed, prevented if an annual check of the teeth is carried out by a veterinary surgeon.

Intractable gingivitis Some cases of this are associated with a generalised illness rather than merely disease of the mouth. For example, chronic kidney disease, and possibly diabetes, may cause ulcers on the gums (as well as elsewhere in the mouth).

Some strains of the feline calicivirus may also cause gum and tongue ulceration. Bacterial secondary invaders are likely to worsen this, especially if the cat's bodily defence systems have been impaired by, say, the feline leukaemia virus, some other infection, or even stress.

Antibiotics or sulphonamides are used to control the bacteria; vitamins prescribed to assist the repair of damaged tissue and to help restore appetite, and other supportive measures taken. However, some cases of feline gingivitis do not respond.

It is likely that all the causes of feline gingivitis have not yet been established. Further research will no doubt bridge the gaps in existing knowledge, and bring new methods of treatment and a better prognosis. (See also FELINE STOMATITIS.)

Feline Haemophilia

This is not a very common condition in cats, mainly seen in males but does involve haemophilia A, haemophilia B and haemophilia in MAINE COON cats. There are varying degrees of haemorrhage usually following trauma, HAEMATOMAS may develop, or bleeding into joints. Prolonged bleeding following any surgery may be the first indication that the animal is affected.

Feline Hereditary Neuroaxonal Dystrophy

This is caused by an autosomal recessive gene; the signs are progressive ataxia in infancy, and the condition appears linked to an abnormal coat colour.

Feline Herpesvirus

One of the causes of feline influenza. Infection may occur in combination with feline calicivirus. Clinical signs may be severe and include epiphora, coughing, dyspnoea and corneal ulcers. Secondary bacterial infection can lead to fatal pneumonia. Cats recovering from acute infection may be left with chronic nasal and ocular disorders; they will also become carriers of the virus. Infection is spread by sneezing, and may be carried on equipment, clothing, hands of attendants, etc. (See FELINE VIRAL RHINOTRACHEITIS; FELINE INFLUENZA.)

Feline Hippocampal Necrosis

An uncommon condition reported in cats, mainly within Europe and initially described in Switzerland in 2000. Usually there are sudden behavioural changes with AGGRESSIVENESS and SEIZURES with no response to treatment. Diagnosis is indicated by the signs and history and used of MRI findings. The cause is not yet known and so the condition is often described as Feline Idiopathic Hippocampal Necrosis.

Feline Hyperthyroidism

(See HYPERTHYROIDISM.)

Feline Hypertrophic Cardiomyopathy

The most commonly acquired heart condition in cats. It is seen at any age, either sex (although common in middle-aged males) and breed (common in Persians). Cats may show laboured breathing after exercise, look depressed, have low appetite, and may show tachycardia, heart murmur, or abnormal rhythm. If undetected it can lead to pulmonary oedema and arterial THROMBOSIS.

Feline Idiopathic Cystitis (FIC)

Cystitis of unknown cause but which can be improved by increasing water consumption, stress reduction, environmental enrichment and modification, and paying attention to an individual cat's needs in a multi-cat household.

Feline Immunodeficiency Virus (FIV)

Formerly known as the feline T-lymphotropic lentivirus (FTLV). It was discovered in California by N. C. Pedersen and colleagues. Spread by the saliva of infected cats, or less often via the milk or placenta, it has a prolonged incubation period leading to permanent infection.

The virus establishes a permanent infection; the prognosis is poor. Clinical signs can be transient and mild – fever, depression, enlarged lymph glands. As the virus causes immunosuppression, secondary infections account for many of the clinical signs.

Diagnosis is confirmed by laboratory demonstration of antibodies. Treatment is aimed at control of secondary infection by antibiotics; many cases, however, end fatally.

Feline Infectious Anaemia

This disease is caused by the bacterium *Mycoplasma haemofelis* (formerly classified as *Haemobartonella*

felis). It is treated with antibiotics. Blood transfusions or fluid therapy may be required in severe, acute cases.

Adult cats may carry the parasite, the disease lying dormant until some debilitating condition (e.g. stress or immunosuppression) lowers the cat's resistance. (See HAEMOTROPIC ANAEMIA.)

Signs are those associated with anaemia: loss of appetite, lethargy, weakness and loss of weight. Anaemia may be severe enough to cause panting.

Diagnosis may be confirmed by identifying the causal agent in blood smears or testing for bacterial DNA.

Feline Infectious Enteritis, Panleucopenia

This was formerly called feline distemper. The disease is caused by a parvovirus. Cats of all ages are susceptible; survivors appear to acquire lifelong immunity. The disease is less common than it was, as a result of successful vaccination programmes.

Cause The virus is indistinguishable from mink enteritis virus, resistant to heat and many disinfectants, and can survive outside its host for over a year. It causes severe damage to the bowel and bone marrow.

Signs Kittens and young unvaccinated cats are most at risk although non-immune cats of any age are susceptible. In susceptible cats the only sign may be sudden death, but more usually the virus causes an acute enteritis associated with fever, loss of appetite, vomiting, bloody diarrhoea with rapid dehydration and death. In newborn kittens infected in the uterus, the CEREBELLUM may be affected giving rise to a staggering gait.

Disease may be less severe in cats that are immune due to previous vaccination or exposure to infection.

Diagnosis may be confirmed by laboratory tests – examination of bone marrow and blood smears. Post-mortem examination reveals inflammation of the ileum, oedema of the mesenteric lymph nodes and liquefaction of the bone marrow. The disease must be differentiated from poisoning, toxoplasmosis, intestinal foreign bodies and septicaemia.

Prevention Live and inactivated vaccines are available; live vaccines, however, are not suitable for use in pregnant queens.

Treatment Supportive measures to counter dehydration and shock and potentially overwhelming secondary bacterial infections. Even though the bowel is often severely compromised, nutritional support is essential. In a cattery, isolation of in-contact animals and rigid disinfection must be practised. (See also NURSING OF SICK ANIMALS.)

Feline Infectious Peritonitis (FIP)

A slowly progressive and fatal disease of young cats, and sometimes of older ones also, caused by a coronavirus. Although the coronavirus is commonly found in cats, most do not develop the disease. Where FIP develops, it usually does so in a 'wet' form in which fluid accumulates in the body cavities. A 'dry' form also occurs. It is the cat's own immune response to the virus that determines which form of the disease is likely to be present.

Clinical signs in the early stages are non-specific. Fever, depression, loss of appetite, gradual loss of weight, distension of the abdomen due to fluid. Occasionally, diarrhoea and vomiting occur.

There may be distressed breathing in the 'dry' form. Inflammation within tissues can cause damage to organs such as the liver, kidneys, eyes, and brain. Both forms are fatal although some individuals with the 'dry' form may survive for many months. Confirmation of a diagnosis of FIP can be strongly suggested on clinical examination but confirmation depends on tissue biopsy or post-mortem examination. Treatment with recombinant feline INTERFERON omega (rfIFN-ω) reduces viral infection.

Prevention is difficult where cats are grouped together as the virus is very infectious. Some catteries try to control infection by repeated antibody testing and isolation techniques combined with stringent hygiene. Where queens are known to be a possible source of infection to their kittens, isolating the queen before kittening and early weaning into a clean environment provides a good method of producing virus-free kittens. A vaccine is available in some countries but its use is controversial.

Feline Influenza

The name is loosely applied to respiratory infections involving more than one virus, known as the feline viral respiratory disease complex. It commonly occurs in cat-breeding and boarding establishments, the infection(s) being highly contagious. Feline calicivirus and feline herpes virus (feline rhinotracheitis) are commonly involved but other infectious agents such as *Bordetella bronchiseptica* and *Chlamydophila* can create very similar signs. Secondary bacterial invaders account for many of the more serious signs.

Signs Sneezing and coughing. The temperature is usually high at first; the appetite is depressed; the animal is dull; the eyes are kept half-shut, or the eyelids may be closed altogether; there is discharge from the nose; condition is rapidly lost. If pneumonia supervenes the breathing becomes very

VetBooks.ir

VetBooks.ir

rapid and great distress is apparent; exhaustion and prostration follow. Diagnosis is confirmed by isolation of the virus from nasal swabs by a specialist laboratory.

Treatment Isolation of the sick cat under the best possible hygienic conditions is immediately necessary. There should be plenty of light and fresh air, and domesticated cats need to be kept fairly warm.

Antibiotics help to control secondary bacterial infection. Food should be highly palatable and easily digested. (See NURSING OF SICK ANIMALS; PROTEIN, HYDROLISED.)

Owing to the very highly contagious nature of the viruses causing feline influenza, disinfection after recovery must be very thorough before other cats are admitted to the premises.

Prevention Live attenuated combined vaccines against feline viral rhinotracheitis and feline calicivirus are available. Vaccines are generally effective, but as there are several strains of feline calicivirus, they may not protect against them all. Other controls include strict hygiene (of premises and attendants) and the segregation of carrier (infected) cats.

Feline Juvenile Osteodystrophy

Feline juvenile osteodystrophy is a disease, of nutritional origin, in the growing kitten.

Cause A diet deficient in calcium and rich in phosphorus; kittens fed exclusively on minced beef or sheep heart have developed the disease within eight weeks. As the use of proprietary diets has increased, then the condition has become less common.

Signs The kitten becomes less playful and reluctant to jump down even from modest heights; it may become stranded when climbing curtains owing to being unable to disengage its claws. There may be lameness, sometimes due to a greenstick fracture; pain in the back may make the kitten bad-tempered and sometimes unable to stand. In kittens which survive, deformity of the skeleton may be shown in later life, with bowing of long bones, fractures, prominence of the spine of the shoulder blade, and abnormalities which together suggest a shortening of the back.

Feline Leishmaniasis

This is a cause of ulcers, and small, palpable swellings under the skin. The disease is transmissible to human beings. (See LEISHMANIASIS.)

Feline Leprosy Syndrome

Formerly thought to be caused by *M. lepraemurium*; now shown to be caused by several MYCOBACTERIA that cause leprosy in rats. It has been assumed that most infection of cats was from rats. The skin shows nodules with or without hair, mainly on the head and limbs and occasionally the body. Some reports include lesions of the mouth and the conjunctiva. Disease progress is related to the infective dose and the ability of the host to establish an immunity.

Feline Leukaemia

A disease of cats caused by a virus (FeLV) discovered by Professor W. F. H. Jarrett in 1964. The virus gives rise to cancer, especially lymphosarcoma involving the alimentary canal and thymus, and lymphatic leukaemia. Anaemia, glomerulonephritis, and an immunosuppressive syndrome may also result from this infection, which can be readily transmitted from cat to cat. Many cats are able to overcome the infection. The virus may infect not only the bone marrow, lymph nodes, etc., but also epithelial cells of mouth, nose, salivary glands, intestine and urinary bladder.

Kittens of up to four months of age are more likely to become permanently infected with FeLV than older cats, but many cases do occur in cats over five years old.

Many cats which have apparently recovered from natural exposure to the virus remain latently infected, but keep free from FeLV-associated diseases. Such cats may infect their kittens via the milk.

Significance of FeLV Most deaths of FeLV-positive cats are not directly attributable to this virus, but to other viral, bacterial or protozoal infections which are rendered far more serious because of the immunosuppression caused by the virus.

Signs These vary and may be vague, with a gradual loss of condition, poor appetite, depression and anaemia; or they may be related to immunosuppression such as stomatitis or chronic diarrhoea. The cancer induced by FeLV may create enlarged lymph nodes leading to breathing difficulties or enlarged abdominal organs.

Diagnosis FeLV infection can be confirmed by detecting viral protein or genetic material in blood samples using techniques such as ELISA tests, immunofluorescence and polymerase chain reaction (PCR) assays. Viral isolation can also be performed. Healthy cats that test positive should always have follow-up testing as false positives can occur with some of these tests.

Control It is possible to spread the FeLV infection from infected cats whether sick or currently healthy. This can be a problem if the

VetBooks.ir

infected cat lives with other cats or goes outside. This can be prevented by a 'test-and-removal' system. Infected cats are removed for euthanasia, and any other cats in the same household are then tested. If FeLV-positive, they too are removed, even if clinically healthy. Retesting of the FeLV-negative cats is necessary after three and six months. If still FeLV-negative, they can be considered clear, and new cats introduced on to the premises, if desired.

The virus may persist in the bone marrow of cats which have ostensibly recovered. Such a latent infection can be reactivated by large doses of corticosteroid; the virus can be recovered by cultivation of bone marrow cells. FeLV is not transmitted from cats with a latent infection.

Inactivated vaccines will not protect cats that are already infected and no vaccines are 100 per cent effective.

Feline Lower Urinary Tract Disease (FLUTD)

Formerly called FELINE UROLOGICAL SYNDROME (FUS). The name is given to the several conditions causing painful and difficult URINATION, often with blood-stained urine. It may also be associated with changes in behaviour and URINATION habits. In cases that lead to obstruction of the URETHRA it can, if untreated, lead to death. In many cases the cause is unknown and is referred to as FELINE IDIOPATHIC CYSTITIS (FIC). Less commonly, bladder stones (calculi), the formation of sand-like material, cancer and bacterial infections can cause the signs of FLUTD. In those cats that develop URETHRAL OBSTRUCTION, it is usually males as the URETHRA is longer and narrower than in females, the cause in IDIOPATHIC cases is due to the formation of urethral plugs. These are composed of varying proportions of STRUVITE and organic matter.

Cause Various theories have been advanced to account for FLUTD: possible contributory factors include as yet unidentified infectious agents such as a virus or viruses, dry diets and poor water intake, and a high level of magnesium in the diet. The effects of heredity and castration have also been mentioned. However, it is now recognised that STRESS can be an important factor. Certain types of cat are recognised to be predisposed on account of their inability to cope with stressful situations such as the presence of other cats in the same household or the outside environment. Stress can trigger inflammation of the bladder wall (CYSTITIS) via nerve pathways, but factors from within the bladder itself can also trigger this nerve-induced (NEUROGENIC) inflammation compounding the problem. Feline dry diets are now formulated to maintain urine at the correct degree of acidity to avoid the problem.

Signs The cat may be seen straining to pass urine, with only very little to be produced. The urine may be bloodstained. Cat-owners sometimes mistake FLUTD for constipation; straining may also be seen with CYSTITIS, when the bladder is usually empty, and when the URETHRA is blocked and so the bladder is full. Other signs include loss of appetite, dejection, and restlessness. The abdomen will be painful to the touch, owing to distension of the bladder.

NB: URETHRAL OBSTRUCTION is an emergency requiring immediate veterinary attention, in default of which there is a great risk of collapse and unconsciousness. The bladder may rupture, causing additional shock, and leading to PERITONITIS.

Treatment If a cause of FLUTD is identified it should be treated appropriately. Often, however, the disease is likely to be multifactorial. In acute cases anti-inflammatory medication and pain relief is indicated. In the case of a blocked urethra, skilled manipulation can sometimes free a urethral plug. If this fails, a catheter will have to be passed to empty the bladder; this is imperative to relieve the back pressure on the kidneys. If CATHETERISATION fails, it will be necessary to empty the bladder by means of direct aspiration (cystocentesis).

Prognosis There are cases in which, after removal of the urethral obstruction, it does not recur. However, FELINE IDIOPATHIC CYSTITIS cases are prone to relapse and in cats with obstructed urethras repeated blockages are common. In these cases specialised surgical procedures or ultimately EUTHANASIA may be advisable. (See also INTERSTITIAL CYSTITIS.)

Post-operative treatment includes antibiotics and urine acid-alkali balance control in an attempt to dissolve the remaining crystals. A low-magnesium, urine-acidifying diet, including TAURINE, is also recommended and proprietary preparations are on sale to meet this requirement. (See PRESCRIPTION DIETS.)

Feline Miliary Dermatitis

(See ECZEMA.)

Feline Mycobacteriosis

A skin condition caused by *Mycobacterium lepraemurium* of mice and possibly *M. tuberculosis*. These are ACID-FAST ORGANISMS. Any skin lesion containing acid-fast bacteria should be considered a potential public heath hazard. If there

is no public health risk, the lesion may be treated by incising the area and then dosing with enrofloxacin. Unlicensed dapsone and clofazimine have been used under the 'CASCADE'. (See also MYCOBACTERIUM.)

Feline Neurodermatitis
A condition caused by stress and/or anxiety resulting in excessive licking of the skin. Any ectoparasites need to be eliminated, before megestrol acetate or anti-stress drugs such as phenobarbitone and diazepam are used.

Feline Odontoclastic Resorptive Lesion
(See FELINE INFECTIOUS ENTERITIS.)

Feline Panleukopenia
(See TEETH, DISEASES OF, TEETH - NECK LESIONS IN CATS' TEETH; FELINE INFECTIOUS ENTERITIS.)

Feline Pneumonitis
(See FELINE CHLAMYDIAL INFECTION.)

Feline Postvaccinal Sarcoma
A high-grade FIBROSARCOMA occurring at sites traditionally used for vaccination in cats and reports started to appear 1991. Cases still occur despite changes in vaccine formulation and in feline vaccination protocols.

Feline Poxvirus
This was formerly thought to be cowpox virus. It is characterised by moist reddened lesions of the skin that may become scabby and purulent. Treatment is with disinfectant shampoos, and by creams to areas not accessible to licking; corticosteroids are contraindicated.

Feline Pyothorax
(See PYOTHORAX.)

Feline Solar Dermatitis
A painful sunburn caused by cats sleeping with their feet or ears pointing to the sun. Ultraviolet light barrier creams have been used to prevent it.

Feline Spongiform Encephalopathy (FSE)
This is similar clinically to BOVINE SPONGIFORM ENCEPHALOPATHY (BSE). The first signs are hypersensitivity to noise and visual stimuli. Ataxia follows and eventually the cat will not be able to get up. The cause is believed to be the eating of material from cattle affected by BSE. In a zoo, two pumas and a stray cat which shared their food were fed on split bovine heads. Both pumas and the cat died from FSE. At the height of the BSE outbreak in the 1990s in the UK, one case of FSE was being reported every six weeks.

Feline Stomatitis
Inflammation of the cat's mouth.

Causes Various, including several viruses.

Signs These include difficulty in swallowing, halitosis, excessive salivation, loss of appetite and sometimes bleeding.

Treatment The aim is to limit secondary bacterial infection by means of antibiotics. A supplement of vitamins A, B and C may help. If the cat will not eat, subcutaneous fluid therapy will be required.

Chronic stomatitis in elderly cats may be due to EOSINOPHILIC GRANULOMA, or malignant growths such as squamous cell CARCINOMA or FIBROSARCOMA. (See also MOUTH, DISEASES OF.)

Feline T-Lymphotropic Lentivirus
(See FELINE IMMUNODEFICIENCY VIRUS.)

Feline Ulcerative Dematitis
This is of unknown aetiology, but may be immune-mediated. It causes painless non-pruritic swellings of the soles of the feet. Often they resolve without treatment; otherwise corticosteroid creams are used.

Feline Urological Syndrome (FUS)
(See FELINE LOWER URINARY TRACT DISEASE.)

Feline Vestibular Syndrome, Idiopathic
The name given to a condition in which head-tilt, ataxia, nystagmus and, occasionally, vomiting were seen. Duration of signs was short, only up to 24 hours.

Feline Viral Rhinotracheitis
Feline viral rhinotracheitis is involved in the feline viral respiratory disease complex (FELINE INFLUENZA). The disease was discovered in the USA to be caused by a HERPESVIRUS, and first recorded in Britain in 1966. Severe signs are usually confined to kittens of up to six months old. Sneezing, conjunctivitis with discharge, coughing and ulcerated tongue may be seen. Bronchopneumonia and chronic sinusitis are possible complications.

Cause A herpesvirus. Infection may occur in a latent form, and a possible link has been suggested between this virus and feline syncytia-forming virus.

VetBooks.ir

Live and inactivated vaccines are available against feline calicivirus and feline herpesvirus which may be implicated in the infection.

Treatment May include the use of a steam vaporiser, lactated Ringer's solution to overcome dehydration and antibiotics. Vitamins and baby foods may help.

Felinine
An odourless sulphur-containing amino acid present in cat urine which degrades to chemicals producing the characteristic 'catty smell'.

Fell Ponies
These strong, useful ponies originated from Cumbria, England. They are normally black, with no white markings, and have FEATHERED legs. They are susceptible to FOAL IMMUNODEFICIENCY SYNDROME (originally called FELL PONY SYNDROME).

Fell Pony Syndrome
(See FOAL IMMUNODEFICIENCY SYNDROME.)

'Felon'
A country term used to describe 'SUMMER MASTITIS'. As the quarter affected is usually non-productive after infection, it probably refers to "stealing the quarter".

FeLV
(See FELINE LEUKAEMIA.)

Feminisation
In the male dog this may occur as the result of a SERTOLI-CELL TUMOUR of a testicle.

Femur
Femur is the bone of the thigh, reaching from the hip-joint above to the stifle-joint below. It is the largest, strongest, and longest individual bone of the body. The bone lies at a slope of about 45 degrees to the horizontal in most animals when they are at rest, articulating at its upper end with the ACETABULUM of the pelvis, and at its lower end with the tibia. Just above the joint surface for the tibia is the patellar surface, upon which slides the patella, or 'knee cap'.

Fractures of the head of the femur are common. Surgical repair may be possible.

Fenbendazole
A benzimidazole anthelmintic used in cattle, sheep, camelids, horses, pigs, poultry, dogs and cats. (See WORMS, FARM TREATMENT AGAINST.)

Fentanyl
An analgesic for use in small mammals (rabbits, ferrets, guinea pigs, rats and mice). In horses long-term relief can be provided by application of fentanyl patches. It is usually combined with FLUANISONE for use as a neuroleptoanalgesic.

Fenugreek
A herb used mainly in dog and cat remedies to stimulate appetite. In the USA it was used in a calf feed produced by one company and became habit forming so the animals would only eat feeds containing it. It was ruled in court that the herb had to be withdrawn.

Fermentation
Carbohydrates in the feed of pigs are sometimes fermented with lactobacilli to produce lactic acid and thereby suppress salmonellae and coliform multiplication.

Ferns
Ferns other than bracken occasionally cause poisoning in cattle. For example, *Dryopteris filix-mas* (male fern) and *D. borreri* (rusty male fern) give rise to blindness, drowsiness and a desire to stand or lie in water. Poisoning is occasionally fatal. (See also BRACKEN POISONING.)

Ferret
(*Mustela putorius furo*) These attractive creatures are increasingly popular as pets and about 20 per cent are working ferrets. They need careful and expert handling – a bite to the finger can penetrate to the bone. In the UK the breeding season begins in March and continues until the end of August. There is seasonal weight variation with weight loss in the spring and weight gain in the autumn. It is preferable that females ('jills' – males are 'hobs') not used for breeding are spayed. Unmated jills may be in oestrus for the whole of the breeding season, with the occurrence of persistently high levels of oestrogen. This can cause severe health problems, including a possibly fatal PANCYTOPENIA. Surgical neutering is a major cause of adrenal gland disease with progressive body ALOPECIA and PRURITUS. The alternatives to spaying are injections of proligestone, given via the scruff of the neck, or mating with a vasectomised male. The latter will result in a pseudo-pregnancy lasting about 42 days; the jill may need to be mated again if she returns to oestrus.

Other diseases of ferrets include HYPOCALCAEMIA, three to four weeks after giving birth; MASTITIS; ALEUTIAN DISEASE; CANINE DISTEMPER (often fatal with respiratory and gastrointestinal signs, vaccination prevents this); BOTULISM (type C); abscesses; enteritis due to *E. coli* or campylobacter. A CROHN'S DISEASE-like condition occurs. Ferret systemic CORONAVIRUS is an emerging fatal disease first recorded in USA in 2002. Skin tumours are not uncommon.

VetBooks.ir

Periodontal disease is often caused by the accumulation of dental calculus. UROLITHIASIS can occur; the ferret can be fed the cat food formulated to prevent this condition. Ferrets are susceptible to zinc poisoning and any galvanised material can be a risk.

Common external parasites include FLEAS, OTODECTES, SARCOPTIC MANGE (see MITES, PARASITIC), and TICKS. IMIDACLOPRID can be used to treat. Internal parasites include COCCIDIOSIS (*Eimeria furo*, *E. ictidea*, *Isospora laidlawii*), CRYPTOSPORIDIOSIS, GIARDIASIS (*Giardia duodenalis*), TOXOPLASMOSIS. Worm (HELMINTH) infestations include HEARTWORMS (*Dirofilaria immitis*), HOOKWORMS (*Ancylostoma* spp.), TAPEWORMS (*Dipylidium caninum*) and ROUNDWORMS (*Toxocara* spp.; *Toxascaris leonina*). Laboratory parameter reference ranges can be found in Veterinary Record (2012) 171 218, and there is a website dealing with health and management of ferrets at www.wildlifeinformation.org.

Ferritin

Ferritin is a form in which iron is stored in the body. Ferritin concentrations in serum are closely related to total body iron stores, and ferritin immunoassays can be used to assess the clinical iron status of human beings, horses, cattle, dogs, and pigs.

Fertilisation

(See REPRODUCTION.)

Fertilisers

Fertilisers should not be stored near feeding-stuffs, as contamination of the latter, leading to poisoning, may occur. Deaths can occur after cattle gain access to the remains of a fertiliser dump, often caused by a crust of superphosphate and ammonium sulphate that remained on the ground.

For the risk associated with unsterilised bone-meal, see under ANTHRAX and SALMONELLOSIS.

Hypomagnesaemia is frequently encountered in animals grazing pasture which has received a recent dressing with potash. (See also BASIC SLAG; FOG FEVER.)

Fertility

(See CONCEPTION RATES; FARROWING RATES; INFERTILITY; CALVING INDEX.)

Fescue

In New Zealand and the USA, a severe hind-foot lameness of cattle has been attributed to the grazing of *Festuca arundinacea*, a coarse grass which grows on poorly drained land or on the banks of ditches, and being tall stands out above the snow. In typical cases, the left hind-foot is affected first, and becomes cold, the skin being dry and necrotic. Signs appear 10 to 14 days after the cattle go on to the tall-fescue-dominated pasture. Ergot may be present, but is not invariably so.

It has been suggested that 'fescue foot' may be associated with a potent toxin, butenolide, produced by the fungus *Fusarium tricinctum*.

Fetal

Adjective derived from FETUS, which is the unborn developing offspring after the embryonic stage.

Fetal Infections

Examples of these are TOXOCARA infection in bitches and TOXOPLASMOSIS *in utero* of cows, ewes, sows, bitches and cats.

Fetal Membranes

(See CHORION; AMNION; ALLANTOIS; also UTERUS, DISEASES OF and EMBRYOLOGY.)

Fetal Resorption

(See MUMMIFICATION OF FETUS.)

Fetlock-Joint

The joint in the horse's limb between the metacarpus or metatarsus (cannon bones) and the 1st phalanx (long pastern bone). At the back of this joint are situated the sesamoids of the 1st phalanx. (See BONES.)

Fetotomy

(See EMBRYOTOMY.)

Fetus

The young growing in the uterus after the organs have been formed. The word is from the Latin fetus, meaning offspring; the spelling 'foetus' is common, but incorrect. For an outline description of the development of the fetus, see under EMBRYOLOGY. For fetal circulation, see the diagram under CIRCULATION OF BLOOD. (See also FREEMARTIN.)

Fever

Fever is one of the commonest signs of infectious disease, and serves to make the distinction between febrile and non-febrile ailments. In true fever the body's own in-built thermostat changes to a higher setting and the core temperature is raised accordingly. It is thought to be beneficial in many cases of infectious disease in countering the infective agent. Fever is a common sign in problems other than infectious disease, such as immune-mediated disease, pain and cancer especially in dogs and cats.

Examples of specific fevers are BLACK-QUARTER, BRAXY, DISTEMPER, EQUINE INFLUENZA and SWINE FEVER.

VetBooks.ir

When fever reaches an excessively high stage, e.g. 41.5° C (107° F), in the horse or dog, the term 'hyperpyrexia' (excessive fever) is applied, and it is regarded as indicating a condition of danger; while if it exceeds 42° C or 42.5° C (108° F or 109° F) for any length of time, death almost always results. Occasionally, in certain fevers or febrile conditions, such as severe heat-stroke, the temperature may reach 44.5° C (112° F). (See also under TEMPERATURE, BODY.)

Signs Animals with a fever are usually depressed, lethargic and have a reduced appetite. They may appear stiff and reluctant to move and have mildly elevated respiratory and/or heart rates. There is usually a certain amount of shivering, to which the term 'rigor' is applied, but this is very often not noticed by the owner. Later, there may be PERSPIRATION, rapid breathing, a fast, full, bounding pulse, and a greater elevation of temperature are exhibited. Thirst is usually marked; the appetite disappears; the urine is scanty and of a high specific gravity; the bowels are generally constipated, although diarrhoea may follow later; oedema of all the visible mucous membranes, i.e. those of the eyes, nostrils, mouth, occurs. (See also HYPERTHERMIA.)

Fever may sometimes have a beneficial effect.

Experiments with newborn mice show that fatal infection with Coxsackie B1 virus can be modified to a subclinical infection if the animals are kept in an incubator at 34° C (93° F) and thus attain the same body temperature as mice of eight to nine days old. Similarly, puppies infected with canine herpesvirus survive longer and have diminished replication of virus in their organs if their body temperature is artificially raised to that of adult dogs. It is also said to assist in treating MYXOMATOSIS in rabbits.

Fibre, Importance of

The term used for the structural parts of plants which are commonly called DIETARY FIBRE or ROUGHAGE. It forms an important part of nutrition and feeding animals. Much of this cannot be digested by CARNIVORES or man, but is able to be partially utilised by HERBIVORES. (See also DIETARY FIBRE; DIET AND DIETETICS; HORSES, FEEDING OF; RATIONS FOR LIVESTOCK.)

Fibrevores

Animals that require fibre as a major part of their diet. RABBITS, GUINEA PIGS and CHINCHILLAS in the wild live on grass, plants, twigs and bark.

Fibrillation

An involuntary contraction of individual bundles of muscle fibres.

Fibrin

Fibrin is a substance upon which depends the formation of blood clots. (See CLOTTING OF BLOOD; PLASMA.)

Fibrin is found not only in coagulated blood, but also in many inflammatory conditions. Later it is either dissolved again by, and taken up into, the blood, or is 'organised' into fibrous tissue.

Fibrinogen, Plasma

A high molecular weight protein in solution in the blood plasma also known as Clotting Factor 1, which following the action of thrombin is converted to fibrin and this is precipitated to form part of the process of clotting. Concentration of this is increased in inflammatory conditions, especially lesions of serous surfaces and in ENDOCARDITIS. (See also CLOTTING OF BLOOD.)

Fibrinolysis

It breaks down FIBRIN by enzymatic action such as blood clots.

Fibroblast

An irregularly-shaped cell responsible for the synthesis of CONNECTIVE TISSUE.

Fibrocartilage

It is a mixture in varying proportions of white FIBROUS TISSUE and CARTILAGE. It tends to be white in colour, and the fibrous tissue provides strength and toughness and cartilage provides elasticity.

Fibrocartilaginous Embolic Myelopathy

This is the protrusion of an intervertebral disc which has degenerated and enters the spinal canal, causing damage of the blood vessels and resulting in restriction of the blood supply (ISCHAEMIA) and damage of the SPINAL CORD (MYELOPATHY). The signs are sudden in onset, do not progress and are often asymmetrical and involve varying degrees of paralysis and loss of, or poor pulse in, the limbs. It is particularly seen in middle-aged dogs of large breeds, and also is common in horses.

Fibroma

(See TUMOURS.)

Fibrosarcoma

A tumour arising from fibrous or CONNECTIVE TISSUE; always malignant and often highly invasive.

Fibrosis

The formation of fibrous tissue, which may replace other tissue. (See also CIRRHOSIS.)

F

VetBooks.ir

Fibrous Tissue

Fibrous tissue is one of the most abundant tissues of the body, being found in quantity below the skin, around muscles and to a lesser extent between them, and forming tendons to a great extent; quantities are associated with bone when it is being calcified and afterwards, and fibrous tissue is always laid down where healing or inflammatory processes are at work. There are two varieties: white fibrous tissue and yellow elastic fibrous tissue.

White fibrous tissue consists of a substance called 'collagen' which yields gelatin on boiling, and is arranged in bundles of fibres between which lie flattened, star-shaped cells. It is very unyielding and forms tendons and ligaments; it binds the bundles of muscle fibres together, is laid down during the repair of wounds, and forms the scars which result; it may form the basis of cartilage; and it has the property of contracting as time goes on so may cause puckering of the tissues around.

Yellow fibrous tissue is not so plentiful as the former. It consists of bundles of long yellow fibres, formed from a substance called 'elastin', and is very elastic. It is found in the walls of arteries, in certain ligaments which are elastic, and the bundles are present in some varieties of elastic cartilage. (See ADHESIONS; WOUNDS.)

Fibula

One of the bones of the hind-limb, running from the stifle to the hock. It appears to become less and less important in direct proportion as the number of the digits of the limb decreases. In the horse and ox it is a very small and slim bone which does not take any part in the bearing of weight; while in the dog it is quite large, and with the tibia, takes its share in supporting the weight of the body.

FIC

(See FELINE IDIOPATHIC CYSTITIS.)

Field Spaniels

A vulnerable breed. They are black coated and popular for hunting. They were bred into a taller type; all are single coloured, including black, dark brown (liver) or roan.

Figs

Ficus carica contain cellulase, xylanase and gluconase and dried fig mean is used in the tropics to improve digestibility of some feeds.

Filarial Worms

(See FILARIASIS.)

Filariasis

Filariasis is a group of diseases caused by the presence in the body of certain small thread-like nematode worms, called filariae, which are often found in the bloodstream. Biting insects act as vectors. (See HEARTWORM and TRACHEAL WORMS for canine filariasis; also EQUINE FILARIASIS; BRAIN DISEASES.) Infection is generally not considered a ZOONOSIS, although a case of conjunctivitis has been reported.

Parafilaria bovicola causes bovine filariasis in Africa, the Far East, and parts of Europe. The female worm penetrates the skin, causing subcutaneous haemorrhagic lesions that resemble bruising. Eggs are laid in the blood there. Downgrading of carcases at meat inspection is a cause of significant loss. MACROCYCLIC LACTONES (DORAMECTIN, IVERMECTIN, MOXIDECTIN) by injection are useful for control.

Filovirus

(See MONKEYS, DISEASES OF.)

Fimbriae

These are minute filaments with specific antigenic properties attached to the surface of bacteria. They can be used in vaccines against *E. coli*, for example. (See also under GENETIC ENGINEERING.)

Fine Needle Aspiration Biopsy (FNAB)

A technique in which a fine hypodermic needle is used to aspirate a tissue sample for cytological examination. (See CYTOLOGY; LABORATORY TESTS; PARACENTESIS.)

Finnish Landrace Sheep, Finn Sheep

Finnish Landrace sheep are remarkable for high prolificacy, triplets being common, and four or five lambs not rare.

Finnish Lapphund

Not a common dog in Britain but is seen at shows. Progressive retinal atrophy may develop as a recessive trait.

FIP

(See FELINE INFECTIOUS PERITONITIS.)

Fipronil

A member of the phenylpyrazole family of non-systemic insecticides/acaricides applied topically for the treatment and prevention of flea and tick infestation in cats and dogs. It acts by blocking the invertebrate neurotransmitter γ-aminobutyric acid, causing uncontrolled activity of the nervous system and death. In cats, one application is active for up to five weeks against fleas and for one month against ticks. In dogs, it is active for two months against fleas and for one month against ticks. It is not recommended for use on cats under 12 weeks or dogs under 10 weeks old, nor for

VetBooks.ir

animals suckling young. In view of the risk of animals becoming infected with tick-borne diseases abroad (see CANINE BABESIOSIS), it may be beneficial to treat them with such long-acting products before travelling. Fipronil is toxic to rabbits, GALLINACEOUS BIRDS and fish.

Fire-Extinguishers

These are required in commercial kennels under the terms of the Animal Boarding Establishment Act 1963.

Fires

Fire is used as a management tool when working with heather and moorland. It also removes non-flying ARTHROPODS such as TICKS and thereby the diseases that they carry. Many fires are accidental or malicious and can result in deaths of animals, BURNS or SMOKE INHALATION. Fires involving animals, particularly farm animals, are included in the WELFARE CODES FOR ANIMALS.

Fireworks

Animals can react adversely to fireworks. All types should be kept away from them. Farm animals and horses should be in field far from bonfires or activity. If used to housing, it is probably best to house them and also try and cover windows etc. Similarly, placing pet or caged animals in a quiet place and away from the noise and flashes is helpful. Staying with pets and horses can be helpful provided the attendant is calm. Sedatives can be used but it is better to try and familiarise the pet by means of specific CDs which allow the animals to slowly become accustomed to loud noises. (See also THUNDERSTORMS.)

Firing

An old-fashioned treatment of thermocautery for locomotory injuries, used mainly in horses and sometimes dogs. It is a form of counter-irritation undertaken with a red hot iron under local anaesthesia, and usually involving the lower limb. It is mainly used in ligament injuries, and is thought to aid healing by resulting in enforced rest from the pain produced. There are doubts about its efficacy and the RCVS proposed a ban in the 1990s. However it was accepted that a veterinary surgeon must justify the need to fire based on the failure or absence of an alternative treatment. It is used commonly in some parts of the world but is not listed in the MUTILATIONS (PERMITTED PROCEDURES) REGULATIONS.

Bar firing involves burning the skin over the and around an area of tendon strain; pin firing involves localised burning directly into an affected tendon or other inflammatory lesion such as a CURB or a bony EXOSTOSIS.

Firocoxib

A non-steroidal anti-inflammatory drug used as a painkiller in canine osteoarthritis and to control inflammatory responses and post operative pain; it is also licensed for horses. It acts by inhibiting prostaglandin synthesis.

FIS

(See FOAL IMMUNODEFICIENCY SYNDROME.)

Fish, Diseases of

These are covered by the Diseases of Fish Act, and all are NOTIFIABLE in Britain: furunculosis and columnaris (bacterial); infectious pancreatic necrosis, viral haemorrhagic septicaemia, infectious haematopoietic necrosis and spring viraemia (viral); whirling disease (protozoan); ulcerative dermal necrosis and erythrodermatitis (of unknown cause).

Yersinia ruckeri infection causes the death of trout and is called ENTERIC REDMOUTH DISEASE. The fish become lethargic, dark and swim near the surface and show exophthalmos and small haemorrhages particularly on the pectoral fin. It appears to affect the heart.

On a fish-farm in England, 4,900 rainbow trout died from CEROIDOSIS over a four-month period. Affected fish swam on their sides or upside down, and often rapidly in circles. A few were seen with their heads out of water, swimming like porpoises.

Aquarium fish may be affected with fish tuberculosis, caused by *Mycobacterium piscium, M. platypoecilus*, or *M. fortuitum*. These cause a granulomatous condition which can prove fatal. Skin infection may develop in people handling diseased fish. (See also PETS, CHILDREN'S AND EXOTIC; WHIRLING DISEASE; SPRING VIRAEMIA OF CARP.)

Fish, Poisoning of

This may occur through liquor from silage clamps seeping into streams, etc. The following, in very small concentrations, are lethal to fish: DDT, Derris, BHC (Gammexane), Aldrin. Many agricultural sprays may kill fish, as will snail-killers used in fluke control. In one case, many thousands of trout died. The owner of the trout farm reported that they had been leaping out of the water on to the banks. The Devon VI Centre's findings suggested that the inadvertent contamination by excessively chlorinated water, into the stream supplying the trout farm, was to blame. In Hampshire the flushing of drains with a chlorine preparation led to similar trouble in river trout. The autopsy findings were 'scalding of the flanks, fins, and gills'. (See also AFLATOXINS.)

Mortality among young salmon in cages was found to be caused by heavy colonisation of gills by *Trichophyra* species protozoa.

VetBooks.ir

Toxins from CYANOBACTERIA in plankton can cause a high fish mortality; though clams, oysters, scallops, and mussels can absorb the alkaloids without harm.

In people, paralytic shellfish poisoning can occur within 30 minutes; deaths from respiratory paralysis within 24 hours have been recorded.

Fish-Farming

Fish-farming is a rapidly expanding industry, especially (in the UK) in Western Scotland. Rainbow trout and Atlantic salmon are the main species farmed. As the salmon cages are floated in sea lochs, the fishes come into close contact with wild fish attracted by the feed which may pass out of the cage. Thus disease may be spread from the wild fish to the farmed, with results that can be devastating. Fish lice are the greatest problem; they literally eat the fish alive.

In mainland Europe, carp and eels are farmed. Tilapia is an African fish which is farmed in various countries; it can be farmed in the warm water effluent from power stations. Sea bream and turbot are also farmed. In the USA, channel catfish are farmed in the southern states. The world's largest producer of farmed fish, however, is China, where more than 20 species are produced.

The FARM ANIMAL WELFARE COUNCIL issued a report on the welfare of farmed fish in 1996.

Fish-Keeping

This very popular hobby mainly concentrates on tropical fish. Many of these are imported and may have travelled a considerable distance before arriving in the UK. The methods used for their capture in some countries may cause injury. The result of this and of subsequent mishandling may not be apparent until the fish are in the possession of the hobbyist. Deaths even then can still be due to the method of capture.

Fish Louse

(See ARGULUS.)

Fish-Meal

Fish-meal is largely used for feeding pigs and poultry, although it is also added to the rations for dairy cows, calves and other farm livestock. It is composed of the dried and ground residue from fish, the edible portions of which are used for human consumption. The best variety is that made from 'white' fish – known in the trade as white fish-meal. When prepared with a large admixture of herring or mackerel offal it is liable to have a strong odour, which may taint the flesh of pigs and the eggs of hens receiving it.

Fish-meal is rich in digestible, undegradable protein, calcium, and phosphorus; it has smaller amounts of iodine and other elements useful to animals. It contains a variable amount of oil. It forms a useful means of maintaining the amount of protein in the ration for all breeding females and for young animals during their period of active growth. From 3 per cent to 10 per cent of the weight of food may consist of white fish-meal. When pigs are being fattened for bacon and 'fattening-off' rations are fed, the amount of fish-meal is reduced; during the last four to six weeks it is customary to discontinue it entirely.

Many investigations have emphasised the very great economic value of fish-meal for animals fed largely upon cereal by-products. It serves to correct the protein and mineral deficiencies of these and thus enable a balanced ration to be fed. It serves a very useful purpose by enabling more home-grown cereals to be fed and largely replaces protein-rich imported vegetable products. (See also AMINO ACIDS; DIET AND DIETETICS.)

Fish Oils

Livestock owners should beware of feeding inferior fish oils, which often cause illness owing to their quickly becoming rancid, in place of good-quality cod-liver oil. (See RANCIDITY.)

Fish Scale Disease

(See ICHTHYOSIS.)

Fish Solubles

Concentrated and purified stickwater; the liquid which is pressed out of fish during oil-extraction and meal-making processes.

Fistula

(plural, Fistulae)

An unnatural narrow channel leading from some natural cavity, such as a duct of the mammary gland, or the interior of the rectum or ANAL SAC, to the surface. A fistula may result from a congenital abnormality or, occasionally, may be created artificially by a surgeon. In cows, treads by neighbours, tears by barbed wire, bites or other injury to the teats sometimes result in a fistula through which milk escapes from the side of the teat. In a dental fistula, which occurs in cats and dogs most commonly but is also seen in the horse, an abscess develops at the root of a molar tooth, and the pus burrows upwards and bursts through the skin on to the surface of the face (See MALAR ABSCESS).

Occasionally a fistula heals, but often it is extremely hard to close, especially if it has persisted for some time. Surgery may be necessary.

Fistulous Withers

Fistulous withers is a condition in which a sinus develops in connection with the withers of the horse. It may follow an external injury such as

VetBooks.ir

from an ill-fitting saddle and infection with bacteria, when, on account of the poor blood supply, local necrosis (death) of the ligaments above the vertebrae, or of the summits of the spinous processes, with suppuration, sets in. *Actinomyces* organisms are sometimes found (also *Brucella* in areas where it has not been eradicated). In other cases, filarial worms have been found embedded in the ligament, and are responsible for those cases which arise without any previous history of injury to this part of the body.

Signs There is pain and swelling over the withers, perhaps more obvious on one side than the other, and working horses resent the application of the collar, or may be reluctant to work. Later on the swelling usually bursts, but it may appear to subside in a few cases. The openings which are left when the purulent material is discharged may heal over in time, but other swellings form and burst as before. In many cases one or two openings remain permanently and a thin stream of pus is constantly discharged.

Treatment Fistulous withers is always a serious condition which should be treated before great and perhaps irreparable damage has been done to the tissues involved. Old-standing cases are notoriously difficult to treat, and many animals have to be destroyed.

The application of poultices and blisters to the outside is absolutely useless. Antibiotics may be effective; otherwise, extensive surgery may be necessary.

The treatment generally takes from two weeks (in very slight cases) to as long as three months or more, where the sinuses are deep and bone is involved.

Fits

Fits is another name for convulsive seizures accompanied usually by at least a few seconds of unconsciousness. Epilepsy is the commonest cause of fits in the adult dog. The animal may be relaxed or even asleep at the time when the fit occurs, and the first phase consists of a tonic spasm of voluntary muscle with arrest of respiration; this lasts 30 to 40 seconds and is succeeded by clonic contractions of limb muscles ('galloping'). After this the dog usually appears to be exhausted for a period varying from a few seconds to a few minutes, with a gasping form of respiration. Some dogs then get up and appear normal almost immediately, while others wander restlessly for half an hour or more, bump into furniture and eat greedily if they find any food. The pattern of the fit is reasonably consistent in any individual dog, but varies considerably from one dog to another. In between these fits, the dog appears to be entirely normal.

Fits may also: occur during the course of a generalised illness such as canine distemper or rabies; follow a head injury; be associated with a brain tumour; accompany hypocalcaemia; or follow some types of poisoning. In puppies, hydrocephalus is a cause of fits, but more commonly cutting of the teeth or infestation with parasitic worms.

Deprivation of drinking-water may cause convulsions in dogs as in pigs. (See SALT POISONING.)

Fits are also encountered in cage birds, especially African Grey and Timneh Grey parrots (*Psittacus erithacus erithacus* and *P. e. s. timneh*). The cause is nearly always dietary (predominantly hypocalcaemia due to feeding a calcium-deficient diet, but sometimes hypoglycaemia is recognised). Treatment is, usually, simply by adjusting the diet. Epilepsy is occasionally encountered in Amazon parrots (*Amazona* species); phenobarbitone is usually effective.

Treatment Anti-convulsant drugs, such as phenobarbitone or bromides, may be successful; the dose being the lowest found to control fits over a period. In dogs in which these drugs produce side-effects, phenobarbitone may be tried, though it may cause whining in some dogs. Diazepam is useful, given rectally during a convulsion. (See CONVULSIONS; EPILEPSY; HYSTERIA, CANINE.)

FIV

(See FELINE IMMUNODEFICIENCY VIRUS.)

'Five Freedoms' for Farm Animals

These are used as a basis for establishing the parameters of welfare for farm animals. It implies both a fitness and a sense of well-being for the animal. The "freedoms" are: 1. Freedom from hunger and thirst. 2. Freedom from discomfort. 3. Freedom from pain, injury and disease. 4. Freedom to express normal behaviour. 5. Freedom from fear and distress. They evolved from a previous set of five freedoms produced by the Report of the Technical Committee to Enquire into the Welfare of Animals Kept Under Intensive Livestock Husbandry Systems, the Brambell Report, December 1965. The so-called Brambell's Five Freedoms were freedom to stand up, lie down, turn around, groom themselves and stretch their legs. (See FARM ANIMAL WELFARE COMMITTEE.)

5-HT

5-hydroxytryptamine. (See SEROTONIN.)

5-HTP

(See 5-HYDROXYTRYPTOPHAN.)

5-Hydroxytryptamine (5-HT)

(See SEROTONIN.)

F

VetBooks.ir

5-Hydroxytryptophan (5-HTP)

A naturally occurring amino acid also known as OXYTRIPTAN and it is a chemical precursor and intermediate stage in the biosynthesis from TRYPTOPHAN of the neurotransmitters SEROTONIN and MELATONIN.

NB. 5-Hydroxytryptophan is used as a dietary supplement for the treatment of depression in humans. If eaten by dogs it can result in sudden onset of nervous signs with vocalisation, twitching, fixed dilated pupils, vomiting, diarrhoea, muscle rigidity, hyperaesthesia and disorientation. Treatment with cyproheptadine and DIAZEPAM may result in recovery over a period of about four to five days.

'Flabby Bag'

A name often used for MILK-DROP SYNDROME in dairy cows or one form of LEPTOSPIROSIS in cattle caused by *Leptospira hardjo*.

Flaccid

Soft, weak; often applied to muscles or organs when lacking muscular tone.

Flagella

(plural, Flagellae)

Whip-like processes possessed by certain bacteria and protozoan parasites and used for purposes of movement.

'Flail Chest'

A condition which may result when one or more ribs are fractured in two places; the damaged area moves slightly inwards on inspiration, and outwards on expiration, rather than as normal.

Flashing

A term used to describe the behaviour of fish when suffering from skin irritation caused by parasites or other conditions. In trying to rub against stones or other objects in an attempt to relieve the condition, they often have to lie on their sides. When turning from the normal position to their side, and back again, 'flashing' is noticed by the observer.

Flat-Coated Retriever

Not a common breed these days. Inherited conditions by unknown mechanisms that are seen include ENTROPION, DISTICHIASIS and GLAUCOMA.

'Flat Pup' Syndrome

'Flat pup' syndrome is a condition in two to three-week-old puppies, in which the hind-legs and sometimes also the forelegs are splayed out sideways. The condition usually corrects itself, although physiotherapy may be helpful. (See 'SWIMMERS'.)

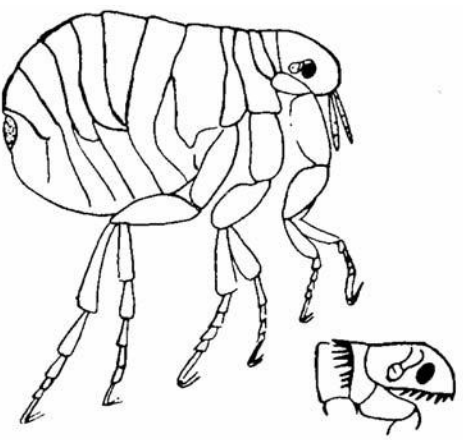
Flavine Compounds

Among these are acriflavine, euflavine, and proflavine, derivatives of aniline. Acriflavine, the hydrochloride of diamino-methyl-acridinium, is an orange-red crystalline powder, soluble in water and forming a powerful antiseptic solution in strengths of 1 in 1000. It stains horn and skin tissues bright yellow. It has been used to control bacterial infection, and stimulate healing, in wounds.

Flaviviruses

Viruses of the family *Flaviviridae* are single-stranded RNA viruses which are arthropod-borne. They cause YELLOW FEVER, hence the name (*flavi*, yellow). They cause ENCEPHALITIS and include JAPANESE B ENCEPHALITIS, LOUPING-ILL, MURRAY VALLEY ENCEPHALITIS, USUTU VIRUS, WESSELSBRON DISEASE, WEST NILE VIRUS, etc.

Flavobacterium columnare



An organism reported as a cause of gill rot in koi carp.

Flavomycin

Proprietary name for the antibiotic flavophospholipol (bambermycin) formerly marketed as an in-feed growth promoter. It is not licensed in the EU. (See ADDITIVES.)

Flea-Collars

Flea-collars for dogs and cats are used to assist in flea control. They are impregnated with a parasiticide, or insect growth inhibitor. Carbaril, propoxur and diazinon are among the insecticides used. All will kill fleas when used as directed; most are active for several months. They should be loosely fastened and the animal should not be allowed to chew them.

Pulex irritans. × 20.
Inset: head of dog flea.

VetBooks.ir

Animal-owners should select a reliable make, for sometimes ineffective collars appear on the market; they should also watch for any signs of skin inflammation as a few animals are allergic to some of the chemicals used. Children should not be allowed to play with the collar.

Fleas

Fleas are members of the order Siphonaptera.

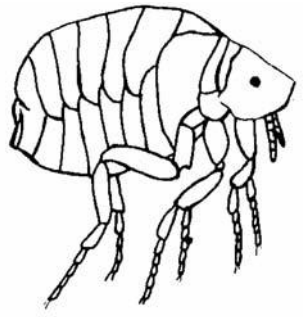
They produce non-sticky eggs that drop to the floor or bedding. They appear as white specks, like small sugar grains, and pop when burst. Hatching is dependent on environmental temperature and humidity and takes from two days (in summer) to 12 days or much longer in cold weather.

When fully grown, the legless larva spins a cocoon, in which the pupa develops. It can remain alive in the cocoon for several years.

If infestation is suspected, but adult fleas cannot be seen, combing may gather some black or dark-brown flea faeces. These will form a reddish halo if placed on moistened cotton wool.

Pulex irritans is the human flea, but it is frequently found on dogs and cats, and occasionally on pigs and goats.

Ctenocephalides canis is the dog flea, but is often found on man and cat. It can transmit *Dipylidium caninum*, as also may the cat flea, *C. felis*, and the human flea, *P. irritans*. Recent surveys indicate that *C. felis* is the most common species found in UK homes. All these fleas cause severe irritation, and in young or debilitated animals may cause anaemia if numerous. Sensitisation to flea-bites is an important cause of ECZEMA.



Spilopsyllus cuniculi, the European rabbit flea, a vector of MYXOMATOSIS, is now considered to be second in importance to the mosquito in this respect; it also infests cats and occasionally dogs. It was introduced in 1966 into Australia, as a vector of myxomatosis, in order to reduce the rabbit population.

Reproduction of the flea is partly dependent on the reproductive hormones of the rabbit, and so the greatest numbers are present during the rabbit's pregnancy.

In cats *S. cuniculi* attach to the ear pinna causing an itchy dermatitis, but do not breed even on pregnant cats.

Archaoppsylla erinacei, the hedgehog flea, only occasionally and temporarily infests dogs, but may cause an allergic dermatitis in them. Cats might become infested too.

Echidnophaga gallinacea, the 'stick-tight' or chicken flea, is usually found attached in dense masses to the head of a fowl or the ear of a dog or cat. Man, horses and cattle are occasionally infected. It is a common parasite throughout the tropics and is frequently the cause of death in poultry. The female flea, after fertilisation, inserts its mouth parts into the cuticle of the host, and remains there. Ulcers may form; and in any case the flea is difficult to move.

Echidnophaga gallinacea. × 30.

Tunga penetrans, the true jigger flea, differs only in slight details from the latter species. The female, however, penetrates the skin, and lying in an inflammatory pocket with an opening to the exterior, becomes as large as a pea. It is found in Africa and America in man and all the domestic mammals, especially the pig. The eggs are laid in the ulcers; and the larvae crawl out and pupate on the ground.

Flea infestation may be of veterinary importance in intensively-reared ruminants.

Destruction of fleas (See INSECTICIDES). Bedding must be destroyed or disinfected and the surrounding floorboards and cracks cleaned thoroughly using a vacuum cleaner or the animal will shortly be reinfested. This is even more important than ridding the host of fleas. There are sprays for use on bedding and soft furnishings and can help kill fleas and stop eggs hatching.

Powders and aerosol sprays, applied externally; 'pour on' or 'spot on' formulations applied to the skin under the fur or coat; shampoos; and tablets to be taken internally are all available for the control of fleas. There are many preparations marketed: natural pyrethrins and their synthetic derivatives; organophosphorus compounds; carbamates and amidines and avermectins are all used in topical applications. Imidacloprid can be used in dogs, cats and rabbits, but fipronil can be used only in dogs and cats, being toxic in rabbits. Collars impregnated with carbamates or pyrethroids are popular among owners, but their effectiveness appears to be limited to prevention of reinfestation.

Cythioate, an organophosphorus compound, and lufenuron, a benzoyl urea derivative, are given as tablets or oral suspension.

Permethrin, a pyrethrin derivative, is formulated as a powder, 'pour on' and shampoo. Aerosol sprays often contain a mixture of piperonyl

VetBooks.ir

butoxide and pyrethrins. All are effective, properly used, but the manufacturers' directions must be followed carefully, with regard both to handling and to the suitability of the particular product for cats or dogs. Puppies and kittens must only be treated with products recommended for use in young animals.

(See also FLEA-COLLARS; INSECT GROWTH REGULATOR.)

Fleckvieh Cattle

A breed formed around 1600 in Germany from the Simmental cattle of Switzerland. They have a white face and are used for milk, meat and as draught animals.

Fleece

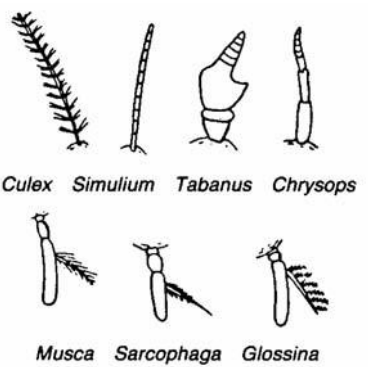
Sheep fleece covers the whole sheep's body and requires shearing annually before the summer except for a few breeds that naturally shed their wool. It is removed from the sheep in one piece. In the Middle Ages, sheep were mainly kept for their fleece, mainly spun into wool for clothing and this resulted in owners becoming very wealthy. In the 20th century the creation of semi-synthetic materials meant that the fleece has had little value and was mainly undertaken for welfare reasons. In the 2010s wool prices have increased. The average sheep fleece is 2.3 kg to 4.5 kg (5 lb to 10 lb), although in sheep bred for wool the weight might be about 13.5 kg (30 lb). Value of the fleece partly depends on its CRIMP.

Flemish Giant Rabbit

A breed of domestic rabbit weighing up to 10 kg. It has a long, muscular body and broad hindquarters. Bucks have larger heads than does.

Flexibacteriosis in Fish

A disease cause by gliding bacteria *Flexibacter maritimus*, it results in erosive lesions on the body surface due to necrosis of the body, head, fins and occasionally the gills. They can be called 'eroded mouth syndrome' or 'black patch necrosis'. It is seen in marine fish including Dover sole (*Solea solea*), sea bass (*Dicentrarchus labrax*), turbot (*Scophthalmus maximus*) and in wild and farmed salmon (*Salmo salar*).



Flies

Flies are mostly, but not exclusively, members of the order Diptera – the 2-winged flies.

Even the common housefly can transmit infection such as ANTHRAX and TUBERCULOSIS, and also various species of parasitic worms. The stablefly's role in the production of summer mastitis is well known, and other flies, such as the sheep headfly, may be responsible for cases of this disease too. The autumnfly (and almost certainly others) can transmit an eye worm of cattle, and also the infective agent *Moraxella bovis* which causes the more commonly recognised contagious keratitis or New Forest disease.

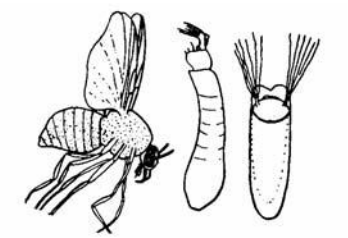
The approach of a cloud of flies, such as the headfly, will cause cattle to cease grazing and huddle together. The movement or presence of a mass of even non-biting flies over the animal's body represents a further cause of 'worry' or restlessness; and both the headfly and the autumnfly feed on secretions from eyes, nose, etc., and on the serum exuding from small wounds.

Cattle may become sensitised to the secretions poured into the bite wound, so that an allergy arises with sometimes the production of serious skin lesions which, in turn, may attract other flies.

Antennae of various flies. The small hair in the lower row is the 'arista'.

Sawfly poisoning was first reported in Denmark in 1974, but it has been recognised in Australian cattle and sheep since 1955, and heavy losses have occurred. Goats are also susceptible.

The sawfly larva (*Arge pullata*) is bright yellow with black dashed lines on the back. It defoliates birch trees, and then drops to the ground to pupate or search for more food.



Order Diptera Insects which have one pair of wings.

Simulium (buffalo gnats) The flies of this genus are small, black or reddish-brown, thick-set hump-back flies – hence their name. The females at certain times appear in swarms and attack cattle, horses and other animals.

The eggs are laid in water. The larvae, which are aquatic and creep about like leeches, can only live in well-aerated running water; in still water they are asphyxiated. The larva when mature spins a silky cocoon which is attached to water weeds. In this the pupa lies loosely, breathing by means of extruded gill-tufts. The fly is very active in Central

VetBooks.ir

Europe, where cattle may die in two hours after an attack. They show laboured breathing, stumbling gait, rapid pulse, and swellings in pendulous places. In less severe cases loss of appetite, abortion, depression, and temporary or permanent blindness may result.

Simulium. Adult larva, and pupa. The adult fly is magnified × about 10.

Sandflies Two-winged flies, of which the blood-sucking females transmit infections, including that of LEISHMANIASIS, which is reported in dogs.

Mosquito The mosquito, the carrier of malaria and yellow fever to man, is also of importance in tropical veterinary medicine, transmitting diseases such as avian malaria (see *Plasmodium gallinaceum*), HEARTWORM of dogs, BLUETONGUE, EQUINE ENCEPHALITIS, HORSE-SICKNESS, AFRICAN and RIFT VALLEY FEVER). In temperate climates, too, mosquitoes are important disease vectors.

Four genera of mosquitoes are of veterinary importance: *Aedes, Anopheles*, *Culex* and *Mansonia*.

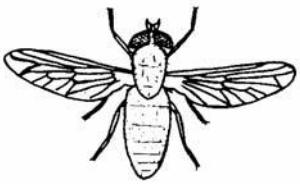
Eggs are laid on the surface of water or floating vegetation, either singly (*Aedes* and *Anopheles*) or as 'rafts' of eggs.

Larvae undergo three moults, and develop only in water, in which they are highly mobile.

Culex modestus is the main vector of WEST NILE FEVER in Europe transmitting infection from birds to humans, the mosquito is found in southern England.

Larvae-eating fish, such as *Alphanus dispar*, are being used in the Nile Delta and elsewhere for mosquito control. (See also DDT and DIELDRIN.)

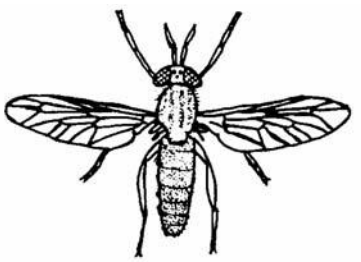
Midges, biting (culicoid) (see under this heading)



Gadflies (tabanidae) The family of the gadflies is a large and important one, as the females are blood-suckers and are found in many parts of the world. In the UK the name 'gadfly' is usually restricted to WARBLES. It is eradicated in the UK but GADDING still occurs.

Gadfly eggs are laid in masses on leaves and plants near water. The larvae are more or less aquatic, but towards maturity they live in damp earth or decaying vegetation. The larva is cylindrical, pointed at both ends, and with most of the segments carrying pseudo-pods or false feet. The pupa resembles that of a moth. In temperate climates, development takes nearly a year. The males feed on plant juices, but the females are blood-suckers, and in addition carriers of various diseases – for example, trypanosomiasis, swamp fever in horses, and filariasis in man.

The bite is painful, and causes much irritation to horses and cattle, resulting in gadding, decrease in milk yield, and so on. No remedies are really satisfactory, although nets have been used with some success on horses.

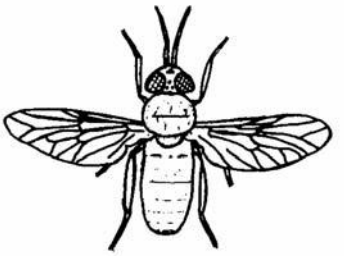


If the pools most commonly frequented by these flies are covered with a thick layer of paraffin oil, the flies are killed. If this plan is adopted early in the season the numbers can be kept under control.

Tabanidae These are large, stout flies, the females of which suck blood and transmit diseases such as SURRA (mechanically) and other blood diseases such as ANTHRAX. Another species transmits swamp fever in horses (see EQUINE INFECTIOUS ANAEMIA).

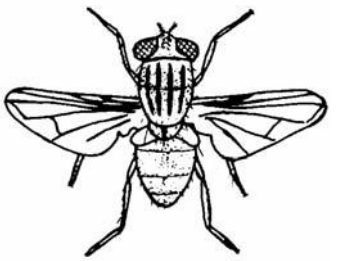
Tabanus. × 2.

Haematopota This is also a worldwide genus. The species has smoky wings, and include the British clegg or horse-fly which, in addition to being a veritable pest to horses and other domestic animals, inflicts a very painful bite in man.



Haematopa. × 3.

Chrysops is distinguished by its long slender antennae, and its green or golden eyes spotted with purple. It is found all over the world, including Britain. This genus is the carrier of the parasite of Calabar swelling in man. It also can inflict a very painful bite.



VetBooks.ir

The non-biting two-winged flies have an even greater significance to man and his animals than the biting flies.

Chrysops. × 2.

Muscidae The flies belonging to this family are smallish to medium-sized flies. The type of this family is *Musca domestica*.

Musca. × 4.

Musca domestica The great majority of flies found in houses belong to this species. It is a medium-sized fly with four black stripes on its back, and a sharp elbow in the fourth wing vein. The eggs are laid; about 120 in a batch, preferably in horse manure, but occasionally in human or other excreta. They hatch rapidly (depending on the environment), and the issuing larva (or maggot) feeds and moults and finally becomes full grown in four to five days. It leaves the manure at this stage, and crawls to a dry spot where it pupates. The puparia are more or less barrel-shaped and dark brown in colour. In another four or five days in summer the adult fly emerges. The shortest time on record between the laying of the egg and the appearance of the adult is eight days; 10 to 12 days is more normal. In three to four days the female is ready to lay eggs. The fly lives over the winter in the pupal stage, although in kitchens and warm places adults may be seen at every season of the year.

The house-fly can transmit disease by swallowing bacterial spores, and either bringing them up in their vomit or passing them out in their faeces; or by carrying them about on its hairs and legs. Two species of stomach worm are carried by this fly, in which they pass part of their life-cycle. Among other organisms known to be carried by this fly are anthrax, tuberculosis, and many species of worm eggs. (See FLY CONTROL MEASURES, below.)

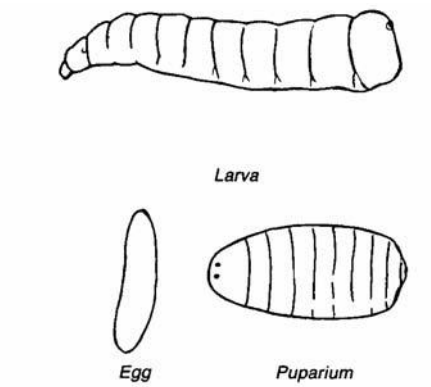


Diagram to illustrate the life-history of *Musca domestica*.

Headfly This is a non-biting fly which, as its name *Hydrotaea irritans* suggests, is a cause of great irritation to cattle, sheep, etc., especially since so many headflies often settle on the same animal. The fly will take advantage of any abrasion on the sheep's skin. Both fly-repellents and head-caps have been used for control. Pine-tar oil is a useful repellent.

The headfly is responsible for carrying bacteria to cows' teats (especially when already damaged by biting flies or other causes), and appears to have an important role in producing SUMMER MASTITIS. It is also involved in the spread of New Forest eye infection caused by *Morexalla bovis*.

The headfly. (Crown copyright photograph.)

Face flies These 'autumn flies' (*Musca autumnalis*) plague beef and dairy cattle, and horses, at pasture, feeding on watery secretions from nostrils and eyes.

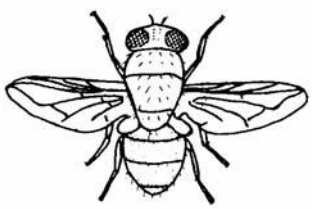
Dipterous larvae or maggots – Myiasis The most important to the veterinary surgeon and the agriculturist are those non-biting muscid flies which have taken on a parasitic existence in their larval stages. Myiasis means the presence of dipterous larvae (or other stages) in organs and tissues of the living animal and the disorders and destruction of tissue caused thereby. (See STRIKE.)

The myiasis-producing flies can be divided into three groups: specific, semi-specific and accidental.

Specific: This group consists of flies which need to breed in living tissue. It includes *Chrysomyia bezziana*, *Cordylobia anthropophaga, Wohlfahrtia magnifica, Booponus intonsus*, and all the Oestridae.

Semi-specific: This group consists of flies which, normally breeding in carcases, may live in the living animal. It includes the blow-flies, the sheep-maggot flies, and some of the flesh-flies.

Accidental: This group includes all flies the larvae of which, accidentally swallowed with the food, may live in the intestine.



The more important of the above flies are considered below.

'Blow-flies' Calliphoridae are largish muscids of a metallic or yellow colour.

'Common blow-fly' or 'Blue-Bottle' (*Calliphora* sp.) has reddish palps, black legs, and a bristly thorax. The general colour is dark blue with lighter patches on the abdomen. The colour, however, is not lustrous. The ova are usually deposited in decaying animal matter, but occasionally in living tissue.

'Green-bottle fly' (*Lucilia sericata*) is the British sheep-maggot fly. It is also found in Australia and America.

L. caesar, a common species in Europe, does not 'blow' sheep in this country, but does so in countries such as Russia, where other species are absent. Other species of *Lucilia* in India and Australia occasionally are also implicated.

Lucilla. This fly is larger than the house-fly and smaller than the blow-fly.

'Copper-bottle fly' (*Lucilia cuprina)* is the strike fly which attacks sheep in Australia and South Africa.

These are of a bright metallic or bluish-green colour, with many strong bristles on the thorax arranged in two parallel rows. There are no stripes on the thorax or abdomen. The cheeks are not hairy as in *Calliphora*.

This genus blows wool, but occasionally infects wounds.

Chrysomyia bezziana, found in India, Africa and the Philippines, is a metallic greenish-blue blow-fly, closely related to *Lucilia*, but with dark transverse abdominal bands and with fewer and less-developed thoracic bristles. The metallic sheen is more brassy than in *Lucilia*. This fly breeds only in living tissue – it discharges from natural orifices, or in sores and cuts. Up to 500 eggs may be laid at one time. They can hatch in about 30 hours, and the larvae rapidly reach maturity, crawl out and pupate on the ground. Several other species of this genus are semi-specific myiasis flies, normally breeding in decaying matter. These include *C. albiceps*, a notorious sheep-maggot fly in Australia.

'Screw-worm fly' (*Callitroga americana*) in America can be distinguished from the old-world species by the three well-marked blue dorsal stripes on the thorax and dark hairs on the abdomen. It is of a dark bluish-green colour, with a well-marked yellowish-red face. (See also FLY CONTROL MEASURES, below.)

This species will lay eggs in decaying animal or vegetable matter, but will also oviposit in any diseased tissue, in wounds in the vulvae of freshly calved cows, the umbilical cord of calves, and so on. The ova can hatch in 24 hours, and the maggots in four to six days. The pupal stage on the ground lasts three to 10 days. The maggot resembles a blue-bottle maggot, but the deeply cut constrictions between segments and the prominent rings of spines give it its popular name.

As soon as the egg hatches, the larva starts burrowing into the flesh. It can penetrate the sound tissue of living animals, and may even lay bare the bones.

'Tumbu fly' (*Cordylobia anthropophaga*) is a specific myiasis fly in Africa, attacking many hosts. It is a dirty brownish-yellow blow-fly with blackish markings. Eggs are laid in dust and rubbish on which the host, usually a dog, is accustomed to lie. The small larva may live apart from the host for 10 days, but it may eventually burrow into the epidermis or die. It moults in this position, and forms a 'tumbu' below the skin with an opening to the exterior through which it breathes. The 'tumbu' does not suppurate unless the larva dies. The larva

VetBooks.ir

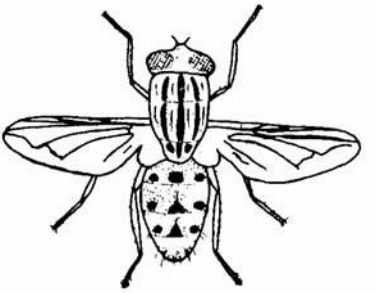
VetBooks.ir

emerges in about seven or eight days, and two or three days later it pupates. The adults emerge in about 20 days. This fly does not burrow into the deeper tissues. The scrotum is a common site of the maggot. Putting a drop of oil or Vaseline over the breathing hole will force the larva to protrude, when it can be removed.

Booponus intonsus is a light yellow specific myiasis fly found in the Philippines, which is somewhat allied to *Cordylobia*. It infects bovines and goats.

The eggs are laid on the hairs on the lower parts of the legs; and the larvae make their way to the coronet and bury themselves in the flesh. The larvae resemble the screw-worm. The larval period seems to last two or three weeks, when it leaves the host and pupates in the ground. The pupal life is 10 days.

The larvae, called the 'foot maggot', cause a considerable lameness with numerous superficial wounds and distortion of the horn.



Cordylobia. × 2½.

'Flesh flies' (Sarcophagidae) are closely related to the Muscidae. The body is more elongated than that of the blow-flies, and they are usually grey in colour, with a mottled abdomen and a striped thorax. They generally produce living larvae instead of laying eggs. Two genera are important.

Sarcophaga spp. These are large grey flies with red eyes and square chequered markings on the abdomen. The third segment of the antenna is long. All the species normally breed in decaying animal matter, but may be found in old festering wounds. They are found throughout the world.

Wohlfahrtia magnifica resembles the preceding genus, but has well-defined round spots on the abdomen. The third segment of the antenna is short and the arista is without bristles. It is widely distributed in Russia, Asia Minor and Egypt. The larvae never attack carcases, but are always found in wounds and natural cavities of living animals. The fly deposits living larvae on sores and discharges.

In Australia the most important sheep-maggot flies are *Calliphora augur*, a large orange-coloured fly; *C. stygia*, the common sheep-maggot fly, often called the 'golden-haired blow-fly'; and *Chrysomyia albiceps* var. *putoni*, the larva of which is known as the 'hairy maggot'.

Wohlfahrtia. × 3.

Injuries due to maggots The injuries due to maggots may be roughly divided into two classes – larvae attacking wounds and discharges, and larvae attacking the wool of sheep. The former type of injury is found on any animal, including man. The flies usually, but not always, select old sores. Some, such as *Chrysomyia americana* (the 'screw-worm') will penetrate into the sound tissue, and prefer fresh wounds or carcases. The infected wound usually has a watery discharge. Prevention is obviously most important. (See also under MYIASIS.)

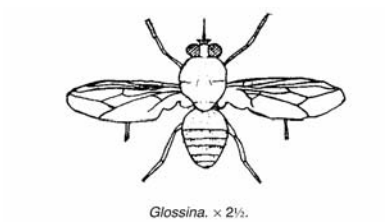
Blood-sucking muscid flies These flies, which resemble the house-fly in general appearance, are responsible for an enormous amount of damage to farm animals. When one considers that they include such flies as the tsetse fly, the stable-fly and the horn-fly, this is easily understood.

Stomoxys This genus is mainly confined to Africa and Asia, but one species, *S. calcitrans*, the stable-fly, is worldwide in its distribution.

Stomoxys breeds in stable manure and in other places where moisture and organic material are found. The eggs hatch in about two to three days, and the larva, which is similar to but smaller than *Musca*, becomes full-grown in two to three weeks. The pupal stage lasts nine to 13 days. Development is more rapid in the tropics, where the time between egg and adult may be reduced to 12 days.

This fly is a serious pest to horses and other animals. It will also bite man. Apart from the extreme irritation of its bite, it can transmit anthrax, surra and other diseases. It is also the intermediate host of *Habronema microstomum*, a worm parasite of horses.

Stomoxys. × 3.



VetBooks.ir

Haematobia *H. stimulans* is a common blood-sucking parasite of cattle, and occasionally of horses and man, in Europe. It resembles *Stomoxys*, but has spatulate palps as long as the proboscis, and hairs on both sides of the arista. It breeds in fresh cattle dung. The larva becomes full-grown in about six to nine days, while the pupal stage lasts five to eight days.

Lyperosia *L. irritans* is very closely related to *Haematobia*, but can be distinguished from it by the absence of bristles from the underside of the arista. It is found in Europe (including the UK) and America. It is a very serious pest to cattle, clustering round the base of the horns, a habit which gives the fly its popular name of horn-fly. The irritation caused by their bites is estimated to cause a drop in milk yield amounting in some cases to 50 per cent. The flies breed in fresh cow dung. Flies emerge in about 15 days after the egg is deposited. The maggots must have moisture, and can be destroyed by any means which will dry the manure quickly. The horn-fly seldom goes far from its host, and may be destroyed by attaching splash-boards to ordinary dippers. The fly leaves the cattle at the moment of entering the bath, but the dip, caught and flung back by the splash-board, drenches and destroys the flies. The hotter and more excited the cattle, the closer the flies stick and the greater the number killed. Any oily dip is suitable. (See also FLY CONTROL MEASURES, below.)

Tsetse flies (glossina) The flies of this genus are, with one exception found in Arabia, confined to Africa. They are the notorious carriers of trypanosomiasis in man and animals. *Glossina* resembles a large stable-fly but has a feathered arista, long slender palps, a slender shaft to the proboscis, and a peculiar wing venation. The life-cycle is unusual: the female produces a single living larva at a time and deposits it when full-grown. It immediately pupates. One female produces only about a dozen larvae in her life.

More than a dozen species of *Glossina* are known. The most important are: *G. palpalis*; *G. morsitans*; *G. brevipalpis*; *G. longipalpis*; *G. pallidipes*; *G. tachinoides*.

Glossina. × 2½.

Bot and warble flies The bot family Oestridae consists of hairy, heavy flies with rudimentary mouth parts. The female attaches the egg, or, in the case of the nostril flies, places the larva on a suitable host, and the remainder of the larval life is parasitic. When mature the larvae leave the host and pupate on the ground.

These flies may be placed in three groups according to the habitat of the larva:

1. In the alimentary canal –
   Gastrophilus, the horse bot;
   Cobboldia, the elephant bot.
2. In the head sinuses –
   Oestrus, the sheep nostril fly;
   Rhinoestrus, the horse nostril fly;
   Cephalomyia, the camel nostril fly; and others.
3. In the subcutaneous tissue –
   Hypoderma, the warble-fly (See WARBLES);
   Dermatobia, the macaw worm fly; and others.

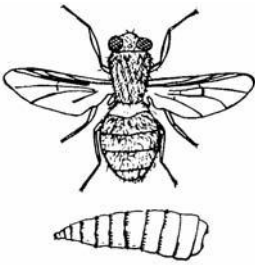
Bot flies The flies of the genus *Gastrophilus* are large and hairy, with large compound eyes and three ocelli. The females have an elongated ovipositor which is bent under the body when at rest. Four species are of importance.

G. intestinalis (*G. equi*), the common horse bot, has cloudy wings; it deposits its eggs on any part of the horse, but especially on the distal ends of the hairs. The eggs require moisture and friction (supplied by licking) before they will hatch.

G. nasalis (*G. veterinus*) is smaller, more hairy, and has a rusty-coloured thorax. It oviposits usually at the proximal ends of hairs under the jaw. It lays one egg and flies to a distance, returning later to lay another.

G. haemorrhoidalis has a bright orange-red tip to the abdomen. It deposits its eggs only at the base of the small hairs on the lips of the horse. The eggs may hatch without moisture or friction.

G. pecorum resembles *G. intestinalis*. In colour it is yellowish-brown to nearly black, with brownish-clouded wings. Its habits are similar to that species.



The distribution of the first three is universal, but the last seems to be restricted to Europe and South Africa.

The life-cycle of the species of this genus is not yet fully understood. Some of the newly hatched larvae may pierce the skin or buccal mucous membrane; in any case the larvae are found in various parts of the alimentary tract. Each species has its own special preference. *G. intestinalis* is usually found in the stomach, occasionally the duodenum; *G. nasalis* prefers the duodenum, but has been found in the pharynx and stomach; *G. haemorrhoidalis* is found in the stomach, duodenum, rectum, and even in the anus; while *G. pecorum* usually occurs in the pharynx or stomach, but may be recovered from any part.

Bots when present in large numbers in the stomach or intestine, or even in small numbers about the pharynx and anus, may cause a considerable

VetBooks.ir

suffering to their host by mere mechanical obstruction. The adult fly worries the horse considerably, especially the species *G. nasalis* and *G. haemorrhoidalis*, and may cause loss of condition.

Gastrophilus. (Adult fly × 2½, and 'Bot' × 2.)

Treatment Formerly, carbon disulphide, administered in autumn and early winter by stomach tube and followed by warm saline. This has been replaced by a haloxon formulation given in the feed and by ivermectin paste, which have both proved effective (also against roundworms). Withholding water four hours before and after dosing is recommended when treating against bots. (See AVERMECTINS; IVERMECTIN.)

Some control is possible by regular removal of the 'nits' from the lower limbs of grazing horses during summer.

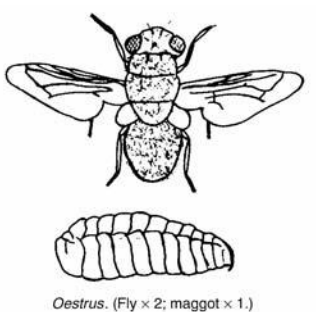
Oestrus *O. ovis*, the sheep nostril fly, is somewhat larger than the house-fly and is greyish-yellow to brown in colour. It is found practically all over the world. It deposits eggs, or larvae. The hovering female 'strikes' at the nostrils, and the young larva crawls up the nose, and may lodge in one of the sinuses of the skull. It remains there until fully grown, when it is sneezed out and pupates in the ground.

Prevention is by applying tar to the nostrils. This may be done by means of a salt lick, access to which may only be obtained by smallish holes (5 cm or 2 in) smeared with tar. Ploughing a single furrow across a sheep pasture allows the sheep to protect their nostrils from the flies, 'strike', and gives some measure of protection. Some anthelmintics are effective.

Rhinoestrus *R. purpureus* (*R. nasalis*), the horse nostril fly, is common in Central Europe and North Africa. It is a smallish fly with the body covered with small tubercles, and is closely related to *Oestrus*. The female deposits a number of living larvae at one time in the eyes or the nose of the horse (and occasionally man). The larvae may be found about the cranial cavities or even in the pharynx or larynx. Russian gadfly is a synonym.

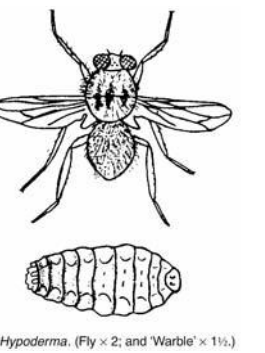
Hypoderma Two species of warble-fly, *H. bovis* and *H. lineatum*, are found in cattle (and occasionally in the horse). Both are very extensively found in Europe and America but have been eradicated from the UK and the disease is NOTIFIABLE.

H. bovis is a largish fly with yellow hair just behind the head. The underpart of the abdomen is nearly black, while the tail end is orange-yellow. The legs have few hairs.



H. lineatum is rather smaller with a reddish-orange tail and rough hairy legs.

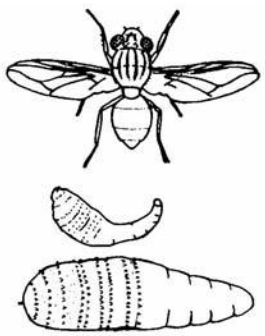
H. bovis lays its eggs one on the base of each hair at a time. The fly has a most terrifying effect on cattle, and causes them to gallop madly in all directions. *H. lineatum* irritates animals less than does *H. bovis*. The ova are generally deposited while the animal is lying in the shade. A number of eggs – up to 14 – are laid on the same hair, and are often in full view.



In both cases larvae emerge in several days and pierce the skin. They travel up through the connective tissue and finally reach the back. Under the skin the larvae form a small swelling (about the middle of winter), which moves about at first, but gradually becomes still and enlarges. A small opening appears in the centre through which the larva breathes. In spring the larva falls to the ground and pupates. Several weeks later the adult fly emerges.

The presence of the larvae may decrease the milk yield by 10 to 20 per cent, cause a considerable depreciation in flesh near the points where the larvae are, and enormously reduce the value of the hide. The adult fly also causes loss through the mad chasing about of cattle. (See also under WARBLES.)

H. diana is a warble-fly affecting deer in the UK and elsewhere.



Oestrus. (Fly × 2; maggot × 1.)

Hypoderma. (Fly × 2; and 'Warble' × 1½.)

VetBooks.ir

Dermatobia *D. hominis*, the macaw worm-fly, is a parasite of cattle and other domesticated animals (and occasionally man) in tropical America. It is a medium-sized fly, grey or steel-blue in colour, with pale brown wings. The female lays its eggs on the body of some blood-sucking arthropod, usually a mosquito. This carrier attacks an animal five or six days later, and the larvae, rapidly escaping from their shells, pierce the skin of the host, and form a local tumour near where they were deposited. In a month or so they emerge and pupate.

Dermatobia. (Fly and maggots × 1½.)

Pupipara This family, which includes the sheep ked and the horse ked (New Forest fly), was so called because live larvae are produced which pupate at once. The adults in this case are blood-sucking parasites with a hard integument with a broad neckless head and very stout legs ending in grasping claws. Wings are present or absent.

Hippobosca equina, the New Forest fly or horse ked, has wings which, however, are seldom used, the fly preferring to run swiftly between the hairs of the host.

Paragle fly *Paragle redicum*, an anthomyiid fly, lays its eggs in canine faeces, and the white specks have been mistaken for tapeworm segments. Larvae may also be passed alive through the canine (and also the human) gut.

Hymenoptera Insects which have two pairs of wings.

Sawflies These have four wings and a saw-like ovipositor. The larvae are said to be poisonous if swallowed.

Fly control measures Perceptive farmers have for many years realised the harmful effects of fly infestation on livestock. Controlled field trials, comparing the productivity of treated and untreated cattle, have convincingly demonstrated the advantages that can be gained by modern fly-control methods.

Flies interfere with normal rest and feeding. The approach of a cloud of flies often causes cattle to cease grazing and huddle together.

The horse fly (*Tabanus*), like the stable fly (*Stomoxys*), has a painful bite, and the wounds inflicted attract other flies; this exacerbates the 'worry' situation and often transmits even more infection. Some animals become sensitised to the secretions of biting flies, so that an allergy results. One example of this is the 'SWEET ITCH' of horses caused by biting (*Culicoid*) midges.

Flies are notorious for spreading livestock diseases. Even the common housefly (*Musca domestica*) can transmit anthrax, tuberculosis, and the larvae of some parasitic worms. The headfly (*Hydrotaea irritans*) is among several species that may transmit the bacteria that cause 'SUMMER MASTITIS'. This can lead to gangrene of part of the udder, usually with the permanent loss of use of one-quarter – and to great pain and occasionally death of the cow.

Besides interfering with grazing, the headfly causes infested sheep to scratch, rub and knock their heads, often breaking the skin. Open wounds then attract other flies, increasing the tendency to self-mutilation. Sometimes the whole poll region becomes raw. Pine-tar oil has been used as a repellent, and head caps for protection, but they are inconvenient to use.

Plastic tags impregnated with synthetic pyrethroids have been effective in the reduction of 'fly-worry' in cattle. For sheep too, tags containing CYPERMETHRIN and PERMETHRIN can be effective in controlling the severity of damage caused by headflies. Cyromazine, in a 'pour-on' formulation, is useful against blowfly larvae on sheep and lambs.

The activities of the autumn fly (*Musca autumnalis*) are very similar to those of the headfly. Both flies feed on secretions from nose, mouth, eyes and wounds and are among several species that transmit the various pathogens causing New Forest disease. This involves an acute and painful conjunctivitis, with inflammation also of the cornea, which becomes opaque, so that cattle are often rendered temporarily blind. Complications may result in permanent eye defects and impaired sight; but even without them the disease causes stress and, since it interferes with feeding, loss of condition can be appreciable.

Other bacterial diseases spread by flies include SALMONELLOSIS and BRUCELLOSIS; while viral diseases such as swine fever and foot-and-mouth have in the past been similarly transmitted in the UK. The larvae of some flies also parasitise animals, for example, the 'green-bottle' fly causing 'strike' in sheep, the sheep nostril fly, and the horse bot flies. The mere approach of warble flies causes cattle to stampede, and the larvae undoubtedly cause pain

during their migration through the cow's body, and probably irritation while present in the skin swellings, or warbles. In a few instances, cows have died following the accidental crushing of larvae in the warbles, and larvae occasionally seriously damaged the spinal cord. In the UK, control measures have virtually eliminated warble infestation in cattle.

Deterring and killing flies The number of flies entering a milking parlour can be reduced by a spray-boom erected over the doorways, and a plain water mist, produced by ordinary sprinklers or misters, has been recommended for use in collecting yards where a spray-boom over the parlour entrance is impracticable. Such measures, however, do not reduce the total fly population of the farm – they do not kill. Electric fly traps do, and they can be useful when installed in piggeries and dairy cattle buildings. Which flies are electrocuted will obviously depend on the feeding and resting habits of the various species.

Of far wider application, and the most effective weapon against farm flies, is the insecticidal spray. This can be used to convert a livestock building into one big fly trap. A wide variety of effective insecticides is available.

For housed stock, spraying walls may suffice; but beef and dairy cattle at grass will be the target of flies coming from their resting places among trees. Fly control, if it is to benefit grazing animals, therefore requires application of an officially approved insecticide direct to their backs. For this purpose, the synthetic pyrethroids are effective.

These insecticides are chemically allied to the active ingredients of pyrethrum, but are more potent as fly-killers and are also light-stable so that they stay effective for longer in the sun.

Fly control for horses and livestock Numerous formulations based on cypermethrin and other synthetic pyrethroids are available, as both a spray and as pour-on applications, which are convenient to use.

A PVC fly band impregnated with cypermethrin, for threading on to either the browband or the crownpiece of a head collar, and an ear tag impregnated with 8 per cent cypermethrin, are also available for cattle at pasture.

Whether measured in terms of reduced animal suffering, or farmers' incomes, or a lowered incidence of diseases – some of which are of public health as well as economic importance – fly control is very worthwhile. Any doubter should note the success of the UK government's five-year plan to eradicate warble flies from the UK. Now, only sporadic outbreaks of warble infestation occur. Since horses, as well as cattle, suffer from warble-fly larvae (although to a much lesser extent), eradication has also benefited them and their owners.

Overseas Similar methods to those described above, suitably adapted for tropical climates, are in use. The spraying of ground with DDT and dieldrin has been very effective for the control of tsetse flies and human trypanosomiasis, but the practice was discontinued because of the development of resistance and the toxicity of those preparations to other species (see also under TROPICS, LIVESTOCK PRODUCTION IN THE).

The release of sterile male flies from aircraft has been used on a large scale in Puerto Rico to control the screw-worm fly.

Genetically engineered blow-fly maggots have been used in attempts to eradicate sheep blow-flies. The maggots were altered so that females which mate produce blind or sterile offspring – a hereditary characteristic which will 'confer genetic death on future generations'.

(See also DIPS AND DIPPING.)

FLKS

(See FATTY LIVER/KIDNEY SYNDROME OF CHICKENS AND TURKEYS; LIVER/KIDNEY SYNDROME OF POULTRY.)

Flocculus

(plural, Flocculi)

A flocculus is a small mass of fibrous material – examples include tufts of wool, coagulated protein in areas such as the aqueous humour of the eye. (See EYE, DISEASES AND INJURIES OF - IRITIS) A flocculus is also a small mass attached to each normal cerebellar hemisphere.

Floods

(See PASTURE, CONTAMINATION OF; SALMONELLOSIS; WATER-DROPWORT.)

Floor

(See BEDDING AND BEDDING MATERIALS Pigs; HOUSING OF ANIMALS.)

Floor-Feeding of Pigs

This practice is attractive to the pig farmer since it eliminates the cost of troughs and also saves space – the normal feeding passage becoming a catwalk over the pigs' sleeping quarters.

From a health point of view, the precise composition of the concrete floor may prove important. The constituents of sand used in concrete, such as 'pit sand', with a high iron content can cause iron poisoning once the surface layer has been licked off.

More important is the fact that, with floor feeding, loss of appetite in pigs – a common early sign of many diseases – may not be noticed. With

trough-feeding, it is easy to see which pigs are uninterested in food.

Feeding pellets on floors instead of meal in troughs may also cause digestive upsets. The method may involve more stress than conventional systems.

Floor Space

As a rough guide, the following minimum figures may be given: bacon pig, 2 m² (6 ft²); veal calf, 3.5 m² (12 ft²); laying hen on deep litter, 1 m² (2½ ft²).

From 1 January 2013 EU minimum floor space standards for pigs were specified:

Less than 10 kg - 0.15m² (less than 22 lb - 1.5 ft²); 10 kg to 20 kg - 0.2 m² (22 ft² to 44 lb - 2 ft²); 20 kg to 30 kg - 0.3 m² (44 lb to 66 lb - 3 ft²); 30 kg to 50 kg - 0.4 m² (66 lb to 110 lb - 4 ft²); 50 kg to 85 kg - 0.55 m² (110 lb to 185 lb - 5.5 ft²); 85 kg to 110 kg (185 lb to 220 lb - 6.5 ft²); more than 110 kg – 1 m²; gilts - 1.64 m² (17.5 ft²); sows 2.25 m² (24 ft²)

Floor Sweepings

Floor sweepings in mill or barn have been added to feed and caused fatal poisoning. For example, pigs have died in this way from nitrate poisoning, and cattle from mustard seed poisoning.

'Floppy' Labradors

The colloquial name for an inherited muscle disease of both Black and Yellow Labrador Retrievers, correctly called muscular dystrophy of Labrador Retrievers. The condition has been seen in both the UK and the USA. Inheritance is associated with an autosomal recessive gene, leading to atrophy of type II muscle fibres.

Signs Poor exercise tolerance, especially in cold weather, a stiff hopping gait, with sometimes collapse. Signs have been shown as early as eight weeks of age, but in other cases after several months.

Prognosis There is no cure but, if not severely affected, with care such dogs can make acceptable pets. They should not be used for breeding.

Florfenicol

A chloramphenicol-like antibiotic which is used in cattle to treat infections caused by *Pasteurella, Mannheimia* and *Haemophilus* spp. It is also used in the treatment of fish, particularly in the treatment of furunculosis (*Aeromonas salmonicida* infection) in farmed Atlantic salmon. It is not recommended for use in breeding stock. The antibiotic is administered by injection in cattle and in the feed of fish. In the USA it has been used to successfully treat enteric septicaemia in Channel catfish (*Ictalurus punctatus*).

Flour

(See AGENE PROCESS.)

Flour-Mite Infestation

Infestation of animal feeds by flour mites (*Acarus farinae; A. siro*) can cause a significant loss of nutrient value, as explained under DIET AND DIETETICS. Like forage mites of various species, flour mites can also cause an irritating parasitic skin disease of animals. In one incident, 36 police horses were stabled in a building which was cleaned and whitewashed before their arrival. Unfortunately a feed barrow was overlooked and still contained oats left over from the previous year. New oats of high quality were delivered in sacks, and the delivery man opened one sack and topped up the barrow. After he had gone, new oats continued to be put on top of what was left in the large feed barrow, which was never completely emptied. A fortnight after the horses' arrival, the last four in the line showed signs of head and neck irritation. One horse had rubbed the side of its neck bare; two others had dermatitis on the poll and alongside the mane.

Examination of the bottom layer of the barrow's contents revealed an enormous number of flour mites, and these were also isolated from the skin lesions.

An unsuspected cause of diarrhoea in dogs may be dog biscuits or meal, stored in large bins, and heavily infested with forage mites. As flies may carry nymphal forage mites, fly control is important in reducing such infestations.

Forage mites and/or their eggs may be found in dog faeces, where they may have been mistaken for the eggs of strongyle worms. However, the mite's egg is nearly twice the size of the worm's.

Flour mites (*A. siro* and *A. farinae*), the house/furniture mite (*Glycyphagus domesticus*), and the mould mites (*Tyrophagus putrescentiae* and *T. longior*) may also be involved.

Fluanisone

A neuroleptic drug of the butyrophenome group used in small animals (ferrets. rabbits, guinea pigs, rats and mice). It is usually mixed with FENTANYL) and the combination can be used as a neuroleptanalgesic for rabbits and small rodents.

Flubendazole

A broad spectrum benzimidazole anthelmintic used in pigs and poultry and the only anthelmintic currently registered for use in UK poultry.

Fludeoxyglucose

Often abbreviated to FDG or F-FDG, fludoxyglucose is a radioactive chemical injected into animals and man and is used in imaging by the PET SCAN.

VetBooks.ir

VetBooks.ir

Flugestone
A hormone preparation supplied in impregnated sponges for the synchronisation of oestrus in ewes. It may also be used to induce oestrus and ovulation in the non-breeding season (see CONTROLLED BREEDING).

Fluid Replacement Therapy
(See under DEHYDRATION.)

Flukes and Fluke Disease
(See LIVER-FLUKES; LUNG-FLUKES; SCHISTOSOMIASIS for blood flukes; PANCREAS, DISEASES OF; and RUMEN FLUKES.)

Flukicide
A medicine that kills flukes, usually referring to LIVER-FLUKES.

Flumethrin
A synthetic pyrethroid compound used for the treatment of sheep scab and tick infestation. Impregnated in plastic strips, it is hung in beehives to treat varroasis in honey bees.

Flunixin Meglumine
A non-steroidal anti-inflammatory drug used for relief of pain and inflammation in horses, dogs and cattle; formulated as granules, tablets or injection. Proprietary preparations are Finadyne (Schering-Plough), Cronyxin (Bimeda), and Binixin (Bayer).

Fluorescent
(See under TETRACYCLINES which make bone fluoresce, and under WOOD'S LAMP which shows ringworm-affected hairs fluorescing. For the fluorescent antibody test, see under RABIES and IMMUNOFLUORESCENT MICROSCOPY.)

Fluorescin, Fluorescein
Fluorescin (Fluorescein) is a useful diagnostic agent in injuries and ulcers on the cornea of the eye. A weak solution is dropped into the eye and the injured area can be seen clearly demarcated from the surrounding healthy cornea. It can be bound to an antigen to provide rapid identification of an infectious agent.

Fluorine
This element occurs in body tissues and in some natural water supplies. Excess of fluorine causes mottling of the teeth. (For fluorine poisoning, see FLUOROSIS.)

Fluoroacetate Poisoning
Sodium mono-fluoroacetate is used to kill rats and mice, and it is in this connection that poisoning in domestic animals and man may arise. The drug causes distress, yelping, sometimes vomiting, and convulsions in the dog. A dose as small as 0.66 mg per kg body-weight is fatal. Treatment consists in the administration of PENTOBARBITONE SODIUM.

In 1963, two outbreaks of fatal poisoning involving numerous dogs, cats, cattle and a pony were attributed to the agricultural insecticide fluoroacetamide, a closely related compound.

Fluoroquinolones
BACTERIOSTATIC antimicrobials which inhibit the replication of DNA. The group includes danofloxacin (Advocin), enrofloxacin (Baytril), marbofloxacin (Marbocyl, Zenequin) and others. The increased use of these products has caused concern over the production of antibiotic resistance especially in *Staphylococcus* and *Streptococcus* species worldwide. Use of fluoroquinolones in juvenile animals has been linked with growing cartilage malformation.

Fluoroscopy
An imaging technique using X-RAYS to provide real-time images of the internal structures of the animal using a fluoroscope.

Fluorosis
Fluorosis, or chronic fluorine poisoning, is of economic importance in cattle, sheep, etc., grazing pastures contaminated by fluorine compounds emanating from iron and steel works and other industrial plant. It has also been reported in dairy cattle receiving mineral supplements with a high fluorine content, the result of incorporation of rock phosphate. This is something which animal feed manufacturers should guard against, and they should offer guarantees concerning maximum fluorine content in their products.

Signs Acute: sudden death, convulsions, cardiac and respiratory arrest, and burns can occur. Chronic: there is severe lameness, and a resulting loss of condition; milk yield is greatly reduced. The teeth may become mottled, and the bones particularly liable to fracture. Cows may stand with their legs crossed in cases of fracture of the pedal bones. Hip lameness is probably more common.

Antidote Calcium aluminate is of some limited value as an antidote to fluorine poisoning.

Fluothane
Fluothane is a trade name for HALOTHANE. It is a volatile anaesthetic used in most species but now has been superseded by the less toxic ISOFLURANE and sevoflurane.

Flurbiprofen
Fluriprofen, Flurbiprofen and Ibuprofen are non-steroidal anti-inflammatory drugs used in human

VetBooks.ir

medicine, and sometimes given to dogs by their owners, or eaten by dogs with access to the tablets, with resultant poisoning (sometimes fatal). Stomach ulceration and kidney failure have been caused.

Eye drops containing flurbiprofen are used as pre-operative treatment for cataract extraction.

Flushing

Used in pig liquid feeding systems to move any feed particles lodged in the pipes. Water at pH 3.5, produced by organic acids, is circulated every night to disinfect the system and can be reused for this purpose. Weekly, the mixing tanks are flushed with alkaline water at pH 12.8, and once every two weeks the entire system is treated with this alkaline water, which once used is pumped into the slurry store.

Flushing of Ewes

Flushing of ewes aims for rising metabolism in breeding ewes some six to three weeks before service, by putting them on to protein-rich feed. The purpose is to intensify subsequent oestrus and thereby ensure that each ewe is in fit condition to breed. Some trials, however, have failed to demonstrate the effectiveness of the practice.

FLUTD

(See FELINE LOWER URINARY TRACT DISEASE.)

Fly Catching Syndrome, Flycatcher's Syndrome

This is a form of EPILEPSY seen in CAVALIER KING CHARLES SPANIELS. The dog behaves as if it were trying to catch flies when none is present.

Fly Strike

Blow-fly myiasis is the condition resulting from infestation of the living skin of sheep by the larvae of blow-flies which, in certain circumstances, lay their eggs in the wool. It can be prevented by INSECT GROWTH REGULATORS such as cyromazine and DICYCLANIL. (See BLOW-FLY STRIKE; FLIES - DIPTEROUS LARVAE OR MAGGOTS - MYIASIS; STRIKE.)

FNAB

(See FINE NEEDLE ASPIRATION BIOPSY.)

Foal Immunodeficiency Syndrome (FIS)

Seen as an inherited disease affecting FELL and DALES PONIES. It was originally called FELL PONY SYNDROME. Affected foals are born normal and healthy but become ill within four weeks of birth with depression, weight loss, diarrhoea, coughing and nasal discharge. There is anaemia, ß lymphocyte deficiency and reduced antibody production. All die. There are FIS DNA-based carriers, which maintain the disease and when mated with other carriers can produce affected foals.

Foaling

(See PARTURITION.)

Foals

Foals are young horses of either sex until the time they are one year old. Male foals are known as 'colt foals', and female foals are called 'filly foals'. Most foals are born between March and June in Britain, although quite a number (especially thoroughbreds) are dropped earlier than this. Thoroughbreds are conventionally aged as from 1 January of the year in which they are born, and all other horses from 1 May, irrespective of whether they were actually foaled before or after these dates.

Generally speaking, foals run with their dams at grass during the summer, and are weaned at four to six months of age. With weakly foals, however, and in the case of highly-bred pedigree animals, it is not uncommon to allow them to run with their dams until nearly Christmas, so that they may get an exceptionally good start in life.

As a rule, foals will begin to eat grass when they are between three weeks and a month old, although some start earlier and some later than this. At about six weeks to 2½ months they will begin to eat dry corn from mangers along with their mothers.

Foals, Diseases of

Diarrhoea may occur as a result of changes in the mare's milk, or as a result of the dam grazing avidly upon rich spring grass, etc.

Salmonella typhimurium may cause a subclinical infection; alternatively acute and severe diarrhoea or septicaemia may occur, the latter often following the former. (See SALMONELLOSIS.)

E. coli is another cause of acute diarrhoea in the foal. (See *E. Coli*.)

Corynebacterium equi is probably a more common cause of pneumonia than of diarrhoea; nevertheless the latter can be severe. Clostridial enterotoxaemia occurs; likewise campylobacter infections.

Viruses causing diarrhoea in foals include a CORONAVIRUS and a ROTAVIRUS. The latter may be associated with a profuse, watery diarrhoea and lymph-node enlargement, sometimes followed by death. (See also GLOBIDIOSIS.)

Navel-ill and joint-ill These are colloquial terms for dangerous infections which may attack the foal within the first fortnight of its life. Pain and swelling at the navel, with sometimes abscesses along the umbilical vein, may occur; but joint-ill

VetBooks.ir

(polyarthritis) signs may be noticed first. Often the hock and stifle joints are painful and swollen, there is fever, and the foal is obviously ill.

Treatment includes the use of appropriate antibiotics (but not corticosteroids, which have an immunosuppressive effect).

Septicaemia is always a danger likely to arise with or after those two conditions. Septicaemia due to *Actinobacillus equuli* infection ('sleepy foal disease') may occur within the first three days of life. The foal becomes dull, disinclined to suck, has stupor and diarrhoea, and prostration and death quickly follow. Polyarthritis may occur in foals which survive a little longer.

Organisms causing septicaemia and joint-ill include *E. coli*, *Actinobacillus equi*, *Strep. zooepidemicus* and *Klebsiella pneumonia.*

Haemolytic disease This results from an incompatibility between the blood of sire and dam, and the consequent production of antibodies which reach the foal in the colostrum and break down the foal's red blood cells. These become so reduced in number that not only is there jaundice, but often also a fatal anaemia. If trouble from this cause were anticipated, the use of a foster-mother might save the situation but, obviously, this is seldom practicable. Moreover, unless the mare has previously had a 'jaundiced foal', there will be no indication of the problem. If she has previously had such a foal, however, it is possible to test her blood against the sire's during pregnancy and obtain a fairly good idea as to their incompatibility or otherwise. Treatment must be undertaken quickly and consists in exchange transfusion – the removal of up to 2.8 litres (5 pints) of the foal's blood and the simultaneous injection of up to 3.5 litres (6 pints) of a compatible donor's blood, previously collected. The transfusion takes about three hours to complete. Recoveries following this treatment have been spectacular.

Worms Strongyles (red worms), *Strongyloides westeri* and ascarids may cause trouble in foals. The former give rise to malaise, cough, unthriftiness, tiredness and sometimes abdominal pain; the latter to diarrhoea and intermittent colic, among other signs. The Animal Health Trust recommends that foals be dosed every four weeks, alternately for ascarids and strongyles, until the age of one year.

Bone diseases in foals include valgus (see under BONE, DISEASES OF); and RICKETS which can render the growth-plate more vulnerable to injury.

Skin diseases Congenital or inherited conditions include *Epitheliogenesis imperfecta* and ICHTHYOSIS. ALOPECIA is sometimes a complication of STRANGLES; to which URTICARIA is an occasional sequel.

Pneumonia *Rhodococcus equi* causes pneumonia in foals, as does *Corynebacterium equi*, which occurs sporadically in the UK. A suppurative broncho-pneumonia, with abscesses in the lungs and pulmonary lymph nodes, it may be associated with 'joint-ill' and osteomyelitis.

Rhinopneumonitis A congenital infection with EHV 1 virus is a cause of early death in foals. (See EQUINE VIRAL RHINOPNEUMONITIS.)

Muscular dystrophy (See under MUSCLES, DISEASES OF.)

Pervious urachus, or 'leaking at the navel', is a condition in which the communication between the urinary bladder and the umbilicus or navel outside, which should close at the time of birth, remains patent and allows urine to dribble from it. The urine blisters the skin around, and ultimately results in considerable swelling and suppuration around the navel. The condition should be corrected by surgery.

Combined immunodeficiency (CID) occurs in some Arab foals. (See IMMUNODEFICIENCY; also under HERNIA; VALGUS; TYZZER'S DISEASE.)

Focal Duodenal Necrosis

This is seen in chickens in the USA and is thought to be due to disturbance in the intestinal flora composition and proliferation of Gram-negative pathogens.

Focal Symmetrical Encephalomalacia

An infection of sheep caused by the epsilon toxin of *Clostridium perfringens* type D (see *Clostridium* SPP.). Any problems that result in reduced ruminal or intestinal movements allow the toxin to build up. It also occurs in animals have often moved. Signs usually include depression and then recumbency.

Fodder Beet

(See POISONING.)

Fodder Mites

(See FLOUR-MITE INFESTATION; FORAGE MITES.)

Foetal

(noun, Foetus)

(See FETAL; FETUS.)

Foetotomy

(See EMBRYOTOMY.)

Fog
(See under SMOG and FOG FEVER.)

Fog Fever
The colloquial name derived from the word 'fog', meaning the second crop of grass taken from pasture already cut once that season for hay or silage, has caused much confusion, since it has been applied to several different syndromes in cattle.

True fog fever has been defined as acute pulmonary emphysema occurring in adult cattle (typically single suckler beef cows) which have been moved from poor to lush grazing in the autumn. It should be differentiated from parasitic bronchitis, and also from extrinsic allergic alveolitis caused by micro-organisms in mouldy hay.

It may be identical with the acute bovine pulmonary emphysema encountered in North American adult cattle moved from range to lush pasture.

Cause The probable cause is the conversion in the cow's lumen of the amino acid L-tryptophan in grass to 3-methylindole, a toxic substance.

Two clinical forms of fog fever may be seen. The mild form affects up to 50 or 60 per cent within affected groups of cattle, the animal remaining bright though breathing rather rapidly. In the severe form, the degree of respiratory distress varies greatly, is often severe, and results in a 30 per cent mortality rate, especially if animals are moved or stressed. Therefore, move animals very quietly to prevent death or pen them in the field and offer hay or silage. FLUNIXIN MEGLUMINE is used as treatment although 10 per cent methylene blue solution given intravenously may be effective.

Post-mortem Lesions include pulmonary congestion, oedema, and hyaline membranes, interstitial emphysema and diffuse alveolar epithelial hyperplasia.

Foggage
Aftermath, 'fog'. Grass grown for winter grazing.

Folate
The name for FOLIC ACID and its derivatives.

Folic Acid
One of the vitamins of the B-complex. Storage in the liver is dependent on adequate dietary zinc. (See VITAMINS.)

Folic Acid Deficiency
This is seen as nucleated red blood cells (MEGALOBLASTS), it may also result in SPINA BIFIDA in offspring of deficient pregnant dams.

Follicle
(See SKIN; OVARIES.)

Follicle Stimulating Hormone (FSH)
This stimulates the development of the Graafian follicles in the ovary, and controls the secretion of oestrogens from the ovary. It is secreted by the anterior lobe of the pituitary gland. In the male animal, FSH stimulates sperm production in the testicle.

Follicular Mange
Follicular mange is another name for DEMODECTIC MANGE due to mites of the genus *Demodex canis*, which lives in the hair follicles of the skin. (See MITES, PARASITIC.)

Fomentation
(See POULTICES AND FOMENTATIONS.)

Fomites
Fomites is a term used to include all articles that have been in actual contact with a sick animal, so as to retain some of the infective material and be capable of spreading the disease. Bedding material, fodder, mangers, stable or byre utensils, clothing, grooming tools, the clothes of an attendant, or even the attendant him or herself, may all be fomites.

Food Allergies
These are a relatively common form of allergy in dogs and cats. There are many allergens containing proteins and can be part of foods such as milk, wheat and meat. They can result in diarrhoea, and/or skin lesions. OTITIS EXTERNA is common in dogs but less common in cats. (See ALLERGY; FATTY ACIDS.)

Food and Agriculture Organization (FAO)
The United Nations organisation whose aim is to prevent hunger. It is a source of data and produces a wide range of statistics and information. It assists developing countries to modernise and improve their agriculture, fisheries and forestry and aims to ensure good nutrition for all, and food security. Headquarters address: Viale delle Terme Caracalla, 00153 Rome, Italy. Telephone: +39 06 57051; email: FAO-HQ@fao.org.

Food Conversion Ratio
(See FEED CONVERSION RATIO.)

Food Inspection
In countries such as Denmark and the USA, the inspection of meat and meat-derived products has long been carried out entirely by members of the

VetBooks.ir

VetBooks.ir

veterinary profession. In the UK this has been only partly so, but to conform with EU regulations meat inspection, including pre-slaughter inspection of food animals, and the examination of organs and tissues as well as inspection of the dressed carcase are carried out under the supervision or direction of official veterinary surgeons under the centralised control of the Meat Hygiene Service. For conditions which render meat dangerous as food, see TUBERCULOSIS; SALMONELLOSIS; ANTHRAX; TRICHINOSIS; HYDATID DISEASE, etc.

Food Poisoning in Man

(See *E. Coli*; SALMONELLOSIS; *Campylobacter* SPP. INFECTIONS; ROTAVIRUS; also BOTULISM). In the UK, *Campylobacter* spp. infection is the most frequent cause of food poisoning, followed by SALMONELLOSIS, but *E. coli* is becoming more common. *Clostridium perfringens*, *Staphylococcus aureus* and *Bacillus cereus* are also found. Yersiniosis and listeriosis, from infected milk or cheese, also occur.

Where meals are prepared for a number of people, as in homes for elderly people whose resistance is lowered, the risk of food poisoning is increased. The very young and immunologically comprised people are also more at risk. Following serious outbreaks of poisoning by *E. coli* O157 in Scotland in 1997, a government report by Professor Hugh Pennington recommended a series of measures to raise hygiene standards in food shops, etc.

Food Safety Act 1990

This sets out regulations covering the whole of the food chain from retailers back to primary producers.

Foods and Feeding

(See DIET AND DIETETICS; NURSING OF SICK ANIMALS; RATIONS FOR LIVESTOCK; also CAT FOODS.)

Food Standards Agency

An independent body established in 2000 by the UK government with a brief to 'protect public health from risks which may arise with the consumption of food, and otherwise to protect the interests of consumers in relation to food'. The agency reports to government but can publish its advice independently. The Meat Hygiene Service, the agency responsible for meat inspection in all licensed abattoirs, reports to the FSA.

Food Transit Times

This is affected by PERISTALSIS. In healthy humans, transit time is from eight to 24 to 36 hours. In healthy dogs using wireless motility capsule gastric emptying, time varied between about 400 and 900 minutes; small bowel emptying time was about 95 to 225 minutes and large bowel transit ranged from about 425 to 2,575 minutes, making a total transit time of about 1,290 to 3,445 minutes (21.5 to 57.4 hours). Although there was no complete relationship between body weight and gastrointestinal transit times, it appeared that low body weight dogs had longer gastric and small intestinal transit times than large and giant breed dogs. In African grey parrots (*Psittacus erithacus*), transit time was 120 to 130 minutes as measured by radiograph and 262 minutes by fluoroscopy. (See also INTESTINES.)

Fool's Parsley

Although a member of the natural order Umbellifera – very many of the members of which are poisonous (e.g. water hemlock, water dropwort, and hemlock) – the extremely common fool's parsley (*Aethusa cynapium*) is not a frequent cause of poisoning in animals. It is dangerous when fed to rabbits, if it is pulled in the early green succulent stage before the flowering tops are formed.

Under ordinary circumstances herbivorous animals do not readily eat fool's parsley, for at the time when its growth is most luxuriant (i.e. in spring) there is generally an abundance of grass, which they prefer.

Signs In cows, there have been seen a loss of appetite, salivation, fever, uncertain gait, and paralysis of the hindquarters. In horses, an instance has been recorded in which a number of animals ate the plant in quantity; those which had white muzzles and feet became attacked with diarrhoea and all white areas of the body became severely inflamed, but other horses of a whole-colour remained unaffected. (See LIGHT SENSITISATION.) In other cases stupor, paralysis, and convulsions have been noticed.

First-aid Drenches of strong black tea or coffee should be given so that the tannic acid in them may combine with the alkaloids of the plant and form inert substances.

Foot-and-Mouth Disease (FMD)

A very highly contagious NOTIFIABLE DISEASE that can affect all cloven-hooved species; other names are aphthous fever or epizootic aphtha. It is characterised by the formation of small vesicles (fluid-filled blisters) in the mouth and on the feet or, in the female, on the skin of the udder or teat. Economically, it can be devastating, particularly in cattle, pigs and sheep. The costs of eradication or control, involving diagnostic services, slaughter of infected or at-risk animals, compensation to farmers, disposal of carcases, or adoption of a

VetBooks.ir

vaccination policy, and loss of trade can be enormous. Where the disease is not dealt rapidly, it can become endemic. Then chronic signs develop such as failure to thrive and consequent loss of production. In such circumstances, a total ban on export of live animals and, to a very large extent, animal products can be very serious. FMD has been considered the single most important constraint to trade in animals and animal products.

Foot-and-mouth disease has occurred in virtually every country in the world in which cattle, sheep or pigs are kept. It has been endemic in parts of South America, continental Europe, Asia and Africa. Except in young animals, where the death rate may be up to 50 per cent, the disease is not characterised by high mortality. Usually fewer than 5 per cent of infected adult animals die.

The disease is transmissible to humans but the infection is usually mild and transient. It is not the same as (human) HAND, FOOT AND MOUTH DISEASE.

Cause Foot-and-mouth disease is caused by an aphthovirus of which seven types are recognised – including the three known as O (now named the PanAsia strain), A and C, which have caused outbreaks of the disease in Britain, and four more types which so far have been confined to Asia and Africa – Asia and Sat 1, Sat 2 and Sat 3. It is the PanAsia strain of type O, now dominant across much of Asia and the Middle East, that was responsible for the major outbreak in 2001. No cross-immunity is exhibited between types, and only partial cross-immunity between subtypes within a type. The virus has a high genetic variability.

The virus is present in the vesicles and in the fluid which comes from them when they burst; and since there is nearly always an excessive secretion of saliva from an animal affected with lesions in the mouth, it is through the medium of contamination with saliva that the disease is perhaps most readily spread. As well as this, however, the urine, faeces, and small amounts of serum from lesions in the feet, are factors in the spread to other animals; livestock markets and transport vehicles are particularly important in causing widening of an outbreak. But as the virus can survive for very considerable lengths of time, it may be picked up and spread by almost any object or animal that has been in contact with affected animals. Migratory birds in their flights from one country to another may act as carriers. Spread can occur by wind, watercourses, people and vehicles.

Bulk collection of milk has also been implicated. FMD virus may be excreted in milk before signs in the cow have appeared or become obvious.

The virus can survive in frozen liver or kidney for four months or more, and in bull semen stored at low temperatures.

The use of swill containing scraps of meat, bones, or other animal tissue for feeding to pigs is a very important factor in the spread of foot-and-mouth disease, and because of the number of outbreaks traced to swill, the (then) Ministry of Agriculture specified that swill shall have been boiled for at least one hour before being fed to pigs. It may have been neglect of this procedure that led to the 2001 UK outbreak. The feeding of swill is now completely banned.

The incubation period before signs of the disease appear after infection varies from 1 to 15 days, but the majority of cases show signs between the second and the sixth day after having been exposed to infection. An important feature of the disease in relation to its infectivity is that virus may be excreted before signs become evident; thus the infection may spread before the farmer is aware that his stock are infected.

With pigs, 10 days may elapse between excretion of virus and the development of lesions. With cattle and sheep, the figure may be five days; or an average of 2½ days.

Signs

Cattle At first, animals become dull, refuse their food, lie about in a sluggish manner, and cows suddenly give a lessened flow of milk. Their temperatures rapidly rise to 40° C or 40.5° C (104° F or 105° F), and fever is maintained until the crop of vesicles form, after which it subsides. A few hours after the initial dullness has been noticed, affected animals usually commence to salivate profusely – long ropes of stringy saliva hanging from the mouth. Lameness may be the first sign of the disease. Foot lesions generally appear four or five days after the vesicles form in the mouth. In these, blisters form around the coronets, between the claws.

The animal frequently smacks its lips in a characteristic manner, yawns, and protrudes its tongue. Blisters are found in all stages of development: the most common locations are on the dental pad and in the upper incisor region; on the tongue, especially around its tip; and on the insides of the cheeks and gums. The blisters each run a similar course; for a few hours they gradually rise, then they burst, liberating a small amount of yellowish, straw-coloured serum (which should be regarded as highly infective and as containing the virus). There remains behind a shallow, eroded, red, raw, ulcer-like area, to the edges of which little pieces of mucous membrane adhere for a short time until they are removed by the movements of the mouth. Adjacent affected areas merge, and in bad cases large irregular, ragged, red patches form, from the surfaces of which the mucous membrane has disappeared. The lesions are always extremely painful,

VetBooks.ir

and in consequence the animal is prevented from feeding. Generally, it can still drink, and it will often take liquid or very soft food, but it refuses dry food entirely. In from six days to a fortnight or so, healing begins, the lesions disappear and the animal appears to have recovered. It is, however, still carrying the virus.

Sheep Foot-and-mouth disease may be difficult to detect. Onset of lameness is variable – between two days and a week – and may pass off quickly. Vesicles in the mouth rupture and heal quickly, leaving no sign of lesions. The sheep may not appear obviously sick and feet and mouth must be examined closely to detect signs of infection.

Pigs Foot lesions usually begin either at the coronet or at the heels instead of between the claws as in cattle. The muzzle and end of the snout may show lesions. Young piglets may squeal with pain when moving.

In all affected species, the illness may cause animals to lose much weight, or to cease to grow. Abortion, infertility and diabetes are occasional complications. Foot-and-mouth disease may be the cause of sudden death in pigs, cattle and young sheep.

Animals in milk – cows, ewes and sows – may develop characteristic lesions on their teats or on the skin of the udder. The lesions are similar to those forming in the mouth, but they take longer to mature. In some cases the whole of the tip of the teat shows a single large blister, which is soon burst by milking or sucking. Subsequently an eroded appearance remains, until healing is established. Milk secretion rapidly diminishes. Permanent udder damage may result from the disease. The pain is usually acute, and the milk – contaminated with the exudate and with discharges from the lesions – is highly infective to young animals.

Differential diagnosis It is necessary to distinguish between foot-and-mouth disease, SWINE VESICULAR DISEASE and VESICULAR STOMATITIS by laboratory tests. In the UK, tissue and blood samples from suspect animals are sent to the Institute of Animal Health (IAH), Pirbright laboratory for testing. If large quantities of virus are present, the test can give a positive result in four hours. In some cases, it may be necessary to multiply the virus by culture in cells and it may take up to four days to confirm that virus is not present. The cell culture technique is also used to provide material for identifying the precise type and strain of the virus.

Control A policy of slaughtering affected and in-contact animals is operated in the UK, Canada, the USA, Norway and countries throughout the European Union where the disease is not endemic. Such a policy, involving compensation to owners of compulsorily slaughtered animals, is normally far less costly than a long-term vaccination policy. Slaughtered animals are disposed of by burning or burial; affected premises are thoroughly disinfected and the holding and surrounding area subject to a period of quarantine. Vaccination is practised in countries where a slaughter policy is unworkable because the disease is endemic and its incidence high; not vice versa, as might be thought by those who condemn the slaughter policy without having studied the reasons for it. 'Overall' vaccination is seldom practicable in such areas for reasons of cost, so 'frontier', or 'ring', vaccination (of all susceptible animals within a given radius of an outbreak) is usually practised. Israel is an exception; the high-yielding diary herds are vaccinated annually.

As a temporary measure, animals in areas surrounding outbreaks may be vaccinated to provide a 'ring fence' against infection. Contrary to its general policy, to protect Greece, the EU operates a vaccination policy in European Turkey and part of Turkey-in-Asia. The use of vaccination was seriously considered in the 2001 UK outbreak when the disease threatened to run out of control and the enormous numbers of animals slaughtered, and disposal of their carcases, created serious difficulties. In 2013 a synthetic vaccine was developed experimentally.

Vaccine bank In 1985, the United Kingdom, Australia, New Zealand, Finland, Ireland, Norway and Sweden formally established a foot-and-mouth disease vaccine bank. The participating countries are all free from the disease and do not normally vaccinate against it, but if an outbreak occurs, supplies of vaccine are held at the international vaccine bank at IAH Pirbright: 0.5 million doses of each of the seven main strains of FMD are kept in store. Any decision to initiate vaccination will depend on epidemiological findings.

Foot-and-mouth disease in Britain A serious epidemic in 1967–8 involved 2,397 outbreaks; the slaughter of more than 211,000 head of cattle, 108,000 sheep, 113,000 pigs, and 50 goats; and payments in compensation to owners of about £27 million. The policy and arrangements for dealing with the disease were subsequently reviewed by the Northumberland Committee, which recommended continuation of the slaughter policy with the option of ring vaccination.

Britain was free of FMD except for a minor, easily eradicated, outbreak on the Isle of Wight in 1981, until February 2001, when the worst outbreak ever broke out. Believed to have originated from a pig farm in Durham, where infected swill

VetBooks.ir

was fed, the disease spread to sheep which were mixed with others at markets in Hexham and Longtown. Transport of animals by dealers to Devon and other parts of the country caused rapid and widespread outbreaks; export to France and Holland caused further outbreaks which were rapidly contained. By the middle of the year, when the disease was subsiding, more than 3 million animals had been slaughtered. Cumbria, south west Scotland, Durham, Northumberland and Devon were the most seriously affected areas. Large parts of the countryside were out of bounds and the effects for the whole of the UK livestock farming industry, and for tourism, were devastating. In 2008, an outbreak occurred locally in Surrey when infection escaped from the Pirbright Institute.

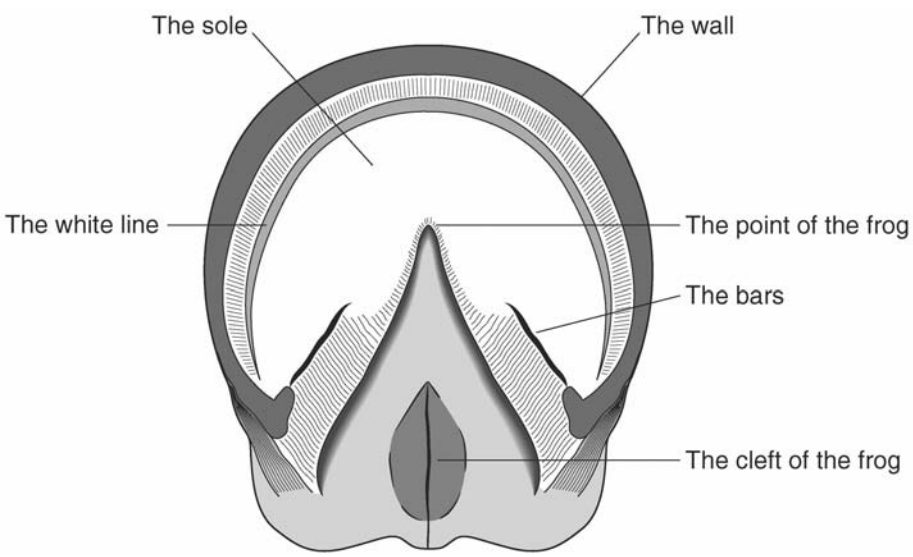
Foot-Baths for Cattle

A foot-bath with 3.75 cm (1½ in) pipes laid horizontally 5 cm (2 in) apart, even if filled with plain water, will help to detach mud; the pipes forcing the claws apart.

Caution A 5 per cent formalin foot-bath is often recommended for the control or prevention of foul-in-the-foot, but it is important not to exceed that strength or to put the cows through it too often. One veterinary investigation centre reported that on one farm, 90 out of 100 cows developed severe inflammation at their heels because they were walked through a 4.7 per cent formalin foot-bath twice daily for two weeks. Fifty of those cows developed further lesions, a few of which had not healed a month later.

Provision must be made in the planning stage for ease of filling, cleaning, and disposal of the formalin solution. It is convenient to have the foot-bath installed at the parlour exit, so that cows become completely familiar with it and readily walk through it, whether filled or empty. (It would not be desirable to have the foot-bath at the entry to the parlour, owing to fumes from the formalin.)

Suggested dimensions for the foot-bath are as follows: length, about 3 m (10 ft); width 1 m (3 ft 6 in); depth 23 cm (9 in). The ideal is to have two successive foot-baths, the first containing plain water, and the second a solution of 5 per cent formalin.



A more recent recommendation is a 1 per cent solution for routine use as an aid to reducing herd lameness.

Foot-Baths for Sheep

Foot-baths for sheep are used for the purpose of treating or preventing foot-rot and the foot lesions of orf.

The solutions most often used for foot-baths are 3 per cent formalin solution; or copper sulphate, 4 to 8 per cent. As a preventative of contagious foot-rot, a three-weekly run through a foot-bath gives excellent results. (See FOOT-ROT OF SHEEP.)

Caution A striking example of overdoing foot-bath use was the disastrous use of formalin in a foot-bath to treat lameness in a flock of 150 ewes. 'As the lameness increased,' MAFF stated, 'so did the frequency and strength of the formalin liquid

Foot of the Horse. Diagram of the underside of a horse's foot. (With acknowledgements to The UFAW Handbook on the Care and Management of Farm Animals, Churchill Livingstone.)

until the entire flock was crippled and had to be slaughtered.'

Foot of the Horse

(See illustration on previous page; also CORNS; QUITTOR; LAMINITIS; SANDCRACK; SEEDY TOE; BRUISED SOLE; INJURIES FROM SHOEING.)

Skeleton of the foot consists of the lower part of the second phalanx, the whole of the third phalanx, and the sesamoid of the third phalanx or navicular bone. (See under BONES.) From the posterior angles of the third phalanx (coffin-bone) project two roughly quadrilateral plates of cartilage, one on either side, which are known as the 'lateral cartilages'. These are important structures in the absorption of shock and in preserving the elasticity of the foot as a whole. Under certain conditions they become ossified, when the name 'side-bones' is applied. The three bones mentioned above are bound together by a series of ligaments which, while they allow free mobility in normal directions, prevent unnatural movements which might rupture the capsules of the coffin-joint. Lying between the two lateral cartilages and behind the third phalanx there is a fibro-elastic structure known as the 'plantar cushion' or digital torus, which, although strictly speaking it is not part of the skeleton of the foot, will be considered here for convenience. This plantar cushion is composed of extremely elastic, dense, fibrous tissue, poorly supplied with blood vessels and not greatly sensitive, and is one of the chief shock-absorbing structures of the foot. From above it is pressed upon by the descending deep flexor tendon, when the foot comes to the ground; from below it is pressed upwards by the horny frog. It cannot expand forwards to any great extent, because of the presence of the coffin-bone; and since it is practically a rubber-like buffer, it expands backwards and sideways. On either side of it, however, are the lateral cartilages, and these are pressed outwards in the process and carry with them the horny wall at the heels.

Sensitive structures Covering the parts described above and accurately moulded to them are the sensitive parts which nourish the horny hoof. These are: around the hoof-head above the coronary band, a perioplic matrix, the periople, which prevents undue evaporation from the wall; around the coronet, from one heel to the other, a structure about four-fifths of an inch wide, the coronary band, or coronary cushion, which nourishes and from which grows the horn of the wall; running down the inside of the wall all the way round and turning inwards and forwards at the heels, a laminar matrix, which is provided with laminae or 'leaves' which interdigitate with corresponding laminae on the inside of the wall; covering the lower surface of the coffin-bone, and nourishing the sole of the hoof, a solar matrix, or sensitive sole; and covering the lower surface of the plantar cushion and nourishing the frog, a furcal matrix, or sensitive frog. The term 'pododerm' is applied collectively to these sensitive structures. The pododermic tissues are in reality modified skin, and produce numerous minute tubular horn fibres which are firmly united to each other.

The hoof is composed of the wall, the sole, and the frog.

The wall is all that portion which can be seen when the foot rests upon the ground. It gives the foot its form. Its horn is hard, solid, only slightly elastic, and affords protection to the sensitive laminar matrix below it.

The inner surface of the wall has about 600 horny leaves or laminae, which dovetail with the sensitive laminae forming a firm union between wall and matrix. The upper edge of the wall is thin, flexible, and grooved for the lodgement of the coronary cushion. The lower edge is called the 'bearing surface', and is the part to which the shoe is fitted.

The sole is that part of the hoof which is nourished by the sensitive tissue covering the solar surface of the coffin-bone. It is divided into a body and two branches, and is roughly crescent-shaped. The sole is markedly vaulted in normal feet, especially in hind-feet, but in very many old horses it becomes flat or even convex; when excessively convex it is called a 'dropped sole'. The white line of soft horn acts as a kind of cementing substance between the wall and the sole. This line is of great importance in shoeing, as it indicates the thickness of the wall, and is used as a guiding line through which the nails can be driven with safety. In the posterior part of the sole there is a V-shaped notch, between the branches of which lie the bars and the frog.

The frog is an exact mould of the lower surface of the plantar cushion which it protects. It is a roughly triangular wedge-shaped mass filling up the space between the bars and the V-shaped notch of the sole. It projects downwards more than the sole, and receives the greatest amount of the concussion in the normal foot; it is only seldom injured, however, for its horn is of very elastic consistency. The ground surface presents a well-marked median cleft, which corresponds to an elevation in its upper (inner) surface.

Foot-Rot of Cattle

This name is used in the USA for what in Britain is called FOUL-IN-THE-FOOT caused by *Fusobacterium necrophorum*. *Bacteroides nodosus* has been isolated from some foot lesions of cattle in Britain, but its role has not been established.

VetBooks.ir

Foot-Rot of Pigs

Abscesses on the sensitive parts of the foot, often seen in pigs housed on rough concrete; this causes abrasions which become infected.

30 per cent of casualty pigs at one UK slaughterhouse had abscesses (a common reason for condemnation of meat) and 12 per cent of these abscesses were on the feet.

In a survey covering more than 6000 pigs, 30 per cent of the lesions were erosion of the heel, 24 per cent of the toe, and 21 per cent of the sole. Fine cracks to deep fissures constituted another 2.7 per cent of the lesions. (See diagram under BIOTIN.)

Causes These include excessively rough concrete, which can be abrasive. Softening of the horn under damp, dirty conditions is another factor; and nutrition may be involved in some instances.

Foot-Rot of Sheep

Foot-rot of sheep is a disease of the horny parts and of the adjacent soft structures of the feet. The organism primarily responsible is *Dichelobacter nodosus (Bacteroides nodosus, Fusiformis nodosus).* The disease is commonly prevalent on wet, marshy, badly drained pastures, in old folds or sheep pens. Wet soil, however, does not cause foot-rot but merely facilitates infection. This is a mixed one, with *B. necrophorus* causing sufficient damage to permit the entry of *D. nodosus*.

In Australia two forms of foot-rot are recognised, in both of which *D. nodosus* is always present. The type of foot-rot which develops depends upon the proteolyptic capacity of the infecting strain of *D. nodosus*. In benign foot-rot the infecting strain is of low proteolytic activity; the resultant disease is limited and does not spread under the hard horn, although it might cause lifting of the sole of the foot. In virulent foot-rot the infecting strain is of high proteolytic activity and results in extensive separation of the hard horn, with uneven horn growth giving the clinical appearance of classical foot-rot.

It appears that transmission of foot-rot infection from cattle to sheep is possible.

D. nodosus cannot survive in the soil or on pasture for more than a fortnight.

Signs Lameness is the first noticeable feature. At first the sheep manages to put the foot to the ground, but after a time it goes on three legs only, the pain having greatly increased.

When the foot is examined either there will be found a swelling over the coronet, or an area of the horn of the hoof is found to be soft, painful on pressure, 'rotten-looking', with a variable amount of foul-smelling discharge present.

If neglected, the horn will begin to separate from the underlying sensitive tissues, and will eventually be shed. Sometimes the disease penetrates into the foot, affecting the ligaments or even the bone. One, two, three, or all four feet may be affected. If the two fore-feet are attacked, the sheep very often assumes the kneeling position for feeding. If the two hind-feet, any three feet, or all four feet are affected, standing becomes an impossibility, and the sheep, still retaining its appetite, will feed from the sitting position, crawling forward a few inches at a time to a new piece of grazing.

Prevention Foot-rot can be eradicated. Leave contaminated pasture free of sheep for three weeks. Isolate and treat all infected or suspected sheep. The feet of heavy sheep should not be allowed to get overgrown during wet weather; turning on to a bare fallow or stubble field, or walking along a hard road, is advocated by some to wear away the feet, but is not a very practicable proposition. The better way is to round up the sheep and trim each foot individually once every six to eight weeks.

Where the disease has not yet taken hold, the use of foot-rot vaccine may obviate much time-consuming work treating diseased feet; the manufacturer's directions must be followed if the vaccine is to be effective. Vaccines contain inactivated strains of *D. nodosus*. The heritability of resistance to foot-rot is about 10 to 20 per cent.

Treatment It is advisable to separate the infected animals from the healthy, passing the latter through a foot-bath and changing the pasture to as high a ground as possible. If the lame sheep can be shut up in a dry, strawed yard, in pig-courts or in pens, and given handfeeding and individual attention daily, they recover much better than if they are left out in the open and only attended to occasionally. The feet should be carefully, but not excessively, trimmed to remove all necrotic material. When all the 'rotten' substance has been removed, the sheep should be passed through a foot-bath. In severe cases, zinc sulphate solution is preferable to formalin, which can cause severe pain; proprietary formulations based on zinc sulphate heptahydrate are available.

The shepherd should take care not to spread the disease to other sheep through the medium of hands or knife; both should be washed after dealing with each case, and all parings, diseased tissue, and infected swabs collected in a pail and burned. Neglect of these precautions often results in a continuance of new cases in a flock.

Aerosol sprays containing the antibiotic oxytetracycline, and a purple dye as marker, are popular. Injection of a long-acting antibiotic can be highly effective.

VetBooks.ir

The old and the new in foot-rot treatment. Two injections with foot-rot vaccine at an interval of six weeks can help minimise the paring and cutting of feet necessary with traditional methods of control.

The economic and welfare consequences of foot-rot can be severe. Losses of up to 15 per cent in weight can be shown in affected ewes with reduced growth rate in lambs.

(See also FOOT-BATHS FOR SHEEP; CONTAGIOUS OVINE DIGITAL DERMATITIS.)

Forage Mites

(See MITES, PARASITIC.)

Foramen

A hole or opening. The word is applied particularly to holes in bones through which pass nerves or blood vessels. The foramen magnum is the large opening in the posterior aspect of the skull through which passes the spinal cord to enter the foramina in each of the vertebrae of the spine. The nutrient foramina are the holes in the shafts, etc. of the bones which penetrate to the marrow cavity, by which blood and lymph vessels and nerves pass to and from the marrow cavity.

Foreign Bodies

(See 'CHOKING'.)

Foreign Body

Any extraneous object which becomes lodged in a body organ or tissue. Examples include a grass seed in the ear or nose, beneath the skin between the toes or beneath the eyelid, or in the prepuce or penis of the cat; a needle embedded in the tongue or a chop bone wedged in a dog's mouth; a piece of bone lodged in the gullet; a piece of wire in the reticulum; pebbles in a dog's stomach; and lead shot and airgun pellets. (See AWNS; under 'CHOKING'; STOMACH, DISEASES OF, etc.)

Most often these are acquired accidentally but they can also include a broken-off portion of an intravenous needle within a vein, or of a catheter.

Formalin

Formalin is a gas prepared by the oxidation of methyl alcohol. For commercial purposes it is prepared as a solution of 40 per cent strength in water. Formalin is a powerful antiseptic, and has the quality of hardening or fixing the tissues. The solution in water gives off gas slowly; this is irritant to the eyes and nose so great care must be taken in its use.

Formalin is used for preserving pathological specimens, occasionally as a disinfectant, and for the production of formaldehyde gas for fumigation of buildings. A 3 per cent solution of formalin has been used in a foot-bath in the treatment of foot-rot in sheep (and 4 per cent in cattle). It may, however, cause considerable pain if it reaches sensitive tissues. Formalin gas has been used to fumigate eggs on farms and in the setters in the hatchery. The process carries some risk and must be done in special chambers; approved alternatives

VetBooks.ir

are available. Formalin gas must never be used to fumigate duck or goose eggs. Formalin has no activity against *Mycobacteria* such as *M. bovis* and *M. tuberculosis*.

(See also under FOOT-BATHS FOR CATTLE; DISINFECTION.)

Formi

(See POTASSIUM DIFORMATE.)

Formosulphathiazole

A SULFA DRUG used in combination with penicillin and streptomycin in pessaries for the treatment and prevention of metritis, leukorrhoea and pyometra in cattle.

Fornix

(plural, Fornices)

A permanent space which exists in the folds of an organ. Examples are the space between layers of conjunctiva around the eyeball and the space between the cervix and the walls of the vagina.

Fossa

Fossa is an anatomical term applied to a depression in a bone which lodges some other structure, such as part of the brain in the skull. It is also used to describe grooves or pockets in soft tissues, such as the renal fossa of the liver in which is lodged the right kidney.

Foul-in-the-Foot

Called FOOT-ROT in the USA. A disease that affects cattle. Technically known as interdigital necrobacillosis, the lesion takes the form of a swelling which tends to force the claws apart. The whole length of the space between the claws may be involved, with one or two fissures seen in the skin, and a slough of dead tissue.

Cause *Fusiformis necrophorus* (*Fusabacterium necrophorum*) is the usual cause, entering tissues through a wound or through devitalisation of the skin from frost, mud, decomposing urine or faeces, or other irritants.

Signs There is nearly always well-marked lameness, with swelling of the interdigital tissues and a typical foul smell. Hind-feet are more often affected than fore-feet, probably owing to their greater liability to soiling from urine and faeces, in which the necrosis bacillus can generally be easily found. In many cases a cow will suddenly stop walking, and shake the affected foot as though she desires to dislodge a stone or other hard object which has become wedged between the claws.

A 'super foul' has been seen, which spreads very rapidly in the foot; it causes severe pain and deep erosion at the heel unless treated promptly. Tissue damage may be so extensive that the animal has to be culled.

Treatment This calls for prompt professional aid. The foot is dried and an oxytetracycline spray applied. In severe cases, parenteral antibiotics may be necessary and are essential in 'super foul'. Affected animals should be isolated until clear. (See FOOT-BATHS FOR CATTLE.)

'Founder'

The common name often used for LAMINITIS IN HORSES and less frequently for LAMINITIS IN CATTLE. It is particularly referred to when the PEDAL BONE loosens from its attachments to the hoof wall and then its tip starts to rotate downwards. This causes the sole wall to become convex or sink. This is often called founder after the maritime term meaning "to sink".

Fowl Cholera

Synonyms: cholera gallinarum, avian pasteurellosis, pasteurellosis of the fowl, haemorrhagic septicaemia of the fowl. This is a contagious disease of fowls, usually epizootic in type and characterised by sudden onset, high fever, extensive blood extravasations into the different organs and severe diarrhoea. The disease occurs all over Europe, in North and South America, in most parts of Africa, and in Asia. All common fowls, including domestic poultry (chickens, ducks, geese, guinea-fowl, turkeys, pigeons, pheasants and fancy birds), are susceptible. Most common wild birds are also liable to infection and serve to spread the disease. Rabbits and mice may also contract it under special circumstances.

Cause *Pasteurella multocida*.

Signs After a brief incubation period (usually two to four days) the birds may be seen to stagger and fall down, or more commonly are just found dead. In the less acute type, which perhaps is the more common, the birds are seen to look ill, to stand apart from the rest, droop their wings, and refuse both food and water. The combs, wattles and ear lobes become discoloured, and there is great nervous prostration. A discharge comes away from the eyes and nose, a frothy saliva from the mouth, and there is usually severe diarrhoea. The respirations become rapid; the temperature may reach 43.3° C or 43.9° C (110° F or 111° F). The feathers are ruffled and draggled, and those of the hinder parts of the body are soiled with faecal discharges. Vomiting may take place, and in one to three days the affected birds usually die. In other cases the signs are more subacute, and the disease may run on for 7 to 9 or 10 days, but as a rule ends fatally. In the more chronic type, arthritis may be

seen and it may take several weeks before death ensues. In acute outbreaks 90 to 95 per cent may die, although in others the death-rate may be only 20 per cent.

Treatment Tetracycline antibiotics, macrolides and penicillin are more useful than sulfonamides as these adversely affect egg production.

Prevention is by vaccination and avoiding contact with wild birds.

VetBooks.ir

Fowl Paralysis

(*Neuro-lymphomatosis*.) (See MAREK'S DISEASE.)

Fowl Pest

This term usually refers to NEWCASTLE DISEASE, but also includes fowl plague (see AVIAN INFLUENZA).

Fowl Plague

(See AVIAN INFLUENZA.)

Fowl Pox

Also known as avian contagious epithelioma and avian diphtheria, this is a disease caused by the avian poxvirus in which wart-like nodules appear on the comb, wattles, eyelids and openings of the nostrils.

The disease attacks the fowl most often, but other domesticated birds are all susceptible; likewise wild and domesticated pigeons. It occurs in almost all parts of the world. (See POX.)

Head of cock affected with avian contagious epithelioma. Wattles and comb are mainly affected.

The virus infects the skin through abrasions, wounds and punctures and may be transmitted by insect vectors (especially mosquitoes). Various secondary organisms are usually responsible for deaths.

The period of incubation is usually between three and 12 days, and bad housing conditions, severe weather and poor feeding serve to lower vitality and render an outbreak much more serious.

Signs There are three types of lesion: (i) nodular eruptive lesions on comb and wattles; (ii) a cheesy, yellowish membrane in the mouth and throat; (iii) oculo-nasal form (possibly due to a different virus).

The mouth lesions consist of patches of a greyish, fairly firm, cheesy-looking material, which is of considerable thickness, and not easy to detach. This is the 'false membrane'. In many cases the entrance to the trachea is partially blocked with these deposits, and the breathing is consequently obstructed. The smell from the mouth is always foul.

Treatment is economically unsound. The best measures consist of the slaughter of all affected birds and the inoculation of the healthy ones with 'pigeon-pox vaccine'.

Prevention Newly purchased birds should be isolated for three weeks before being added to the flock, and after returning from shows, laying trials, etc., the same procedure should be adopted.

Vaccination (in regions where vaccine is available) can be given at six weeks of age; or, more usually, between three and five months of age. (See AVIPOX.)

Fowl Typhoid

This is an acute infectious disease of fowls (also of ducks, geese, turkeys, game and wild birds) caused by *Salmonella gallinarum*. The disease (also called KLEIN'S DISEASE) has a worldwide distribution, but has been virtually eradicated from the UK.

Most outbreaks occur in pullets near point of lay, but birds of all ages are susceptible – even chicks. The disease is usually introduced into a flock by the purchase of 'carrier' fowls, and thereafter spreads by contamination of food and water with the droppings of such birds. The incubation period is from four to six days.

Signs are not always characteristic. There is generally marked drowsiness, loss of appetite, and great weakness. The fowls prefer to sit about in dark corners. The comb and wattles are sometimes pale and anaemic; they may in other cases be markedly congested. Diarrhoea is usually present. Death, following progressive weakness, occurs in from four to 14 days after the onset of the signs.

VetBooks.ir

The percentage mortality varies from about 20 to 30 per cent, and many or most of the recovered birds become 'carriers', which serve to spread the disease to other birds.

Diagnosis If fowl typhoid is suspected, samples of blood from the surviving and apparently healthy birds should be submitted to the agglutination test, and all reactors should be isolated and destroyed – the carcases being burned or buried in quicklime. The remaining birds should be treated with antibiotics, moved to fresh premises, and retreated.

After removal of the reacting birds, the houses, utensils, etc. should be disinfected.

Fox, Diseases of

There are about 37 species of fox with the red fox (*Vulpes vulpes*) being most common. They are OMNIVOROUS and not a pack animal. In Europe, North America and other parts of the world, wild foxes often become victims of RABIES, and spread this disease to farm livestock which they may attack. A history of aggressiveness and atypical behaviour does not, however, point conclusively to rabies; DISTEMPER or partial domestication by well-meaning, but misguided, people, may be the reason. (See also FOX ENCEPHALITIS; 'CHASTEK PARALYSIS'.)

The fox acts as host of the roundworm *Toxocara canis* and of the *Toxascaris leonina*, and if silver fox cubs are reared by a cat, they may become infected with *Toxocara mystax* of the cat. The fox harbours the dog tapeworms *Taenia serialis* and *T. multiceps*, and *Echinococcus granulosus*. Leptospirosis occurs in foxes in the UK and may be spread to farm livestock (five strains have been isolated). Flukes may infest foxes, and sarcoptic mange is quite widespread in urban foxes.

Fox Encephalitis

Fox encephalitis is of commercial importance on the fox ranches of North America, where these animals are bred for their fur. The disease is considered identical to RUBARTH'S DISEASE of dogs.

Signs Young foxes in good condition are most frequently affected. A violent convulsion is followed by a lethargic or 'sleep-walking' state. This may be followed by excitability and more convulsions – during which the slamming of a door or any loud noise may prove fatal. The illness runs a very rapid course, from one hour to three days, 24 hours being the average duration.

Control By means of serum and preventive inoculation.

This disease, or one caused by a similar virus, may have accounted for the deaths of (wild) foxes in Britain, but the deaths may have occurred as the result of eating birds poisoned by dieldrin. Signs are similar.

Foxglove Poisoning

(See DIGITALIS - DIGITALIS POISONING.)

Fox Terriers

Small, lively dogs classed as smooth-haired or wire-haired, according to the coat; usually with a short tail. In both breeds deafness and lens luxation may be inherited but by unknown mechanisms. Pulmonary STENOSIS and aortic stenosis are probably polygenic traits but ACHALASIA is possibly an autosomal dominant trait. Atopic dermatitis occurs only in the wire-haired terrier and is inherited by an unknown mechanism; while cerebellar ataxia in the smooth is an autosomal recessive trait. (See also SMOOTH-HAIRED FOX TERRIERS; WIRE-HAIRED FOX TERRIERS).

Fractures

Simple fractures are the commonest variety, and consist of those in which the bone is broken clean across, with or without tearing and laceration of the soft parts surrounding it, but without any wound leading from the fracture through to the skin. They are spoken of as being transverse, longitudinal, or oblique, according to the direction of the break.

Compound fractures are those in which the skin is injured, so that a direct or indirect communication between the fracture and the outside air exists. The broken end of the bone very often penetrates through the skin and is found exposed. Bleeding is apt to be severe; infection of the ends of the bones with pathogenic organisms may occur.

Closed fractures are covered by skin and/or other tissues.

Open fractures are seen when the bone protrudes via a wound. These fractures can be contaminated or infected, which may affect healing.

Incomplete or greenstick fractures are those in which the bone is broken only partly across, or in which the tough periosteum (the tissue covering the bone, which is thicker in juvenile animals than adults) is not torn. They occur in the shin-bones (tibiae) of horses which have been kicked, and in the bones of young animals. The bone cracks like a twig half-way across, and then splits for some distance along its length, just as does a branch which has been cut halfway through and then bent.

Fissured fractures are mere cracks in the bone which are found in the skull and face bones after blows or falls. They are usually not serious unless haemorrhage accompanies them and the blood clot presses upon a nerve or on the brain itself.

Deferred fractures occur when the bone has actually been fractured, but the fractions do not

separate until or unless some extra severe strain is put upon the part.

Distracted fractures are those in which muscular contraction causes the detached fragment to be drawn away from the main body of the bone.

Depressed fractures occur in the skull bones as a rule, and consist of fractures in which a fragment of bone is forced in below the level of the surrounding surface. They may give rise to very serious clinical signs when the depressed portion presses upon the brain substance.

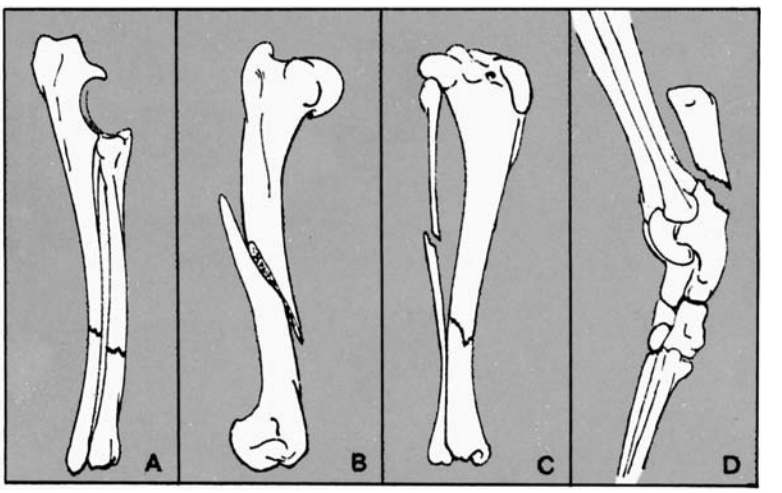
Complicated fractures are those in which there is some other serious injury produced in addition to the fracture, e.g. dislocation of the dog's hip along with fracture of the shaft of the femur; tearing of a large nerve, etc.

Comminuted fractures are those in which there is much splintering, the term 'sequestra' being applied to those splinters of bone which are separated and eventually die.

Impacted fractures are those in which, after the break has occurred, one fragment is jammed inside another, usually at an angle.

Ununited fractures are those in which, after the usual time has elapsed for the fracture to heal, it is found that union has not taken place. The failure to unite may be simply due to 'delayed union', on account of debility or illness or due to the fact that the limb or other member is not kept at rest sufficiently for the process of healing to occur. In other cases of ununited fracture, a piece of muscle or other tissue becomes displaced between the broken ends of the bones and effectively prevents their union.

Causes of fractures Disease, such as osteomalacia, in which there is a reduction in the density of bone and of its tensile strength, is one cause. However, the common cause is external violence. (See also ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION.)



Horses Fractures result from kicks, falls or blows; errors in judgement during jumping; accidentally placing a foot into rabbit-holes when galloping; and accidents when the animal collides with some stationary object, or is struck by a vehicle.

Fractures incurred by 53 race horses at a New York track were found to be due to three lesions: OSTEOCHONDROSIS, chondro-osteo necrosis, and degeneration of tendons and ligaments. (See also SHOEING OF CATTLE.)

Cattle Fractures result from injuries during fighting, slipping, and falling when struggling; from running, BULLING and mounting or during service; from jumping fences, hedges and ditches; from crowding accidents at markets, etc.; and from crushes in cattle-trucks.

Fracture of the third phalanx in a medial front claw is commonly associated with fluorine poisoning, and causes cattle to stand with their legs crossed. (See also SHOEING OF CATTLE.)

Pigs and sheep The causes are usually similar, but legs are broken more easily. Careless use of the shepherd's crook is responsible for many. Falling over precipices and getting a limb stuck in a gate, fence, or hurdle may also result in a broken bone.

Classification of fractures. A. Transverse fracture with excellent stability after reduction. B. Oblique fracture with no stability after reduction. C. Slightly oblique fracture which, by virtue of the irregularity of the fracture lines, provides a useable degree of stability after reduction. D. A typical distracted fracture. (With acknowledgements to the British Veterinary Association.)

VetBooks.ir

Dogs and cats In dogs and cats, road accidents account for the majority of fractures, especially of the femur, tibia, pelvis, radius and ulna, spine and jaw.

Signs The chief signs of a fracture are uselessness of the part, CREPITUS of the fragments, and sometimes unnatural mobility and deformity. If a limb is affected there is usually an unnatural mobility, inability to sustain weight, distortion or deformity, shortening of the length of the limb (due to overlapping of the fragments), a thickness or swelling at the seat of the fracture, and a variable amount of pain. (See also 'Fractures of special parts', below.)

Healing of fractures When the bone breaks, many blood vessels are torn, and accordingly a large clot of blood forms around the ends, between them, and for some distance up the inside of the bone. Later, great numbers of white blood cells find their way into this clot, which becomes 'organised' – blood vessels and, later, fibrous tissue being formed in it (soft callus). Next, lime salts are gradually deposited in this fibrous tissue, which thus develops into bone (hard callus). In this process a thick ring of new bone forms round the broken ends, filling up all crevices; and when union is complete, this thickening is again gradually absorbed, restoring the bone as it was before the injury.

Treatment There are many ways of stabilising a fracture after reduction and apposition are brought about by manipulation of the fractured bones under anaesthesia. External methods include bandages and splints and specially moulded casts of plaster of Paris, and various proprietary mixtures impregnated into bandages. (See SPLINTING MATERIALS.) Whenever splints, plaster, or other bandages are being applied to fractured limbs it is essential to ensure that the surface of the skin is well padded with cotton-wool, and that the pressure is evenly distributed. Failure in this respect may result in parts of the skin developing pressure sores or becoming gangrenous through obstruction to the blood-flow. Thus other methods are now often replaced by sophisticated surgical techniques. (See SPLINTING MATERIALS.)

Special types of extension splints, having transverse pins which transfix the bone, have been used with success in appropriate cases. Medullary pins, driven down the marrow cavity of long bones; wiring; and plating have all been used with success. (See BONE-PINNING.)

Bone Grafts These are used to a limited extent in veterinary surgery to repair fractures of the femur, humerus, tibia, radius and ulna; or to replace comminuted fragments, to lengthen bones or to correct delayed or faulty union.

Metal splints which have transverse pins to penetrate and fix the bone are used in treating fractures in small animals, and have succeeded in cases where other methods would be ineffective.

The allografts are harvested aseptically from the patient or from an outside source such as a conspecific animal or from synthetic sources. Ordinary orthopedic techniques are used to secure the implant.

Fractures of special parts

1. The cranium Cases of traumatic fracture of the skull result in concussion; if not severe they may recover with conservative treatment and nursing. Depressed fractures involving the cranial cavity or the cranial nerves are difficult to treat and usually carry a poor prognosis. (See also CONCUSSION.) Surgical treatment may be successful in cases in which fractures involve bones of the jaws and face.

2. The face bones Fractures may be simple or serious according to bones involved. Nasal bones, often fractured from accidents, may be accompanied by swelling, pain, haemorrhage, difficulty in breathing, and much watering of the eyes. Jawbones broken from falls, kicks, etc. usually interfere with feeding. Lower-jaw fractures usually result in an open hanging mouth, escape of saliva, and altered expression; frequently, loose teeth, torn lips, and haemorrhage are seen. Bones of orbit fractured by falls on to side of head, collisions, etc. interference with vision and with movements of the lower jaw, in most cases serious. Treatment usually necessitates operation – removal of broken pieces, elevation of depressed portions, removal of loose teeth, wiring or plating broken

VetBooks.ir

parts together. Feeding must be carefully undertaken when jaws are injured – sloppy food, mashes, etc., for horses; hand-feeding for dogs. Sometimes in small animals a feeding tube may be needed.

3. The vertebrae Commonest in horse and dog through accidents (e.g. in horses being cast in stall or for surgery, road-traffic accidents in dogs, falls from heights). If a vertebra is fractured, paralysis results. There is often a fatal termination, or a need for euthanasia. Tail-bones are often broken in dogs, cats and cattle through getting caught in doors, gates, fences, etc.

4. The ribs These are usually due to trauma. Most rib fractures heal spontaneously without any surgery or treatment. Flail chest describes multiple adjacent rib fractures, which can then severely affect breathing. First rib fracture sometimes happens through muscular action in a side-slip and violent recovery in horses, when it often results in RADIAL PARALYSIS. Otherwise, broken ribs show little or nothing characteristic except local pain and deformity, unless many are involved, when breathing may be short and/or difficult. (See 'FLAIL CHEST'; PNEUMOTHORAX.)

5. The pelvis In dogs and cats, loss of conformity of the pelvis may lead to DYSTOKIA or intractable chronic CONSTIPATION and so surgery is recommended when a pelvic fracture is comminuted.

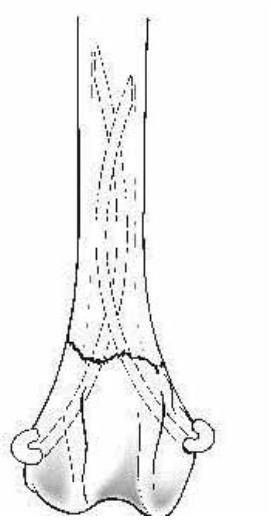
6. The scapula Fractures are uncommon. Mostly, they occur through the neck of the bone, or on the projecting spine. The musculature covering the bone may impede diagnosis but assists recovery, and it may act as natural bandage.

7. The humerus Lameness, intense in all animals, follows fracture; the limb is usually quite useless. Horses and cattle do not make good recoveries except when young, but healing in small animals is more satisfactory. The majority of fractures affect the middle and distal third and almost all require surgery for repair. Fractures of the distal humerus are common in young dogs and may also affect the elbow. (See BONE-PINNING.)

8. The radius and ulna One or both bones may be broken; fracture of the ulna is less serious unless the elbow-joint is involved. In dogs and cats, if one is broken the other acts as a natural splint. Lameness is always marked, and there is pain on pressure. Local swelling and deformity are usually noticed. Young horses should be placed in slings. Surgical fixation has been carried out successfully in the dog and the horse.

9. Coronoid process Young dogs with mild lameness due to fragmented medial coronoid processes probably do not benefit from surgery, but dogs with chronic, moderate or severe lameness do.

10. Bones of knee These are seldom fractured, but if they are it is usually impossible to bring about recovery without stiffening of the joint (ankylosis).



11. The metacarpals In the horse, good recoveries are made in cases of clean transverse fractures without complications or splinters. Prognosis is best in fractures occurring in the middle of the cannon. The limb is bandaged with a plaster or proprietary resin-impregnated bandage and the horse slung; the plaster is left in position for at least 6 weeks. In the dog, the treatment depends on which bones are involved. Metacarpals three and four are the main weight-bearing bones and if both of these are affected surgery is normally indicated. Fractures where only one or two bones are affected usually respond well after setting and a supporting dressing of the affected limb, as the other unaffected bones act as natural splints.

12. The pastern bone Fractures may be transverse, oblique, or longitudinal ('split pastern'), often comminuted. Severe lameness always results. In the horse, simple transverse fractures can be treated satisfactorily if the temperament of the horse will allow rest and slinging; oblique, longitudinal, and all comminuted cases are unsatisfactory and if recovery occurs, usually some deformity or blemish is left.

13. The second phalanx, coffin and navicular bones Fractures in these bones are rare; they may the caused by direct violence, and sometimes follow an operation of neurectomy (unnerving); may be seen in cattle as a result of weakening of bone through FLUOROSIS. Fracture of the coffin-bone, if simple and joint surfaces are not involved, makes good recovery as a rule, since the hoof acts as splint and bandage. Fracture of the second phalanx (short pastern bone) is usually difficult to resolve.

Most fractures of the navicular bone are sagittal and minimally displaced, but the prognosis is usually poor because the fibrous callus causes permanent lameness. Such fractures have been repaired by inserting a 50 mm screw which exerts compression between the two fragments. The pilot hole is drilled and the screw is inserted precisely along the transverse axis of the navicular bone by means of a mechanical guide, the process being monitored by image-intensifying fluoroscopy. The fractures are said to heal without superfluous callus formation.

14. The femur Very commonly fractured in dogs after road traffic accidents. Shaft, neck, or one of the trochanters may be involved. Frequently in dogs, dislocation of the hip-joint accompanies fracture, but dislocation may occur without damage to the bone. Extreme lameness, shortening of the limb, local swelling, and great pain on movement are usually seen. There may or may not be crepitus. In horses, fracture of pelvis very often accompanies fractured femur and makes diagnosis difficult. A fractured femur usually necessitates euthanasia in large animals, but in small animals the chances of recovery are usually improved by surgery. (See BONE-PINNING.)

Two Rush-type intramedullary pins used to repair a supracondyloid fracture of the femur.

15. The patella Fracture is a very serious condition, resulting in a lowering of the affected stifle and inability to advance the limb. There is great pain. Treatment is union of the fragments by wire sutures; this may be difficult to perform satisfactorily, and complete recovery may not occur.

16. The tibia Many fractures of tibia become compound from sharp points of broken bones penetrating through the skin. (See BONE-PINNING which has been used successfully in the dog, cat and horse.) The poor blood supply of the tibia means that it takes longer to heal than other long bones.

17. Bones of hocks In fracture of the os calcis (point of hock) – the proximal epiphysis becomes displaced from the rest of the bone by an undue pull of the Achilles' tendon (gastocnemius or hamstring). Fractures of other bones of hock are less common (with the exception of the SCAPHOID in the racing greyhound).

Framycetin

An aminoglycoside antibiotic with activity against some Gram-positive and some Gram-negative bacteria. It is mainly used in intramammary cerates, topical applications and to treat intestinal infections. It is little absorbed. An injection is available for treatment of acute bacterial MASTITIS in cows caused by *E. Coli*, KLEBSIELLA, STAPHYLOCOCCUS AUREUS or *Trueperella pyogenes*. It is not widely used in human medicine.

Francisella

(See TULARAEMIA.)

'Freedoms' for Farm Animals

(See FARM ANIMAL WELFARE COMMITTEE; 'FIVE FREEDOMS' FOR FARM ANIMALS.)

Freemartin

Usually defined as a sterile heifer born twin to a normal bull calf; the most widely accepted explanation being that sex hormones from the earlier developing male twin pass across to the female twin, with the result that sexual differentiation of both male and female proceeds under control of male hormones.

However, as long ago as 1917 it had been suggested that hermaphrodites might occur in female single births, as a consequence of early fetal death and resorption of the male twin in the uterus. During the 1970s chromosome analysis had revealed the presence of both male and female cells in single-born bull calves. Dr W. V. S. Wijeratne and colleagues were the first to demonstrate this condition – technically known as secondary chimerism – in single-born freemartins. (Primary chimerism can occur where two sperms fertilise the same ovum.)

Not every female fetus having a male twin sharing the uterus will become a freemartin, because in some instances death of the male twin fetus occurs before about day 39 of pregnancy – when a common blood supply may become established. Moreover, in between 5 and 10 per cent of heterosexual twin pregnancies a common blood supply is not established.

About 90 per cent of heifer calves born twin to a bull calf are freemartins. Many freemartins can be detected on clinical examination, since the vagina is often only one-third of the normal length and, in addition, there is often an enlarged clitoris and a vulval tuft of hair.

The condition is associated with anastomosis of the placental blood vessels (see diagram).

Pig freemartins may also occur. (See also H-Y ANTIGEN.)

Free Radicals

Highly reactive molecules, formed in the presence of oxygen and capable of damaging living tissue.

VetBooks.ir

VetBooks.ir

They have been implicated in human heart disease and arthritis. They may also be a cause of sudden death of pigs – those being transported for long distances or subject to other forms of stress. However, it has been suggested that protection may be given by feeding vitamin E, which 'scavenges' radicals.

Free Range Eggs, Free Range Hens, Free Range Poultry

A system where birds have daily access to the outside, but will also have access to housing. The maximum number of birds outside per square metre is nine. There must be two metres (6 ft 6 in) of opening per 1000 birds. In 1975 three per cent of whole eggs sold were free range; in 2011 50 per cent of eggs consumed were free range. IMPACTION of the GIZZARD is common due to the excessive ingestion of coarse fibrous material. They are more likely to be exposed to wild birds and animals and develop AVIAN TUBERCULOSIS and SALMONELLOSIS. Poultry eating EARTHWORMS of *Eisinea foetida* produce garlic flavoured eggs. Tree-covered pens reduce FEATHER PICKING and second-quality eggs.

Freeze-Branding

(See BRANDING.)

Fremitus

Fremitus is a sensation which is communicated to the hand of an observer when it is laid across the chest in certain diseases of the lungs and heart. Friction fremitus is a grating feeling communicated to the hand by the pleura or pericardium (see HEART DISEASES) when it is roughened as in pleurisy or pericarditis. On rectal examination of cows over five months pregnant, fremitus can be felt in the middle uterine artery.

French Bulldog

A small dog resembling the English bulldog of the 19th century. BRACHYCEPHALIC airway obstruction syndrome is inherited by an unknown mechanism, as is SPONDYLOSIS DEFORMANS, intervertebral disc disease and HEMIVERTEBRAE. Haemophilia, both A (Factor VIII deficiency) and B (Factor IX deficiency). may be found as sex-linked recessive traits. Ununited anconeal process (elbow) is a dominant trait and patellar luxation may be a recessive trait. Inherited CATARACT occurs (DNA test available). NICTITATING MEMBRANE GLAND PROLAPSE is seen.

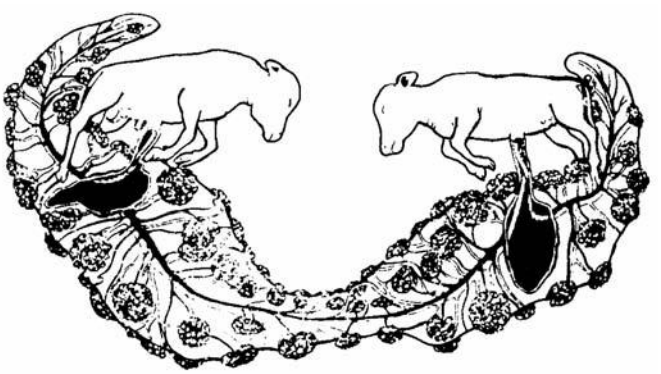
French Mastiff

(See DOGUE DE BORDEAUX.)

French Moult

(See BUDGERIGAR FLEDGLING DISEASE.)

Friesian Cattle



A black and white breed of milking cow which was predominant in the UK from the 1960s to late 1980s. It produces good volume of milk and is well fleshed so that the male calves can be used for beef production. It became superseded by crossing with the HOLSTEIN, producing the HOLSTEIN-FRIESIAN CATTLE. Most UK milking herds became pure Holstein; however, the Friesian is more robust than the Holstein and is able to survive longer with more lactations. It also appears to have fewer lameness and fertility problems. Many organic herds favour its use.

Friesian Horses

These horses originate from the Netherlands, where they were bred in Medieval times as war horses. They have to be black without any white present and with a long mane and tail. The limbs are FEATHERED and they have a high-stepping gait.

Friesland Sheep

Also known as the British Friesland. A white sheep, naturally polled, with a thin white face; fine boned and a long bald tail. They are used for milk. The

The bovine freemartin.

rams weigh about 75 kg (165 lb) but can be 120 kg (265 lb) and the ewes 50 kg (110 lb), with about 5 kg (11 lb) fleece.

Frog
(See FOOT OF THE HORSE.)

Frogs
They are amphibians from the Order *Anura*, usually with short bodies, webbed feet, absence of tail, protruding eyes and a forked tongue; some produce mild toxins. Their hind legs are developed for jumping. They are mainly semi-aquatic and can live in humid climates outside water because they have a permeable skin. They occur in most parts of the world but more species are found in the tropics, and some of these in particular are kept as pets. In recent years they have suffered a fatal fungal dermatitis due to BATRACHOCHYTRIUM DENDROBATIDIS. A dead vaccine has been developed producing IgG and IgY antibodies.

Frontal Bone of the Skull
A roughly quadrilateral plate-like bone which forms part of the roof of the cranium and passes forward between the eyes to meet the nasal bones. In the horned breeds of cattle and sheep it is extended laterally to form the horn cores. (See BONES; also SINUSES OF THE SKULL.)

Frontal Sinus
(See SINUSES OF THE SKULL.)

Frost-Bite
Frost-bite may affect any animal exposed for long periods to severe cold, resulting in freezing of the skin, particularly of the extremities, with precipitation of blood proteins, occluding blood vessels. It is less common in animals than humans because of the protection given by the winter hair coat. Hairless species and parts of the body are, however, susceptible. For example, in poultry on the wattles, comb and face; and around the CORONARY BAND of horses.

Frounce
TRITRICHOMONIASIS in hawks and falcons. (See FALCONS, DISEASES OF.)

Frozen Embryos
(See EMBRYO TRANSFER.)

Fructans
These are used in nutrition of animals and man. They are POLYMERS of FRUCTOSE molecules. Those that are short chains are called FRUCTO-OLIGOSACCHARIDES and long chain ones are called INULIN.

Fructo-Oligosaccharides
Used to stabilise the intestinal microflora in many species including horses, calves, chickens and fish (rainbow trout, tilapia, shrimp). They can be used after enteritis.

Fructosamine
A plasma protein which helps to indicate the average blood glucose measurement in the previous one to two weeks. It is a combination of fructose with ammonia or an amine.

Fructose
It is a sugar (monosaccharide) and ISOMER of GLUCOSE also known as 'fruit sugar', 'grape sugar' or laevulose. It is found in honey and fruits and is absorbed.

Frugivorous
Fruit-eating.

Frusemide
A potent diuretic suitable for the treatment in dogs and cats of some cases of OEDEMA associated with cardiac insufficiency, renal dysfunction or trauma. Frusemide acts about one hour after oral administration and is effective for about four hours.

'Frying Pan' Deaths
Overheated fat gives off acrolein, which can be highly poisonous and was, indeed, used in chemical warfare in 1914–18. A dog died after being shut up in a kitchen for half an hour with a smoking chip pan. Ante-mortem signs were distressed breathing and cyanosis.

Cage birds are susceptible to fumes from an overheated non-stick frying pan coated with plastic polytetrafluoroethylene (TEFLON). It is quite a common accident in birds kept in kitchens. Death occurs rapidly following exposure. (See 'KITCHEN DEATHS'.)

FSA
(See FOOD STANDARDS AGENCY.)

FSH
(See FOLLICLE STIMULATING HORMONE.)

Fucosidosis
A lysosomal storage disease caused by the absence of an enzyme – alpha-L-fucosidase.

It is an inherited disease in the English springer spaniel, affecting mainly those between 18 months and four years old. The signs of this ultimately fatal disease include ataxia, change in temperament, depression, apparent deafness and impaired sight. Swallowing may be difficult. Loss of weight occurs. A DNA test exists to identity affected dogs

VetBooks.ir

and carriers of the disorder. (See LYSOSOMAL STORAGE DISEASE.)

Fucus
An extract from seaweed found in some herbal remedies for dogs and cats, which claims to assist in the treatment of obesity, constipation and iodine deficiency.

Fulguration
The destruction of a superficial lesion with electric or radiation energy. (See RADIOSURGERY.)

Fumes
(See CARBON MONOXIDE; 'FRYING PAN' DEATHS; SLURRY; ANAESTHESIA, GENERAL; AEROSOLS.)

Fumigation
(See DISINFECTION.)

Fundus
Fundus is the base or innermost part of a hollow organ distant from its opening.

Fungal Diseases, Mycoses
Broadly speaking, these include both the invasion of tissues by fungi, and the effects on organs of fungal poisons (see MYCOTOXICOSIS).

Ringworm offers a good example of the invasion of tissues by pathogenic fungi; one should, perhaps, say potentially pathogenic fungi, for many are present in the alimentary canal of healthy animals, and cause lesions only when circumstances favour invasion or multiplication. (See MASTITIS IN COWS, MYCOSIS, for an example of the latter; also ASPERGILLOSIS; BLASTOMYCOSIS OF DOGS; HISTOPLASMOSIS; MUCORMYCOSIS; MONILIASIS; STREPTOTHRICOSIS; CRYPTOCOCCOSIS; *Fusarium*; MORTIERELLA; COCCIDIOMYCOSIS; RHINOSPORIDIOSIS; SPOROTRICHOSIS.)

Fungal Toxins
(See MYCOTOXICOSIS.)

Fur, Diseases of
(See FUR RING; FUR SLIP.)

Fur, Swallowed
(See HAIR-BALL.)

Furazolidone
A nitrofuran compound used against antibacterial and antiprotozoal infections. Its use in food animals is no longer permitted in the EU.

Fur Chewing
This is seen in chinchillas and is caused by boredom, nutritional deficiencies or stress.

Furcula
Commonly called the 'wishbone', the furcula comprises a fusion of the clavicles or 'collarbones' of birds. Together with the coracoids, scapulae and sternum it forms the pectoral girdle and acts to maintain the proper spacing of the shoulder joints.

Furfuraceous
Furfuraceous is a term applied to skin diseases which produce a bran-like scaliness.

Fur Mites
(See MITES, PARASITIC.)

Furosemide
A diuretic (removing fluid) acting on the ascending loop of Henle in the kidney. It is used to treat OEDEMA due to CONGESTIVE HEART FAILURE or RENAL INSUFFICIENCY and HYPERTENSION. It can result in excessive potassium loss, increased retention of uric acid and glucose.

Fur Ring
A condition in which fur is found encircling the penis of chinchillas. The usual clinical presentation is PARAPHIMOSIS, the fur ring being found on closer inspection of the penis. Clinical signs include excessive grooming, discomfort, POLLAKURIA, or dysuria. Often, the animal injures its own penis in its attempts to remove the fur.

Fur Slip
Seen in chinchillas as hair loss and localised alopecia following rough handling. Regrowth occurs in four to six months.

Furunculosis
This is the dermatological term for a boil (or furuncle). It follows the rupture of an infected follicle into the dermis and subcutaneous tissues, where it may spread extensively. The cause of the original infection may be bacterial, fungal or parasitic. Often there is associated disease. The condition occurs in all species. (See INTERDIGITAL CYSTS.) Perianal furunculosis also occurs in dogs.

Furunculosis in fish is caused by *Aeromonas salmonicida*. Raised furuncles can be seen all over the body and they may be complicated by secondary fungal infection. A sudden increase in water temperature can trigger the appearance of the disease.

Furunculosis in salmon is caused by *Aeromonas salmonicida* but may be triggered by a sudden rise in water temperature. Young fish stop feeding and may die soon afterwards. Older fish are more resistant; they develop large, boil-like swellings on the shoulder and back. If these burst, a reddish fluid rich in bacteria is released. The

bacterium persists in some fish between outbreaks and is present in wild fish. Treatment is by medicating the feed with sulfonamides or tetracyclines but the fish may be reluctant to take medicated food. It is a NOTIFIABLE DISEASE under the Diseases of Fish Act 1937.

Furze, Gorse

(*Ulex europaeus*.) A very common and plentiful shrub in waste lands in Britain, it was formerly often cut and used as fodder after chaffing or bruising. The plant contains a very small proportion of a poisonous alkaloid which is called *ulexine*, and is practically identical with cystine from broom. It is a nerve and muscle poison, but it is seldom present in dangerous amounts.

FUS

(FELINE UROLOGICAL SYNDROME; see FELINE LOWER URINARY TRACT DISEASE)

Fusarium

A mould that can produce toxins including T_2 TOXIN. Mouldy shelled maize containing *F. moniliforme* has caused diarrhoea and ataxia in cattle; and in BROILERS the same species, contaminating maize and wheat, has with *F. culmorum*, *F. Tricinctum* and *F. nivale* been implicated in poor growth rate, poor feathering, and abnormal behaviour. *Fusarium* species may also cause keratoconjunctivitis. In pigs, it causes refusal of food. (See under EYE, DISEASES; also MYCOTOXICOSIS; ZEARALENONE.)

Fusemide

(See FUROSEMIDE.)

Fusidic Acid

An antibiotic used in topical applications for otitis externa (See EAR, DISEASES OF), PYODERMA, and conjunctivitis.

Fusobacterium necrophorum

An anaerobic bacterium, formerly known as *Fusiformis necrophorus*, which causes FOUL-IN-THE-FOOT of cattle, CALF DIPHTHERIA, ABSCESSES in the liver and other organs. Also involved in foot-rot in sheep. (See table under BACTERIA, and FOOT-ROT OF SHEEP.)

Fusus Coli

An area of the large colon of LAGOMORPHS, more muscular and more highly innervated than the rest of the organ. During digestion, it is responsible for control of the passage of food to and from the CAECUM.

FVE

(See FEDERATION OF VETERINARIANS OF EUROPE.)

VetBooks.ir

G

GABA
(See GAMMA-AMINOBUTYRIC ACID.)

Gadding
Excitement, restlessness, uncontrolled rushing around in horses or cattle due to the presence of biting flies; also, in the case of cattle, warble flies. Although eradicated in the UK, gadding still occurs.

Gad-Fly
(See FLIES; WARBLES). In the UK, before warble fly eradication, they were on the wing from mid May onwards.

Gag
1. A device to facilitate oral examination or treatment by holding the mouth open.
2. An action whereby an individual attempts to cough and vomit, not necessarily successfully. A sign in dogs of a sore throat (pharyngitis), palatial injury or the presence of a foreign body in the pharyngeal area.

Gait, Abnormal
(See ATAXIA; 'GOOSE-STEPPING'; LAMENESS.)

Gall-Bladder
A pouch-like sac in which bile produced by the liver is stored until it is required during the process of digestion. It is a hollow, pear-shaped organ lying in a depression on the posterior surface of the liver. The gall-bladder is not present in the horse and other *Equidae* or in several avian orders including *Psittaciformes*, *Columbiformes* and *Struthiformes*, but is found in the other domesticated mammals. (See also LIVER.)

Blockages of the bile-duct by liver flukes or by gallstones may result in jaundice as well as severe local inflammation. Acute inflammation of the gall-bladder is painful, and there is danger of rupture or gangrene.

Gallinaceous Birds
Birds of the Order *Galliformes* including poultry and game birds.

Galloway Cattle
One of the world's oldest breeds of beef cattle, originating from the Galloway region on the borders of Scotland and now found all over the world. It is polled with a long thick woolly undercoat coloured black or dun (due to a red recessive gene). This coat acts as very effective insulation and so there is only a relatively thin layer of superficial fat under the skin. The coat is shed in the summer and warm climates. They are extremely hardy and they can live in harsh environments, but often resent handling because of their ranging lifestyle. Although small they are stocky and are deceptively heavy. Bulls weigh 730 kg to 860 kg (1,600 lb to 1,900 lb) and cows 410 kg to 570 kg (900 lb to 1,250 lb) and calves weigh at birth about 33 kg (72 lb). TIBIAL HEMIMELIA reported in the breed. A variety of the Galloway is the BELTED GALLOWAY.

'Gall Sickness'
(See ANAPLASMOSIS.)

Gallstones
Gallstones, which are also known as biliary CALCULI, are concretions which are formed in the gall-bladder or in the bile-ducts of the liver. As a rule they are hard, brownish in colour, coated with mucus, and of a more or less rounded shape. They may be composed of cholesterol; of cholesterol and bile pigments; or of pigment and lime salts. One or several may be present, causing pain and jaundice.

Gallstones are more prevalent in sheep than in cows, dogs, cats and horses. Sophisticated diagnostic imaging techniques have vastly improved recognition of this condition.

In human medicine, ursodeoxycholic acid has been used to dissolve gallstones.

GALT
The acronym for GUT-ASSOCIATED LYMPHOID TISSUE – the lymph tissue found in the intestines. (See PEYER'S PATCHES.)

Galvanised Aviary Wire
Psittacine birds housed in recently constructed wire aviaries and cages can acquire zinc toxicity from their habit of pecking the galvanised layer from the new wire. They develop neurological signs similar to LEAD POISONING. The condition is confirmed by blood examination. Washing the wire with dilute vinegar (acetic acid) will prevent the condition. (See 'NEW WIRE DISEASE'.)

Galvanised Bins
Galvanised bins, used to store swill, have led to ZINC POISONING in pigs.

Galvayne's Groove
A vertical groove in the front surface of the horse's upper corner incisor teeth. It first appears at the gum margin at about 10 years old and gradually moves down the surface of the tooth as the horse ages until it grows out at about 30 years old. (See

DENTITION – Horses.) The groove is of limited use in age estimation as time of growth is too variable.

Galway Sheep

Almost a smaller version of the ROSCOMMON LONGWOOL SHEEP. Mainly found in the west of Ireland, they are polled with a white full head and a characteristic mop of wool on the poll. The outer lips are dark coloured and there are often dark spots on the ears. The wool is white, long fleeced and curly with the legs woolled. They are thought to be like Robert Bakewell's Dishley breed. The ewes weigh about 80 kg to 85 kg (175 lb to 190 lb).

Game Birds, Mortality

This may be considered under two headings:

From farm chemicals Many farm chemicals can cause poisoning in game and other birds. Deaths have resulted from the use, as seed dressings, of compounds such as dieldrin, aldrin and heptachlor, now banned in the UK. Some of the organophosphorus insecticides; dimethoate; and the 'nitro-type' of weedkillers such as DNC (3,5-dinitrophenylmethylsulfone), which stains the carcase yellow; are among other chemicals hazardous to birds.

Pheasant poults have died as a result of being treated for lice with a 5 per cent gamma benzene hexachloride (BHC) dusting powder.

An organophosphorus insecticide does not necessarily act quickly. Death may occur eight weeks after eating the poisoned food. The signs shown by poisoned birds include ruffled feathers, saliva around the beak, high-stepping gait or unsteadiness on the legs, distressed breathing, and paralysis. However, as their use is now reduced, problems caused by organophosphorus compounds are less frequent.

Spraying an orchard with either DDD or DDT (now banned) has caused heavy game-bird losses. Partridges have died within a few hours of eating earthworms which came to the surface of the soil soon after spraying. Rat poisons may perhaps be included in the term 'farm chemicals'. Owls die after eating poisoned rodents.

From natural causes Impacted gizzard, tuberculosis, aspergillosis, swine erysipelas, fowl-pox, fowl cholera, fowl typhoid, infectious sinusitis. Gapes is another cause of death; also in the USA, encephalomyelitis. Deaths from fowl pest (NEWCASTLE DISEASE) have been reported in the UK, and BLACKHEAD in pheasants and partridges. From 2012 game birds, particularly pheasants, have died in large numbers with *Sarcina* isolated, usually other diseases and problems.

'Grouse disease' is the colloquial name for infestation with the helminth *Trichostrongylus tenuis*. Mortality occurs when food is in short supply as a result of poor growth or overpopulation of birds on a moor. In some circumstances, it has been concluded that grouse have died because not enough were shot the previous year. Grouse tend to remain in a locality and not move to other moors.

Louping ill, transmitted by sheep ticks, is generally fatal to red grouse (*Lagopus lagopus scoticus*), the commonest game bird on British heather moorland, and can reduce stocks to very low densities.

Inclusion-body hepatitis A nine-day viral disease that can result in a high mortality among intensively reared pheasant poults (19 days old when one large outbreak began).

Salmonellosis Outbreaks in pheasants infected with *S. typhimurium* are recorded with a high mortality, often with deaths beginning at a few days old. Antibiotic treatment may control the disease.

Coccidiosis is an important disease of pheasants and other game birds, in chicks two to four weeks old. Milky-white droppings are the most obvious sign (but these are also seen with excess urate excretion due to kidney disease).

Yersiniosis is another important disease of pheasants.

Moniliasis causes lethargy, stunted growth and a heavy mortality in partridges. Treatment with formic acid, sprayed on food, has proved successful. (See also BOTULISM.)

Gametes

These are the ova and spermatozoa, and contain half the number (haploid) of chromosomes present in all other body cells (diploid).

Gametocide

Gametocides kill gametes (spermatozoa, ova) and so control fertility. (See TEM.)

Gametocyte

An oocyte or spermatocyte, the cells which produce an ovum or spermatozoon.

Gamma-Aminobutyric Acid (GABA)

One of the main inhibitory neurotransmitters in the central nervous system.

Gamma Globulin

Gamma globulin is a protein fraction of the blood serum which contains the antibodies against

VetBooks.ir

certain bacteria or viruses. (See COLOSTRUM; IMMUNOGLOBULINS.) It can be prepared in a concentrated form and can be used to give temporary protection against infection. Gamma globulins may be used as a treatment of certain diseases.

Gamma Glutamyl Transferase (GGT)

An enzyme that tends to increase in liver disease and indicates damage of the bile ducts. Higher than normal concentrations are found in liver-fluke infection of sheep and cattle. In a blood sample it can be used as an indirect measure of colostrum intake by calves.

Gammexane

Gammexane products contain the gamma isomer of benzene hexachloride, a highly effective, persistent insecticide. Not now used in treating farm animals. (See BENZENE HEXACHLORIDE; also BHC POISONING.)

Ganglion

A ganglion is a group of nerve cell bodies.

Ganglioside

A glycolipid found in central nervous system (CNS) tissue.

Gangliosidosis

An inherited disease causing poor growth and progressive neuromuscular dysfunction. It results from an accumulation of gangliosides in CENTRAL NERVOUS SYSTEM tissue and may be seen in cattle, pigs, dogs and cats. There is an abnormal gait and head tremors in dogs and cats. (See PORTUGUESE WATER SPANIEL DOGS; SIBERIAN HUSKIES; see also GM_1 GANGLIOSIDOSIS.)

Gangrene

The presence of necrotic (dead) tissue in a live animal. It may result from a blocked artery or bacterial infection toxins and for a variety of reasons including frost-bite, prolonged pressure and the application of chemical irritants or burns. There are two varieties of gangrene, dry and moist; dry gangrene is a condition of mummification in which the circulation stops and the part withers up, while in moist gangrene there is inflammation accompanied by putrefactive changes.

Poisoning by ergot results in the same condition in the most distant parts of the body, e.g. the feet, tip of tail, ears and the combs and wattles of poultry.

Signs There is at first a degree of pain when the affected part is handled, and in a short time it becomes reddened and swollen. Later, there is a loss of sensation. The skin turns blue or black, the hair falls from it, and there is a distinct line of demarcation between the gangrenous and the healthy surface. Around the dividing line there is usually some degree of inflammation, and pus production.

Moist gangrene is considerably more serious, since it is accompanied by putrefaction and the absorption of toxins. The whole area turns black or greenish, the hair falls out, an offensive smell is evident, and much fluid exudes from the decomposing tissues. A high temperature, disturbed heart's action, and rapid breathing, are shown. (See also GAS GANGRENE.)

Treatment depends on the cause and is mainly surgical, and with the use of appropriate antibiotics or sulfonamides. In advanced cases, euthanasia becomes necessary. (See also FROST-BITE.)

Gangrenous Dermatitis

A disease of poultry caused by *Clostridium perfringens* Type A. The organism is very resistant to disinfectants and can exist in a wide range of environmental conditions. The disease can be exacerbated by concurrent immunosuppressive diseases such as INFECTIOUS BURSAL DISEASE, MAREK'S DISEASE, aflatoxicosis (see AFLATOXINS) and INCLUSION BODY HEPATITIS, it usually affects birds between 17 and 140 days of age.

Mortality can range from 15 to 60 per cent. The disease often occurs in crowded conditions that cause feather breakage and entry of the bacterium. It may start as a scratch around the lumbar or sacral region; skin lesions are 'crackly' when palpated. The birds become lame, recumbent and can die within 24 hours. Post mortem lesions are oedematous and emphysematous swellings in muscles and subcutaneous tissues, with congested heart, lungs and kidneys. Treatment is by topical and systemic antibiotics.

Ganjam Ulrus

The Indian name for a bunyavirus infection transmitted by ticks.

Gapes

Gapes is a disease of young chickens, turkeys, pheasants and other game birds particularly, although all the domesticated and many wild birds may also be affected. It is caused by infection with the gapeworm, *Syngamus trachea*.

The presence of worms in the bronchial tubes and trachea of the bird causes it to gasp for breath or 'gape', from which the name of the disease originated. Part of the life-cycle of the worm is passed in the body of the earthworm, and young chickens eating earthworms may become affected.

Earthworms can live for 16 years. (See also under CAPILLARIASIS.)

Pharmaceutical products used for treatment include fenbendazole, flubendazole, ivermectin, levamisole and tetramisole, but clinical signs may persist due to the continued presence of dead HELMINTHS in the trachea.

Garden Chemicals

Birds, dogs, and cats may be poisoned as a result of the use of pesticides. For the poisoning of birds, see preparations listed under GAME BIRDS, MORTALITY. Dieldrin is highly toxic for cats, and like DDT, should not be used on them or in their vicinity. In fact, all the CHLORINATED HYDROCARBONS are best avoided in places where small domestic animals or their food may become contaminated.

For the dangers of slug-baits, see METALDEHYDE POISONING. (See ORCHARDS for the dangers of fruit-tree sprays. For seed dressings, see under SEED CORN, DRESSED. See also PARAQUAT; HERBICIDES.)

Garden Nightshade Poisoning

Garden nightshade poisoning results from animals eating *Solanum nigrum*, which is found in many parts of the world. Its toxicity appears to vary in different localities. The berries contain an active alkaloidal glycoside called solanine, which is readily converted into sugar and the poisonous solanidine by the action of the gastric juices in the stomach.

Garden nightshade (*Solanum nigrum*), also known as black nightshade, has small purple flowers, and large black shiny berries, several of which are attached to a single stalk. Height: 1.3 to 2 m (4 to 6 ft).

Signs Staggering, loss of sensation and consciousness, and sometimes convulsions. First-aid: strong black tea or coffee.

Garget

Common term for MASTITIS.

Garlic

It is found in some herbal remedies. It has been used as an expectorant, intestinal disinfectant and diuretic; it possibly has antimicrobial properties.

Garron

A useful type of horse for hill-farm work and carrying deer. Garrons do not constitute a separate breed, but were a cross between Western Island ponies and the Percheron. Nowadays, the Garron is regarded as a larger version of the Highland pony.

Gas

(See AIR; BLOAT; CARBON MONOXIDE; OZONE; ANAESTHESIA, GENERAL; SLURRY; NITROGEN DIOXIDE.)

Gas Bubble Disease

A condition in which fish swim 'belly up' vertically; the cause is supersaturation of gases in the water in very intensive farming. It can be prevented by proper maintenance of pumps and normal (not pressurised) aeration of the water. A similar condition may occur in pond fish and may be due to internal disease. Temporary relief may be achieved by aspiration of the swim bladder. Tank-kept fish may be seen swimming upside-down and may respond by simply feeding a quarter of a dried pea.

Gas Gangrene

Gas gangrene is an acute bacterial disease due to the inoculation of wounds with organisms belonging to the 'gas gangrene' group.

Gas gangrene may attack any of the domestic animals and man. The horse is least resistant and the cow least susceptible.

Causes Gas gangrene is produced by *Clostridium oedematiens*, *Cl. perfringens* (formerly *Cl. welchii*), *Cl. septicum* and *Cl. chauvoei* gaining access to the tissues of an animal through a small wound; after castration or docking, or parturition, etc.

Signs A few hours after the organisms gain entrance, the area of invasion is found swollen, hot, painful on pressure, and may crackle when handled. This latter effect is due to gas formation below the skin. The skin and underlying tissues rapidly become discoloured.

In a series of nine cases in horses, the signs were fever, depression, painful muscular swellings, and toxaemia. All were dehydrated. Colic had been

VetBooks.ir

evident in six of the horses; laminitis in two. Infection had followed intra-muscular injections in eight of the horses, and a puncture wound in one. The *Clostridia* isolated were: *chauvoei* (one); *septicum* (six); and *perfringens* (six).

Prevention Vaccination is effective. (See also BRAXY; BLACK-QUARTER; GANGRENE.)

Gastralgia
Pain in the stomach.

Gastrectasis
Dilatation of the stomach.

Gastrectomy
Gastrectomy is an operation for the removal of the whole or part of the stomach.

Gastric
Gastric means anything connected with the stomach, e.g. gastric ulcer, gastric juice.

Gastric Dilation in Dogs, Gastric Dilatation in Dogs
(See GASTRIC TORSION.)

Gastric Dilation in Rabbits
This is often associated with intestinal obstruction. Rabbits continually salivate; the saliva is swallowed and the obstruction causes the fluid to build up in the stomach. The animal cannot regurgitate because of the cardiac sphincter. Treatment is difficult but the parenteral administration of opiates and NSAIDs with radiographic monitoring often produces a visible improvement. Laparotomy to 'milk' the obstruction through the caecum may be necessary or, in non-responsive cases, enterotomy and removal of the foreign body (usually a fur ball).

Gastric Lavage
The irrigation and washing out of the stomach, usually to remove caustic, poisonous or toxic materials. (See also LAVAGE.)

Gastric Torsion, Torsion of the Stomach
Except in the giant breeds of dogs, torsion or twisting of the stomach is rare. It is seen particularly in BLOODHOUNDS, GREAT DANES and ITALIAN SPINONES. The abdomen becomes painful to the touch, swelling may be apparent, and vomiting is likely to occur. The dog is soon in a very distressed condition, and needs emergency treatment or death will result.

Gastric Ulcers
These are seen in pigs in some cases (but not all) of SWINE FEVER. They have also been found in piglets under a fortnight old, due to *Rhizopus microsporus*, isolated from both stomachs and bedding. (See MUCORMYCOSIS.) Associated with this infection may be another fungal one – MONILIASIS – caused by the yeast-like organism *Candida albicans*.

Gastric ulcers may also be produced by the toxin of *Aspergillus flavus* (see AFLATOXINS) and by COPPER POISONING. They are also seen in racehorses in training and competition horses and can be treated with OMEPRAZOLE.

In mini-pigs, gastric ulcers are quite common when the diet lacks roughage.

For gastric ulcers in cattle, see under STOMACH, DISEASES OF.

In the USA, gastric ulcers have been an important cause of foal mortality.

Gastritis
Inflammation of the stomach.

Gastrocnemius
The gastrocnemius is the large muscle which lies behind the stifle-joint and the tibia and fibula, and ends in the Achilles tendon or 'hamstring' which is attached to the 'point of the hock'.

Gastrodiscus
Amphistome flukes, e.g. *G. aegyptiacus*, are common parasites of horses and pigs in the tropics and subtropics. A heavy infestation has caused collapse in the horse.

Gastroenteritis
Inflammation of the stomach and intestines, causing vomiting and diarrhoea. It is an acute condition commonest in young animals. It may be specific or due to irritant organic or inorganic poisons. (See also HAEMORRHAGIC, PARASITIC, and TRANSMISSIBLE GASTROENTERITIS OF PIGS; also DIARRHOEA.)

Gastrointestinal
Pertaining to the digestive or alimentary tract.

Gastrointestinal Tract, Gastro-intestinal Tract
The STOMACH and INTESTINES. (See DIGESTION.)

Gastropege
Gastropeges are the enlarged scales found on the ventral skin of a snake; they assist in the flowing locomotion of the animal. (See also OSTEODERM.)

Gastropexy
A surgical operation in which the stomach is fixed, usually, to the abdominal wall to prevent a recurrence of torsion. In dogs it has been carried out after spot coagulation of the surface of the

fundus by diathermy. The stomach is fixed in its normal position against the diaphragm by seven to ten rows of silk sutures (seven or ten to a row).

The incision into the abdominal wall is closed by absorbable synthetic sutures.

This operation is also known as fundupexy.

Gastrotomy
An operation to open the stomach, usually to remove a foreign body.

Gavage
Feeding an animal by means of a stomach tube.

GCCF
(See GOVERNING COUNCIL OF THE CAT FANCY.)

Gel
Gel is a colloid substance which is firm in consistency, although containing much water, e.g. ordinary gelatin.

Gelatin, Succinylated
A modified, fluid, gelatin used as a plasma substitute to restore blood volume and pressure in cases of hypovolemic shock. It is used as a first aid measure as it is excreted within 24 hours.

Gelatin Sponge
Gelatin sponge is prepared as a haemostatic, and can be left in a wound; complete absorption taking place in 4 to 6 weeks. The sponge may be sterilised in dry heat, and applied either dry or moistened with normal saline, an antibiotic solution, or a solution of thrombin. Absorbable gelatin sponge complies with the requirements of the *British Pharmacopoeia*.

Gelbvieh Cattle
This German yellow breed of cattle, as it is also known, was evolved by crossing Swiss breeds with German breeds, and is dual purpose, averaging nearly 3,640 litres (800 gallons) of milk at 4 per cent butterfat. Fattening stock give a daily liveweight gain of 1.1 kg (2.5 lb) and are ready for the butcher at 405 days in Germany.

Gelding
A castrated horse. Occasionally a horse which has had both testicles completely removed shows stallion-like behaviour, when it is known as a 'false rig'. Such an animal may mount mares and achieve both erection and intromission. The chasing, or rounding up, of mares, and nipping them, may also occur. This behaviour is not hormonally induced or hormone dependent; it has been suggested that it is part of the normal social interaction between horses. 'False rigs' and cryptorchids may show similar behaviour.

Blood samples from 104 horses with either sexual and/or aggressive male behaviour, but which had no palpable or visible testes, were assayed for testosterone levels 30 to 100 minutes after an intravenous injection of human chorionic gonadotrophin. All but 8 horses were classified as either geldings (<40 pg/ml) or cryptorchids (>100 pg/ml). Surgical investigation confirmed the diagnosis in 23 geldings and 47 cryptorchids; the remaining horses were not operated on. (See also CASTRATION – Immunocastration, for treatment of an aggressive cryptorchid stallion.)

General Anaesthetics
(See ANAESTHESIA, GENERAL.)

Generic Products
Those sold under their *Pharmacopoeia* names rather than brand names.

Genes
The biological units of heredity, arranged along the length of the CHROMOSOMES. (See also CELLS.)

Genetically Modified Feeds, GM Feeds
Genetically modified crops are used in many parts of the world. They are generally not grown in the EU. However, farm animals can be fed GM feeds such as SOYA, MAIZE, etc.

Genetically Modified Organisms
Organisms (bacteria, yeasts, animal or plant) that has been altered genetically to remove some or introduce new characteristics.

Genetic Engineering
This may be defined as the recombination of genes from different organisms into one organism in a way that would never occur naturally; e.g. from a plant into an animal. However, in practice, the terminology also includes genetic manipulation, although some changes brought about by manipulation may also occur quite naturally.

Advances in knowledge of nucleic acids led to the creation in the laboratory of new combinations of genetic material. This was achieved by splicing together DNA from entirely different sources to form hybrid molecules that are less likely to occur during evolutionary processes.

Micro-organisms virulent for cattle (for example) will, if they can be adapted to grow in laboratory animals, become less virulent for the original host, and may have usefulness for later vaccine purposes. One method of adapting the micro-organisms to grow in laboratory animals is to fuse, artificially, cells to form a HETEROKARYON. (See illustration on next page.)

VetBooks.ir

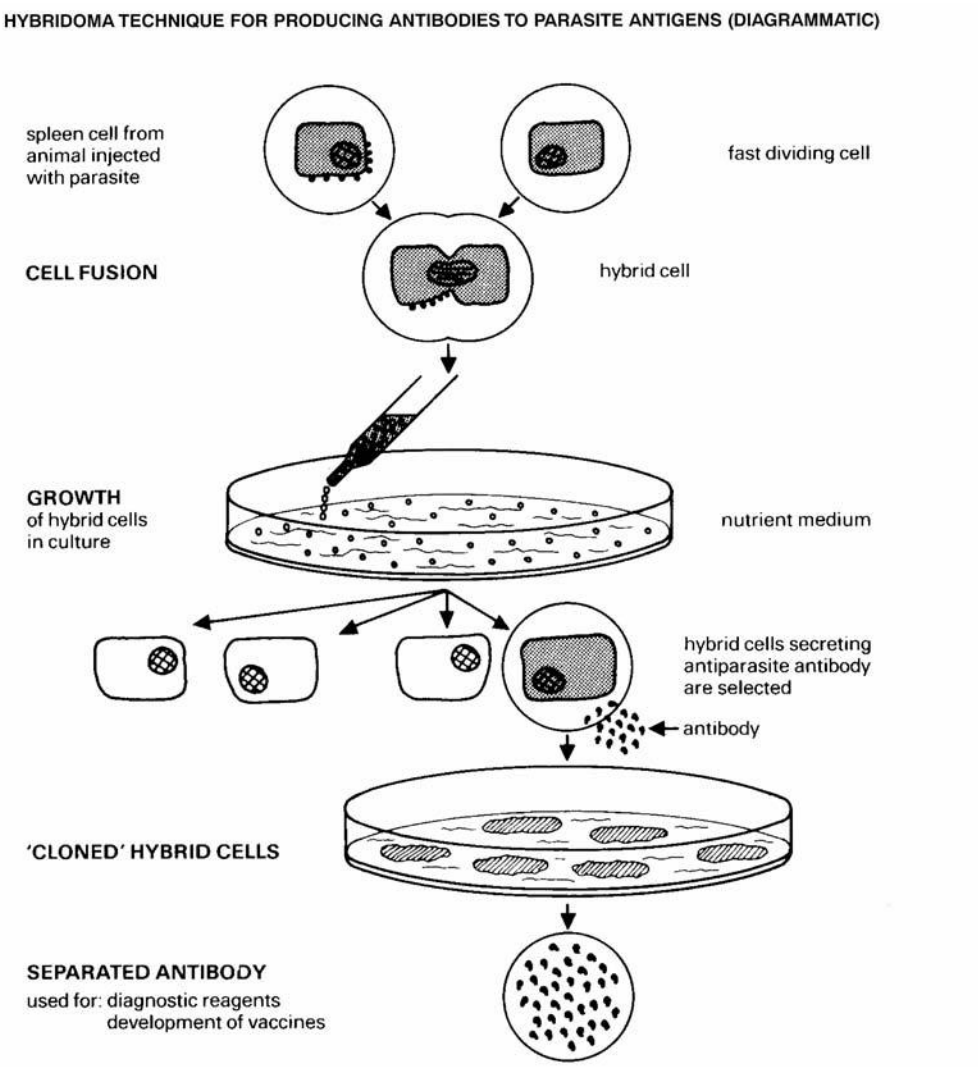
VetBooks.ir

A bovine/hamster heterokaryon formed by the fusion of *Theileria parva*-infected bovine lymphoid cells and baby hamster kidney cells. The cell contains 3 hamster nuclei and 1 bovine nucleus (arrowed) with a prominent nucleolus. The intracytoplasmic masses are macroschizonts of *T. parva*. (× 1600). (With acknowledgements to the Institute for Research on Animal Diseases.) Monoclonal antibodies from mouse hybridomas have been produced for use in blood typing in cattle.

Uses Genetic engineering has provided information on the molecular basis of gene action, on bacterial virulence and bacterial resistance. In agriculture it offers the hope of being able to transfer from bacteria to plants the genes which confer the ability to fix nitrogen – and so reduce farmers' dependence on scarce and costly nitrogen fertilisers.

In the UK, at the AFRC's Unit of Nitrogen Fixation, genes for nitrogen fixation were transferred with the aid of a PLASMID from a naturally occurring nitrogen-fixer *Klebsiella pneumoniae* to *E. coli*, which had never fixed nitrogen before. The plasmid, of the exchangeable class, was able, when transferring, to take along fragments of its host's chromosomes, including pieces bearing the nitrogen-fixation genes.

Some of the new nitrogen-fixing *E. coli* strains converted these fragments of *Klebsiella* chromosome into new, separate PLASMIDS. Geneticists in the unit therefore constructed, by ordinary genetic manipulations, plasmids carrying nitrogen-fixation genes which would transfer themselves alone, without the aid of another plasmid.



In veterinary medicine the greatest potential lies in the preparation of completely safe viral vaccines. One of the first successes was with FOOT-AND-MOUTH virus. The specific viral protein, free of infectivity, was produced by a genetically manipulated *E. coli*. This protein from a bacterial culture is capable of stimulating antibody production in animals. The technique is used also in the production of a number of other vaccines.

Recombinant DNA Development of such techniques involved three lines of research: (1) recognition and isolation of extrachromosomal DNA, or PLASMIDS; (2) the manipulation of DNA with 'restriction' enzymes which selectively split DNA into fragments which could then be rejoined; (3) reinserting the fragmented DNA into living cells so that it became part of the genetic material of the cells.

In this way, genetic instructions for producing mammalian enzymes could be transferred into *E. coli*, the bacterial cell most used for propagating such plasmid vectors to produce insulin, for example.

The next step was to develop synthetic nucleotides, actually to construct genes. This has been done successfully and nucleotides of up to 500 characters have been constructed.

Another technique in genetic engineering involves monoclonal antibodies. These are produced by fusing antibody-producing cells from an immunised donor with another type of white blood cell, thereby producing hybrid cells which in tissue culture could

Spleen cells from mice previously injected with parasite, and secreting antibody to the parasite, can be fused with other cells to form hybrid cells that live and multiply. From these a cell line is selected by 'cloning' (i.e. a colony that represents the progeny of a single cell is isolated) which secretes appropriate antiparasite antibody. (With acknowledgements to *WHO Chronicle*, **36**.)

provide the desired antibodies. Among potential uses are, again, vaccines, but also diagnostic reagents; for blood-typing, in race-horses, for example.

Introduction The science of genetics deals with the physiology of heredity – the mechanism by which resemblance between parent and offspring is

VetBooks.ir

conserved and transmitted; and with the origin and significance of variation – the mechanism by which such resemblance is modified and transformed. It seeks to define the manner in which the hereditary characters of the individual are represented in the fertilised egg in which the individual has its beginning.

Stock-breeding is a craft concerned with the maintenance of the desirable qualities of a stock, the improvement of these qualities generation by generation, and the elimination through breeding of qualities which are held to be undesirable. The problems of the geneticist and of the stock-breeder are identical, though their interests are dissimilar.

The geneticist has made much progress by studying, quickly maturing, very highly fertile animals such as the mouse, rat, guinea-pig, rabbit and, above all, the fruit fly *Drosophila*.

A better understanding of heredity was rendered possible by the concept that the individual as a whole was not the unit in inheritance, but could be regarded as a definite orderly combination of independently heritable units.

Breed was now interpreted as signifying different combinations of independently heritable characters, all drawn from the common source of the stock in which modern domesticated cattle had their origin – just as different arrangements and combinations of letters make different words, though all words are made up of letters derived from a common source: the alphabet.

The breeder has employed the methods of hybridisation and inbreeding associated with selection in the creation of the modern breeds. He has practised inbreeding with selection in order that the desired type of his stock may be fixed, and he has sought hybrid vigour in outcrossing. The geneticist has employed these very same methods in his studies. The method of genetics is character-analysis. The object of the breeder is character-synthesis.

Instead of the hereditary mechanism being a simple affair as was first thought, it is one of the most complex.

Phenotype and genotype Allan Fraser MD, DSc, when senior lecturer in animal husbandry at Aberdeen University, once drew a helpful analogy between heredity and a game of cards, with each card representing a gene, and Honours cards representing genes most desirable to a breeder.

A game of cards is preceded by the shuffling of packs, and so also is the conception of an animal preceded by a shuffling of genes. Each pack is then halved – just as before sperm and ovum meet, and the number of genes in both is halved by what is called the reduction division. Fertilisation then reunites the two half-packs to form one new pack. The cards in this represent the genes in the new individual animal.

'The cards in any one hand or the gene sample in any individual animal are the result of pure chance – no one can predict how the run of the cards or of the genes will go.'

Of two animals, sharing the same sire and dam, one may have a much better genotype, be a more valuable breeding animal than its full brother or sister.

If the cards dealt at conception be called the unalterable genotype of the animal, the playing of that hand may be called the environment, which includes climate, nutrition, exposure to infections, stocking rates, and every aspect of husbandry and animal management.

Some stockmen can make a surprisingly good job with poor genetic material; others a sorry job with the best stock; but of course the most skilful stockman cannot improve upon the hand of genes once dealt.

Genotype can be defined as the entire array of genes carried by an individual (or, in another sense, the genetic constitution of an individual with respect to any limited number of genes under examination).

Phenotype is the appearance and/or the performance of an individual animal. Phenotypic variation of a population results from the combined effects of inheritance and environment. Genetic variation is that part of the phenotypic variation which is due to genes.

Homozygous and heterozygous In order to illustrate one of the simpler aspects of heredity in relation to stock-breeding, the appearance of red calf in a herd in which the fashionable coat colour is black, and in which all red animals are eliminated, will serve as an example.

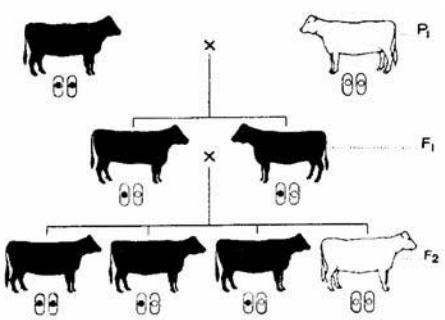
Black-and-red coat colours in cattle constitute a typical pair of Mendelian characters, black being the dominant and red being the recessive member of the pair. A red calf can only be produced by black parents when both of these are heterozygous in respect of their coat-colour character. For the character black-coat colour, there is a determiner or factor: this factor may be present in the zygote in the duplex state, having been conveyed thereinto by both egg and sperm. When the factor for black is present in the duplex state, the individual that arises for that fertilised egg or zygote is spoken of as being 'homozygous' for the character black-coat colour. On the other hand, into the zygote there may have been brought a factor for black from one parent and a factor for red, the alternative character, from the other parent. Under these circumstances, of these two factors (that for black and that for red) it is the former alone that determines what the coat colour shall be. Black is said to be dominant in its relation to red. Homozygous and heterozygous blacks will be indistinguishable on inspection. If

VetBooks.ir

two heterozygous blacks are mated there will occur on the average in every four, three black calves to one red. To explain this 3:1 ratio it is assumed that half of both male and female gametes of such heterozygous individuals (i.e. sperm and ovum) carry the factor for the dominant character black, and the other half the factor for the alternative recessive red, and the two sorts of egg and of sperm occur in equal numbers. If it is assumed that for every pair of factors that correspond to a pair of characters, only one can pass into the ripe gamete, it follows that a 3:1 ratio in the next generation will be obtained, and of the individuals exhibiting the dominant character, 1 will be homozygous for that character and two heterozygous, whilst the individual exhibiting the recessive character must of necessity carry the factor for that character in the duplex state, since if in its hereditary constitution it carries a factor for the dominant, it will exhibit the dominant character. It is possible by examining the records of the coat colours of the offspring to define the hereditary constitution of the parent in respect of the coat colours black and red. The following matings are possible:

Homozygous black to homozygous black will give none but blacks, all homozygous.

Homozygous black to heterozygous black will give all blacks, of which 50 per cent will be homozygous and 50 per cent heterozygous.



Homozygous black to homozygous red will give all heterozygous blacks.

Heterozygous black to heterozygous black will give 25 per cent homozygous blacks, 50 per cent heterozygous blacks and 25 per cent reds.

Heterozygous black to red will give 50 per cent heterozygous blacks and 50 per cent red.

Red to red will give all reds, of necessity homozygous. The only mating of blacks that can yield a red calf is that of two individuals heterozygous in respect of this coat-colour character.

The coat-colour character has to be considered quite apart from all the rest of the characters that in their association make the animal what it is. An individual is a pure black when it is in respect of this character homozygous, when in its hereditary constitution the determiner or factor for this character has been received from both its parents.

Black × Red. (Red is necessarily white in the diagram.)

Inheritance through multiple genes The above example shows how a character – coat colour – may be inherited through single genes. This is the mechanism of heredity at its simplest. Most characters, however, including many of economic importance to the farmer, are inherited in a far more complex manner through multiple genes.

Multiple genes may have an additive effect as regards the expression of some character; or they may interact, one with another, in the production of a character, inheritance of which is even more complex.

Inheritance and high milk yields It seems that it is easier to increase the butter-fat content and solids-not-fat content than it is to increase the milk yield through breeding. The heritability of milk yield is not as high as that of some other characters.

There is a correlation between high yields and body size, but conformation is by no means always associated with high yields. A few of the highest-yielding cows have had, to put it mildly, an unfashionable conformation.

The diagram below shows how two bulls, full brothers, may influence milk production in their daughters in opposite ways. It also shows how the 'gene lottery' can make nonsense out of the expectations of a breeder.

For this reason, progeny testing has proved of the greatest importance in the selection of bulls, each of which – through AI – may have not 100 offspring but tens of thousands.

It is possible for a farmer to use (by means of AI) a bull with the proved ability to produce daughters with a high milk yield, as compared with the yield resulting from use of an improved or average bull. Proven bulls are listed in terms of 'a bonus of 50 or of anything up to 100 gallons' and also in terms of a butterfat bonus. (See also PROGENY TESTING.)

Researchers have reported an association between blood groups and production characters in cattle and other animals. The work on transferrin and milk yield is an example; that of blood groups and milk yield another. However, the results were not sufficiently significant to be of practical value in selecting for productivity.

Selection is the systematic choice of animals in a population (defined in the genetic sense as a group of interbreeding animals sharing a common gene pool, e.g. a closed herd, an AI district, a breed) as parents for the next generation.

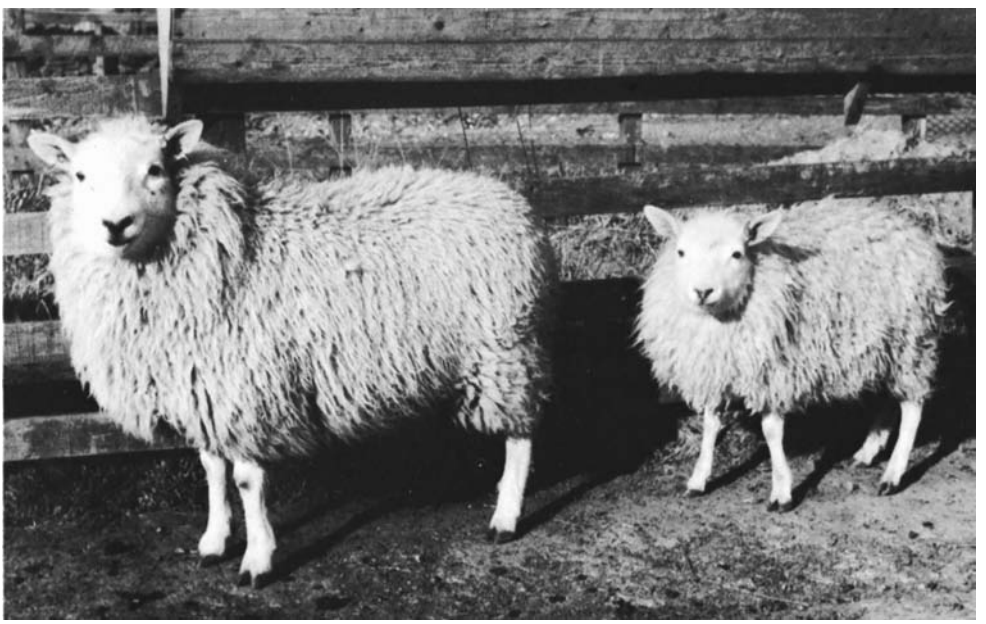
VetBooks.ir

Family selection means the selection of individuals on the performance of their relatives (sibs, half-sibs or progeny), i.e. selection between families instead of between individuals.

Genotypic selection is that based on progeny testing with a very large number of progeny, so that the breeding value of the parent is exactly known.

Inbreeding may be defined as the mating of individuals more closely related than the average relationship of the population.

Both crossbreeding and inbreeding are methods of bringing about genetic change.



Inbreeding was practised by the early developers and improvers of livestock breeds in order to fix the type of their animals. Inbreeding can be expected to increase the proportion of animals homozygous for a given desired character. As the process proceeds, however, individuals with undesirable characters are likely to appear – animals which are abnormal in some respect, sterile, or weak. Inbreeding could prove disastrously expensive if the proportion of such animals were high. (Test mating of a bull to related or carrier females may be carried out in order to detect specific genes such as lethal factors; the carriers then being culled from the herd.)

Prolonged inbreeding will lead to disappointing regression, diminution of vigour, decreased fertility, and a reduction in body size.

The fusion of two inbred lines By inbreeding for a specific character, and by practising rigid selection for two, three, or more generations, a strain of relatively homozygous individuals for the selected character can be created. If two such strains are developed separately but simultaneously for two different but highly desirable characters, and if these two strains are then crossed, the resulting progeny can be expected to possess both desirable characters to a useful degree. The mechanism has been notably successful in producing strains of poultry with large egg size and high annual yields, and has been exploited commercially.

When the generation in which the two desirable characters are expressed is bred from again, an immediate reassortment of characters occurs, and only in a small percentage of the individuals will the desirable characters be expressed. The others are most likely to be useless.

Hybrid vigour (Heterosis), usually demonstrated by increase in size, better liveweight gains and greater resistance to disease and in the earlier attainment of sexual maturity, occurs in the first cross-bred generation out of the mating of two widely dissimilar pure-bred parental stocks. Hybrid vigour is an indication of heterozygosis. The two parental breeds must be within reason as dissimilar in their characterisation as possible; then in the pooling of those hereditary constitutions there

The effect of inbreeding and crossing. These 2 sheep were sired by the same ram, but the smaller one was highly inbred (59 per cent) and when 10 months old had attained little more than 40 per cent of the weight of its half-sib (left), which was a 3-way cross of inbred lines, its dam being a 2 way line cross. These hoggs are of Cheviot × Welsh extraction. (Animal Breeding Research Organisation photograph.)

VetBooks.ir

will be a very considerable degree of heterozygosis in the first cross-bred offspring; the desirable characters are pooled, and in respect of those characters exhibited by the two parents the offspring will be heterozygous. Generally, a characteristic with poor heritability is enhanced more than one of high heritability.

If the first crosses which exhibit this hybrid vigour so markedly are interbred, their offspring will not exhibit this vigour to the same extent.

'Nicking' Two individuals not remarkable in themselves may produce superior offspring. This fact can be explained on the assumption that the mating brings together the chance association of factors which are complementary or supplementary, and that these in conjunction determine characters that are greatly esteemed.

'Pedigree and purity' Pedigrees and registration in the appropriate herd book have been an essential part of breeders' work in all but 'commercial' herds. The system has been of service, though not free from abuse. Pedigrees have from time to time been falsified or genuine mistakes made (including use of the wrong semen in AI work), and until the advent of blood typing there was no means of checking such errors. This has been superseded by DNA 'FINGER-PRINTING'.

It is easy to exaggerate the importance of 'family name' or of remote ancestors; and in terms of production traits or characters it has been stated that 'the concept of "purity" of pure breeds is not only something of a myth, but might actually be detrimental to the possibilities for improvement.'

Chromosomes A male can be distinguished from a female not only by external appearances and by differences in the architecture of the reproductive system, but also by differences in the organisation of the cells of which their bodies are composed.

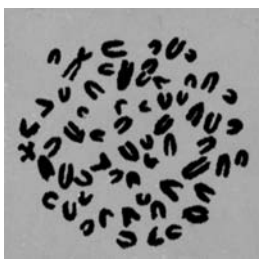
The nucleus of the resting cell appears in stained microscopic preparations as a vesicle containing a network of delicate threads upon which are borne, like beads upon a tangled skein, minute masses of a deeply staining material known as chromatin. As the cell proceeds to divide into two, this tangled mass of fine threads resolves itself into a constant number of filaments of definite shape and these become progressively shorter to assume the form of stout rods known as chromosomes. The number of chromosomes is usually some multiple of two, and is constant and characteristic of the species to which the individual belongs, e.g. dog 78; horse 64; cow 60; sheep 54; pig 38; cat 38.

(The study of chromosomes is known as CYTOGENETICS.)

The gametes, egg and sperm respectively, differ remarkably in size and form, but they are alike in that each contains half the number of chromosomes that is characteristic of the somatic cells of that species.

At fertilisation, the characteristic number is restored, and in the case of each pair one member is derived from one parent, the other from the other. In this distribution of the chromosomes one finds a mechanism by which offspring may inherit from both parents by means of the constituent genes.

It is possible to distinguish male from female by differences in the chromosome content. While all other pairs of chromosomes consist of two chromosomes exactly alike in size and shape, one pair differs in the two sexes. As they influence sex determination, these chromosomes are referred to as the sex chromosomes.



The ovum (or egg) contains the X chromosome in mammals.

The sperm of mammals may contain either the Y chromosome, which will produce male offspring (XY), or the X chromosome, which will produce female offspring (XX).

In most female mammals the paired sex-chromosomes are identical, and called the X chromosomes on account of their shape.

In the male, the sex-chromosomes are dissimilar, one being the X chromosome and the other the Y.

The autosomes are all the other chromosomes except the sex-chromosomes. In mammals it is the male that determines the sex of the offspring, although the opposite is true in birds.

A bull's lymphocyte showing chromosomes in the 2nd stage (metaphase) of cell division (mitosis). (With acknowledgements to Dr C. R. E. Halnan and the *Veterinary Record*.)

Genetic aspects of infertility These are briefly discussed in the following paragraphs. Chromosome screening (see CYTOGENETICS) and, to a lesser extent, blood-typing are likely to be of increasing value in eliminating a proportion of bovine infertility due to hereditary causes. (See also INFERTILITY.)

Inheritance of twinning It is mainly cows over three years old which have twins, and although twinning may be a desirable character for the farmer it is not one which is easy to obtain through breeding. It seems that there is a rather

VetBooks.ir

low level of genetic variation in frequency of twinning, and that prospects for rapidly increasing litter size in dairy cattle do not at present seem good. In some breeds of sheep, and perhaps also in cattle, it may not be the ovulation rate which is the limiting factor but, as indicated above, the survival rate of fertilised eggs.

Heritability of certain traits The following table, compiled at the Animal Breeding Research Organisation, shows the degree of heritability of certain traits sought by the pig breeder.

Trait	Heritability %
Litter size at weaning	7
Average weaning weight	8
Daily gain, after weaning	0
Food conversion	5
Average back fat	50
Percentage of lean meat	45

It will be seen that litter performance has a low heritability, and must be achieved by suitable crossbreeding. The crossbred sow has a marked superiority in this respect.

Lethal and semi-lethal factors Lethal factors have been defined as genes which, when present in the homozygous condition, cause the death of the embryo and when present in the heterozygous conditions cause a serious impairment in the individual often leading to non-survival.

Lethals may be dominant or incompletely dominant, but many are certainly recessive. They are not always recognised since they may cause death of the embryo early in development, and the mating may be regarded as having been infertile – another illustration of the difficulty of defining the genetics of infertility.

Several lethals are met with in cattle, such as parrot-mouthed, in which calves die at a few hours of age, or amputated, in which calves are born dead with legs and lower jaws absent.

Semi-lethals include over-shot jaws in calves.

Heredity and disease Diseases exhibit a spectrum according to the genetic influence. Canine haemophilia is entirely genetic. Swedish gonad hypoplasia is mainly genetic, mastitis is mainly environmental and injuries are entirely environmental. Simply dividing diseases into genetic and non-genetic is, therefore, inaccurate.

Recessive inheritance: many diseases are inherited as autosomal recessives. Neither parent is usually affected, but the disease comes from both; the sexes are affected equally, inbreeding is often being practised, the incidence is generally low and exact genetic ratios are obtainable. Few diseases, however, fulfil all the criteria of simple recessives.

Diseases due to sex-linked recessives, e.g. canine haemophilia, are uncommon in domestic mammals and, not being transmitted by unaffected males – the carrier female transmits the disease to half her male offspring – are unlikely to be a major problem. In poultry, however, sex-linked abnormalities such as familiar cerebellar degeneration are transmitted by the male to half his female progeny and are relatively common.

Diseases such as cryptorchidism (see CRYPTORCHID) and inter-sexes are sex-limited and sometimes regarded as due to recessives, the homozygote only expressing itself in one sex. While both parents are probably involved, their exact inheritance is unknown and cryptorchidism is certainly subject to environmental modification.

Irregular inheritance: many defects have a complex inheritance. Sporadic abnormalities, which increase on inbreeding, such as chicken 'crooked toes' or pig 'kinky tails', are called phenodeviants, and are probably caused by recessives exhibiting a threshold of manifestation.

Dominant inheritance: the disease usually comes from one affected parent, and half its offspring are affected. Few dominant diseases are known in livestock, except in poultry. Irregular dominants, exemplified by 'curved limbs', where an unaffected male transmits a gene producing defective offspring out of unrelated females, and less than half are affected, do, however, occur. Environment or modifying genes may cause the defect inherent in the gene to develop.

Semi-dominant inheritance: several diseases are due to semi-dominants, the heterozygote being distinguishable from both homozygotes. A single dose of a semi-dominant gene produces a Dexter, a double dose a bulldog calf, and the homozygous normal allele produces a long-legged Dexter. Some American dwarf cattle result from semi-dominants (with acknowledgements to Dr G. B. Young, Animal Breeding Research Organisation).

Genetic defects All breeds of livestock may harbour some genetic defects, but their incidence is usually low. However, specific defects sometimes become more frequent in certain breeds and give cause for concern. In companion animals, genetic diseases and their welfare impact can be studied on a website www.ufaw.org.uk/geneticwelfareproblems.php.

Cattle Examples of genetic defects include the following:

Arthrogryposis in CHAROLAIS cattle. This defect is characterised by twisted limbs, cleft palate, and twisted spine. In France about 1 per cent of Charolais cattle are affected. AI records show that while many bulls transmit an occasional defect of

VetBooks.ir

this nature, a few sire about 5 per cent of offspring having this abnormality. Another defect encountered in some Charolais cattle involves the eyes. (See EYE, DISEASES AND INJURIES OF - COLOBOMA.)

Decapitated sperms. This defect causes the rejection for AI in Britain of many Hereford bulls 'with superior test performance' because their semen contains a high percentage of sperms with the head separated from the tail.

Tibial hemimelia. A dog-sitting position in the newborn GALLOWAY calf is suggestive of this defect, which involves bones missing from the hind legs (but has to be differentiated from another defect involving the pelvis, which also prevents the calf from standing on its hind legs). It is estimated that about 16 per cent of Galloways now carry the gene which transmits this defect. (The Galloway Breed Society has an excellent scheme, requiring compulsory insurance and compulsory slaughter of any bulls leaving offspring with this defect.) (See also MANNOSIDOSIS.)

Sheep Genetic defects include ACHONDROPLASIA in some South Country Cheviot flocks. A 'squashed-in' face, shortened forelimbs and defective hooves are characteristic of these 'dwarf lambs'.

Cerebellar ATAXIA is seen in some Border Leicester flocks, and these 'daft lambs' have a staggering gait and incoordination of the head. This is due to a recessive gene.

Genetic Sequencing

As a result of the increased power of computers, it has become possible to determine the sequence of nucleotides within a DNA molecule.

Genital Organs

(See diagrams for PENIS and UTERUS.)

Genome

A complete set of chromosomes derived from one parent; or the total gene complement of a set of chromosomes. Following the sequencing of the human genome in 2003, that of the chimpanzee (*Pan troglodytes*), mouse and rat soon followed. The dog genome was sequenced in 2004, a HEREFORD cow in 2009 and an ABYSSINIAN cat, a sheep and a Northern White-cheeked gibbon (*Nomascus leucogenys*) in 2014. (See also DNA; DNA 'FINGERPRINTING'; DNA TESTING.)

Genotype

This can mean the entire array of genes carried by an individual; or the genetic constitution of an individual with respect to any limited number of genes under examination; or (more loosely) the individual within a given genotype. (See also under GENUS.)

Genotypic Selection

Genotypic selection is that based on progeny-testing with a very large number of progeny so that the breeding value of the parent is exactly known. The expression is also loosely used as a synonym for PROGENY TESTING without this proviso.

Gentamicin

A narrow-spectrum antibiotic effective against Gram-negative bacteria, especially *Klebsiella* and *Pseudomonas* spp. It should be used with caution parenterally, especially in animals with impaired renal function. Gentamycin-impregnated beads are used as implants to provide long duration activity in infected joints.

Gentian

The dried and powdered root of the yellow gentian plant (*Gentiana lutea*). It is a bitter tonic used as an appetiser in ruminants. Combined with oils of thyme and juniper, tannins and salicylic acid it has been used in some feeds.

Gentian Violet

A stain used in microscopical work and a valuable antiseptic, of use against fungal and bacterial skin infections. (See also ANTISEPTICS– Crystal violet.)

Genus

Genus is a group of species. One of the species is chosen as being typical, and referred to as the genotype.

Geophagia

The eating of soil. It can be a bad habit, or due to deficiencies such as sodium deficiency in cattle or an adaptive syndrome to neutralise toxins in ingested feed. Negatively-charged clay binds with bacteria, viruses and toxins, thereby inactivating them. This property might also explain the activity of KAOLIN.

Gerbil

They form part of the suborder Myomorpha of the Rodentia order. Also known as 'desert rats', there are about 100 different species found in Africa and Asia, including India. The Mongolian gerbil (*Meriones unguiculatus*) is a small burrowing rodent, originating in deserts. Gerbils are popular as pets. They live for three to five years; adults weigh 50 g to 90 g (1.7 oz to 3 oz), the females being larger than males. Sexual maturity occurs at 10 weeks. The gestation period is 24 to 26 days and the young are weaned at 21 to 24 days. Rectal temperature is 37.4° C to 39° C (99.3° F to 102.2° F). They are naturally healthy animals, remarkably free from infectious diseases except for occasional outbreaks of Tyzzer's disease, but neoplasia is seen in animals over two years old and dental problems

VetBooks.ir

are encountered in those fed unsuitable diets. Cystic ovaries occur frequently and ovarian tumours are the most common NEOPLASIA. 'Gerbil nose' is nasal dermatitis. (See NOSE AND NASAL PASSAGES, DISEASES OF.) In the wild they 'play dead' when attacked; this is a self-induced epileptic seizure which may occur in captive specimens when they are handled. Gerbils should be handled by scooping up the torso; they should never be handled by the tail as the skin is easily detached and does not heal. Some antibiotics can result in fatal ENTEROTOXAEMIA. (See also PETS, CHILDREN'S AND EXOTIC.)

Geriatrics
The study of the problems and diseases of the older animal.

German Shepherd Dog
Previously known as the Alsatian, this is a medium to large-sized dog with a tan and black coat. The breed is extremely popular and, to fulfil demand, some unsuitable animals were used for breeding. In consequence a number of inherited defects are associated with the breed. These include conditions where inheritance mechanisms are unknown such as MEGAOESOPHAGUS, CALCINOSIS CIRCUMSCRIPTA, cleft palates, distortion of the nictitating membrane, epilepsy, OSTEOCHONDROSIS, PANNUS (chronic superficial keratitis), PATENT DUCTUS ARTERIOSUS, persistent right aortic arch, and SPONDYLOSIS DEFORMANS. AORTIC STENOSIS is probably polygenic in origin while VON WILLEBRAND'S DISEASE is inherited as an autosomal dominant with variable expression. Ununited ANCONEAL PROCESS is probably a dominant multiple and cataract and dwarfism are recessive traits. HAEMOPHILIA A (Factor VIII deficiency) is sex-linked. A campaign to eliminate HIP DYSPLASIA requires all potential breeding dogs to be X-rayed for evidence of the defect. It is a breed where EOSINOPHILIC MYOSITIS is common.

Other inherited problems include MUCOPOLYSACCHARIDOSIS VII, PYRUVATE KINASE DEFICIENCY, DEGENERATIVE MYELOPATHY, ANAL FURUNCULOSIS (DNA tests available). It is a breed where EOSINOPHILIC MYOSITIS and occasionally SPINAL MUSCULAR ATROPHY occur. They are prone to calcium gout, INFLAMMATORY BOWEL DISEASE and PERIANAL FISTULAE.

German Short-Haired Pointer Dogs
A dog breed with short hair, long ears and docked tail. They are medium to large sized and weigh 25 kg to 30 kg (55 lb to 66 lb) with a liver, black and white spot or ticked in colour. The breed has few reported inherited problems except ENTROPION, also CONE DEGENERATION and VON WILLEBRAND'S DISEASE type 2 (DNA tests available) which is possibly a dominant trait.

German Wire-Haired Pointer Dogs
A medium to large breed (20 kg to 30 kg;, 44 lb to 66 lb) with harsh hair, liver, black and white spots or ticked in colour. It suffers from HAEMOPHILIA B (Factor IX) and VON WILLEBRAND'S DISEASE (DNA tests available).

Germ Cells
The gametes, i.e. ovum or sperm.

Gestation
(See PREGNANCY AND GESTATION.)

Getah Virus
A mild infectious disease of racehorses, characterised by fever, dermatitis, and oedema of the limbs, appeared in Japan in 1978, and was found to be due to Getah virus. Antibodies to it had previously been detected in man, horses, pigs and birds; none showed signs.

GGT
(See GAMMA GLUTAMYL TRANSFERASE.)

Ghrelin
An important hormone in birds and mammals that affects appetite. Obesity occurs if the hormone is over-produced.

Giant Cells
Seen in various infections, e.g. the poxes, tuberculosis and Johne's disease, these multinucleate cells are formed by cell fusion, stimulated by viruses. Giant cells can be obtained *in vitro* in cell cultures, as well as being found in the body.

Giant Hogweed, *Heracleum Mantegazzianum*
This plant grows to a height of up to 3.65 m (12 ft), and has white flowers. The stem is hollow, and has reddish/purple blotches. Human contact with the plant, and subsequent exposure to sunlight, leads to dermatitis as a result of LIGHT SENSITISATION. A suspected case of this was seen in a goat, which was subdued, refusing food or water, and salivating profusely. Severe ulceration was found in its mouth. Two sheep were sensitive to the cut stems of the plant and developed mouth ulcers.

In another case, circumstantial evidence suggested involvement of this plant in week-old ducklings which had foot and beak lesions. Two ducklings with white beaks could manage only 'open-beak' breathing; whereas the beaks, which were pigmented, in the other five ducklings, were not affected. The foot lesions consisted of large blisters.

Giant Rabbits
These are large rabbits weighing about 6.4 kg (14 lb), many are derived from Flemish giant rabbits with a long back and broad hind quarters. The head is broad and there is often a dewlap.

Giant Schnauzer
A German dog breed which has become popular in UK. They have a wiry coat, which is black or grey 'salt and pepper'. They are strong muscular dogs weighing 32 kg to 45 kg (70 lb to 100 lb) and stand about 60 cm to 70 cm (24 in to 28 in) high. Hereditary CATARACT occurs but the inherited mechanism is unknown and COBALAMIN MALABSORPTION and HAEMOPHILIA (Factor VII).

Giardia
A genus of flagellate protozoa.

Giardiasis
In dogs a low-grade infection with *Giardia canis* may interfere with the absorption of fat and vitamin A; while if large numbers of *G. canis* are present there is likely to be chronic diarrhoea (sometimes dysentery), with resulting dehydration. The infection is usually via drinking-water.

The flagellate parasite occurs in two forms: the trophozoite, which divides by binary fission, and is seldom seen in the faeces; and the cyst form which is found in the faeces but is not easy to identify. In farm animals giardiasis is caused by *Giardia intestinalis* and seen in young animals, usually without any signs.

Giardiasis is frequently encountered in captive psittacine birds especially cockatiels (*Nymphicus hollandicus*), in which it is alleged to cause feather-plucking of the abdomen. Metronizadole is used in treatment.

In the USA *G. lamblia* is a common cause of human gastroenteritis. The infection is usually via drinking-water.

Gid, Sturdy
Gid (sturdy) is a condition in sheep, and occasionally in cattle, caused by tapeworm cysts lodged in the brain. The sheep become infected through swallowing unhatched eggs of the dog tapeworm *Taenia multiceps*. The eggs are passed out in the dog's faeces. As the cysts (coenuri) develop, they press upon brain cells and give rise to nervous signs, such as staggering, circling, blindness. The name 'sturdy' derives from the 'sturdy' manner in which an affected sheep may struggle when caught. (See COENURIOSIS.)

Gilchrist's Disease
Infection in man with *Blastomyces dermatitidis*. (See BLASTOMYCOSIS OF DOGS.)

Gill Maggot
(See SALMINCOLA.)

Gills
The external breathing apparatus of fish and some other water dwelling creatures and they act as their LUNGS. They are in folds or lamellae which produce a large surface area to the water and have a plentiful blood supply. They are delicate structures, prone to damage, infection and parasites. Chemical pollutants in the water cause fusion of the lamellae of the gills, reducing the absorptive surface.

Gilt
A female pig intended for breeding purposes before she has her 1st litter.

Gimmer
A ewe lamb up to its 1st shearing, or ewe which has not yet produced offspring (see under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC.).

Gingivitis
Inflammation of the gums as a result of injury or disease; they show various degrees of reddening, some swelling and may bleed. Onset may be acute or gradual. (See MOUTH, DISEASES OF.)

Gizzard, Ventriculus
The thick-walled, muscular stomach in a bird; it has a tough keratin lining. The gizzard's main function is to grind food, and in this it is assisted by swallowed grit and small stones. (See under GRIT FOR POULTRY.)

Gizzard Erosion
A condition mainly seen at post-mortem examination. It can be caused by mycotoxins (see MYCOTOXICOSIS), dosing with caustic substances, eating decaying animal protein, poorly prepared fish-meal, vitamin B_6 deficiency, adenovirus infections, NEWCASTLE DISEASE and AVIAN INFLUENZA.

Gizzerosine
A by-product of RANCIDITY of fish-based meal, toxic to birds, sometimes encountered in BROILER units due to inadequately stored or out-of-date feed. It can also occur in home-made feeds for cage and aviary birds to which COD-LIVER OIL has been added and has been allowed to deteriorate. The signs of toxicity include vascular changes and erosion of the gizzard lining.

Glabrous
Literally meaning smooth or bare, glabrous generally refers to areas of mammalian skin which are normally bald i.e. devoid of guard hairs. However, a number of diseases may produce localised or generalised hair loss. (See also HIRSUTE.)

VetBooks.ir

Glanders

Glanders is a NOTIFIABLE DISEASE throughout the EU. It is a specific, contagious disease of the horse family (Equidae), but also liable to be contracted by other mammals, including man. It is characterised by the formation of nodules in the lungs, liver, spleen or other organs; ulcerations occur of the mucous membranes, especially those of the upper air passages, accompanied by changes in the lymphatics and also by skin lesions. The condition is due to the entrance and growth in the body of the glanders bacillus *Burkholderia mallei* (formerly known as *Pseudomonas mallei* and before that *Pfeifferella mallei*).

History Glanders has been known as a serious disease since about 450 BC, when it was mentioned by Hippocrates, and its contagious nature was pointed out by Vegetius (a veterinary writer) in the 4th century.

Distribution Glanders has been distributed to practically every country in the world at some time or other, and was once a usual concomitant of wars. It became prevalent, both in the United Kingdom and in South Africa, after the South African war (1899–1902). In the year 1892 there were more than 3,000 cases of glanders recorded in Britain; in 1904 between 2,000 and 3,000; while only nine outbreaks were recorded in the year 1923, and none since 1926.

Glanders is still endemic in Mongolia, other parts of Asia, East Africa and South America and, recently, it has been spreading from enzootic zones.

The donkey is the most susceptible to the disease and nearly always suffers from the acute form, from which it dies in two to three weeks.

In the horse, glanders occurs in an acute or a chronic form, the latter existing for months or even years before it finally kills its victim; however, under modern conditions it is rare to allow the disease to run its natural course. The mule is intermediate in susceptibility between the donkey and the horse, but usually shows the acute type. Dogs and cats may become infected if fed upon meat from a horse which had glanders. The camel is susceptible, though natural cases are very rare.

Horses can be infected naturally by three different channels:

1. By the digestive tract, through the medium of infected food and water. This is by far the commonest method of spread.
2. By inhalation (rarely) when some abrasion of the respiratory passage is present.
3. By skin infection.

Incubation period This may last several months in the horse.

Signs The signs of glanders in the horse are very varied. The disease may run an acute course of only two to three weeks, but by far the greatest number of cases met with are of a subacute or chronic nature. A horse may be affected and show no outward sign of disease, and yet it may have nodules in one or both lungs.

Glanders may be of the nasal, pulmonary, or glandular form, of the type producing skin lesions (FARCY), or an admixture of these, and it may also become generalised. One of the dangers of the disease is that a horse may work for weeks or even months with 'open' lesions – not losing a great deal of flesh nor appearing very ill – and so spread the disease to healthy horses with which it comes into contact.

When farcy is present the glands inside the axilla or inside the groin may be somewhat enlarged and even painful to the touch. In entire horses the testicles often become enlarged and painful, or even the site of glanderous abscesses.

There may be a nasal discharge, thin and watery in the early stages, but later becoming thick, greyish, or yellow and oily. Examination of the nose in these cases is dangerous; strict hygienic precautions should be taken, as man may easily contract the disease by this means.

Farcy: in this form of the disease, the skin is involved. It is usually chronic in nature, but farcy buds and subcutaneous swellings may complicate the most acute form of the disease shortly before death. This complication is especially common in the mule, which often succumbs to the disease before the farcy buds have time to burst. In chronic farcy there is usually swelling of one or more limbs, more frequently a hind one. The lymphatic glands of the affected limb become enlarged, the lymph vessels corded, and usually a chain of farcy buds develops along their course.

In acute glanders there may be all the signs of an acute broncho-pneumonia, a high temperature, a rapid loss of flesh, rapid and sometimes noisy breathing, followed by death in a few weeks; in fact, this is the common form seen in the donkey and often in the mule, with or without the complication of farcy.

Diagnosis This is confirmed by means of the mallein test.

Treatment Sulfathiazole has been used, but in most western countries treatment is not permitted; the policy being one of slaughter and eradication.

VetBooks.ir

Glanders in man is a distressing and nearly always fatal disease, and may be contracted by grooms and others working with infected horses. Laboratory workers handling infected material or pure cultures of the organism are especially liable to infection, so that every precaution against this contingency has to be taken; in fact, the glanders bacillus is amongst the most dangerous of all disease-producing bacteria cultivated.

The causal organism is present in all the lesions, though it does not – except the rare cases – circulate in the bloodstream.

Glands

A term loosely applied to a number of different organs. In each there are epithelial cells which have a secretory function (e.g. tear production). Glands are often classified as either *endocrine*, which are ductless, or *exocrine*, which usually have ducts to carry their secretion to an epithelial surface. (See ENDOCRINE GLANDS, HORMONES.)

A description of the various glands will be found under headings such as THYROID GLAND, LIVER, MAMMARY GLANDS, OVARIES, PANCREAS, SALIVARY GLANDS and TESTICLE. Sweat and sebaceous glands are referred to under SKIN.

Lymphatic glands are more often referred to as *lymph nodes*.

Glanzmann's Thrombasthenia

A genetic condition affecting blood platelets, resulting in defective clot retraction and impaired platelet aggregation. There is a DNA test for OTTERHOUNDS and PYRENEAN MOUNTAIN DOGS.

Glasgow Composite Measure Pain Scale (GCMPS)

This allows assessment of ACUTE pain by using psychometric methods to measure the apparent pain level in dogs. It involves the completion of a form which allows a total score to be provided.

Glass, Soluble

Soluble glasses containing cobalt, copper and selenium have been used in BOLUSES.

Glässer's Disease

An infection which causes swelling of the hock or knee joints, or both, in the pig. There is fever, lameness and a disinclination to move; it can also cause pericarditis, pleurisy and peritonitis. Death is usually a sequel, unless early treatment with, e.g., penicillin is undertaken. Glässer's disease is differentiated from joint-ill. Pigs of 5 to 14 weeks old are chiefly affected. The cause is *Haemophilus parasuis*, or a mycoplasma, or both. Vaccines are available.

Glauber's Salts

Glauber's salts is the popular name for sodium sulphate, a saline purgative.

Glaucoma

A condition characterised by an increase in pressure within the eye (intraocular pressure). It is associated with obstruction of the drainage system, in which fluid continues to be formed but the excess is not removed. It may follow cases of PROGRESSIVE RETINAL ATROPHY. It eventually results in swelling and bulging of the affected eye, and blindness occurs if untreated. Glaucoma can be primary or secondary (subsequent to other eye disease, such as LENS LUXATION), the latter being more common. It is seen more commonly in dogs than in other species. The primary form is inherited and seen in over 40 breeds including AMERICAN COCKER SPANIELS, BASSET HOUNDS, BEAGLES, BORDER COLLIES, BOUVIER DES FLANDRES dogs, COCKER SPANIELS, DANDIE DINMONT TERRIERS, ENGLISH SPRINGER SPANIELS, FLAT-COATED RETRIEVERS, GOLDEN RETRIEVERS, GREAT DANES, HUNGARIAN VISLAS, HUSKIES, LEONBERGERS, PETIT BASSET GRIFFON VENDEEN DOGS, POODLES, SHAR-PEI, WELSH SPRINGER SPANIELS, WELSH TERRIERS. It is inherited in NEW ZEALAND WHITE RABBITS. Treatment may be surgical or medical and is best handled by a veterinary surgeon experienced in OPHTHALMOLOGY. (See under EYE, DISEASES AND INJURIES OF.)

GLDH

(See GLUTAMATE DEHYDROGENASE.)

Glen of Imaal Terrier Dogs

These are Irish terriers originating in County Whitlow. A low-slung dog developed for herding and removing vermin. The male weights about 16 kg (36 lb) and stands 35 cm (14 in) at the shoulder. A short legged, medium-length double coat which is wheaten, blue or brindle. They suffer from PROGRESSIVE RETINAL ATROPHY. They are on the KENNEL CLUB's ' vulnerable list'.

Glenoid Cavity

Glenoid cavity is the shallow socket on the shoulder-blade into which the humerus fits, forming the shoulder joint.

Gleptoferron

An injectable colloidal solution of iron used in piglets to prevent iron deficiency anaemia.

Glibenclamide

Also known in USA as glyburide, it is used to treat DIABETES MELLITUS type II in man and is also animals. It acts on the beta cells of the PANCREAS resulting in an increase in calcium

in the cells and causing increased INSULIN secretion.

Glioma
Glioma is a tumour which forms in the brain or spinal cord. It is composed of neuroglia, which is the special connective tissue found supporting the nerve cells and the nerve fibres. (See TUMOURS.)

Gliosis
A proliferation of ASTROCYTES. It may follow a brain injury.

Global Warming
Animal involvement in climate change has begun to be appreciated. It will mean efforts will be made to ensure animals are productively using areas unsuitable for other crop production and not overcontributing to carbon ouputs. (See CLIMATE CHANGE; METHANE.)

Globidiosis
A disease characterised by enteritis and closely resembling coccidiosis. It occurs in Africa, SW Europe, the USA, and Australia. The cause is a species of *Globidium*. Cysts may be formed in the skin or underlying tissue. Horses, cattle, and sheep are affected; in horses, severe diarrhoea may be caused. Fatal cases of *Globidium (Eimeria) leuckarti* have occasionally been recorded in horses in the UK and Ireland.

Globoid Cell Leukodystrophy
An inherited condition seen in dogs, cats and POLLED DORSET SHEEP. There is a deficiency of the enzyme beta-galactocerebrocidase. This results in weakness from a young age and then paralysis. It is quite common in CAIRN TERRIERS and WEST HIGHLAND WHITE TERRIERS. It is also called galactocerebrocidosis and Krabbe's Disease.

Globulin
Globulin is a protein fraction of the blood plasma, associated with immunity. (See also GAMMA GLOBULIN.)

Glochidia
The larval stages of mussels. (See MUSSEL, FRESHWATER.)

Glomerulonephritis
Inflammation of the kidney, also called glomerula disease. (See KIDNEYS, DISEASES OF.)

Glomerulus
Glomerulus is a small knot of blood vessels from which the extraction/absorption/reabsorption of fluid out of the blood into the tubules of the kidney takes place. (See KIDNEYS.) Glomerulonephritis is referred to under KIDNEYS, DISEASES OF.

Glossectomy, Partial
A surgical operation to remove part of the tongue. It has been performed in horses following severe laceration by a sharp bit, and in dogs that have their tongues lacerated by office paper-shredders.

Glossitis
Inflammation of the tongue.

Glossopharyngeal Nerve
This is the ninth cranial nerve, which in the main is sensory. It is the nerve detecting taste for the back of the tongue, sensation in a general way for the upper part of the throat and the middle ear, and it supplies the parotid gland.

Glottis
Glottis is the narrow opening at the upper end of the larynx. (See AIR PASSAGES; 'CHOKING'; LARYNX.)

Gloucester Old Spot Pigs
A breed of pigs which is white with black spots. It used to be a popular breed but is now mainly kept in small herds; there are only about 1000 registered breeding females. Because of its long back it is a good bacon pig.

Gloves, Surgical
Sterile gloves of fine rubber, latex or polyethylene worn during surgical procedures. A sleeve-length glove is worn by veterinary surgeons for carrying out e.g. rectal examinations in cattle.

Surgical glove powder (sterilised maize starch) can cause IATROGENIC starch peritonitis in patients, which can be prevented by washing gloved hands in povidone iodine followed by rinsing thoroughly in water. Hypersensitivity to latex has been recorded in people who have used such gloves frequently.

Glucagon
This is a polypeptide hormone secreted by alpha-cells in the islets of Langerhans of the pancreas, and increases the amount of glucose in the blood. (See DIABETES MELLITUS, INSULIN) Diabetes mellitus in birds is due to glucagon excess rather than to an insulin deficiency, as it is in mammals.

Glucagon-Like Peptide-1
Also known as GLP-1. It has a stimulatory effect on INSULIN secretion and a powerful inhibitory effect on GLUCAGON. It is mainly secreted in the intestines.

VetBooks.ir

Glucocorticoids
Hormones, from the cortex of the adrenal gland, concerned with the formation of glucose. Cortisol (hydrocortisone) is one of the most important of these. Excessive secretion of glucocorticoids is a feature of Cushing's disease.

Glucomannan
An environmentally-friendly mycotoxin binder derived from yeast cell walls.

Gluconeogenesis
The production of glucose from non-carbohydrate sources such as proteins (amino acids), glycerol and proprionate. It occurs when there is a lack of energy sources (carbohydrates) to meet the animal's needs. The process mainly occurs in the liver and kidney. It is stimulated by CORTISOL, CORTICOSTEROIDS and GLUCAGON. It used to be called GLYCONEOGENESIS.

Glucose
Glucose is the form of sugar found in honey, grapes, fruits, etc., and is the form in which sugar circulates in the bloodstream. It is very useful as an injection or drench when there is a deficiency of circulating sugar in the blood or an excess of ketones. (See ACETONAEMIA.) DIABETES MELLITUS is a condition in which glucose is absorbed by living cells and excess is excreted in the urine.

Glucose is a most valuable food to give during the course of acute illnesses, since it puts no strain upon the digestive system yet provides fuel for the muscles, etc. Glucose saline is given as a drink or administered *per rectum* or by subcutaneous injection during the course of jaundice, gastroenteritis, etc. (See SUGARS.)

Glucoside
A GLYCOSIDE derived from GLUCOSE.

Glucosinolates
Substances found in *Brassica* spp. that are broken down in the rumen to form thiocyanates, which can interfere with iodine absorption. If brassica are eaten to excess during pregnancy by ruminants, goitre may result in the offspring. Garden tortoises (*Testudo* species) that eat excessive amounts of brassicas have been known to develop goitre.

Glucosurea
The presence of glucose in the urine. It is seen in DIABETES MELLITUS, and in some other conditions, and in all animals after severe shock. (See also under URINE – Abnormal constituents of.)

Glucuronic Acid
It is a uronic acid with a structure is similar to glucose except the six carbon is oxidised to carboxylic acid giving the formula $C_6H_{10}O_7$. It is used in GLUCURONIDATION to produce GLUCURONIDES.

Glucuronidation
The process by which glucuronic acid is combined with drugs, pollutants, bile salts, fatty acid derivatives, BILIRUBIN, ANDROGENS, CORTICOSTEROIDS, MINERALOCORTICOIDS, OESTROGENS, many of which are non-water soluble to form more water soluble compounds (GLUCURONIDES) that can be excreted. Glucuronidation mainly occurs in the liver, although it also does take place in many other organs such as adrenal glands, brain, intestines, kidneys, spleen, and thymus.

Glucuronides
These are formed by the combination of any substance to GLUCURONIC ACID using the process of GLUCURONIDATION. Glucuronides are GLYCOSIDES. This makes the compounds more water-soluble and they are eventually excreted by the kidneys.

Glutamate Dehydrogenase (GLDH)
An enzyme which coverts glutamate to α-ketoglutamate and vice versa in animals and produces AMMONIA which can be converted to UREA. High blood levels in ruminants indicate LIVER problems.

Glutamine
An amino acid important in brain and muscle metabolism. High levels of exercise, as in racing or endurance riding, can seriously deplete levels of glutamine in the muscle. If extreme, anabolism (growth and repair of muscle) is prevented and muscular exhaustion occurs.

Glutaraldehyde
A disinfectant. Used in dilute solution in preparations for cleaning udders. Its former use to sterilise endoscopic equipment was discontinued because of its toxicity.

Gluteal
Gluteal is the scientific name applied to the region of the buttocks, and to associated structures, such as gluteal arteries, muscles, nerves.

Glyburide
The American name for GLIBENCLAMIDE.

Glycerides
Organic esters of glycerin. (See FAT.)

Glycerin, Glycerine, Glycerol
Glycerin (glycerol) is a clear, colourless, odourless, thick liquid of a sweet taste, obtained by

decomposition and distillation of fats. It is a trihydric sugar alcohol, being the alcoholic component of triglycerides. It dissolves many substances and has a great power of absorbing water.

Uses Given by the mouth, diluted, it has been used with success in the treatment of PREGNANCY TOXAEMIA IN EWES and of ACETONAEMIA in cattle. Internally, glycerin acts as a LAXATIVE to the dog in moderate doses. It is soothing and antiseptic to inflamed mucous membranes in the mouth and throat. In amounts of 15 ml to 30 ml (½ to 1 oz) it is useful as a rectal injection to induce passage of impacted faeces in obstinate CONSTIPATION in the dog, and it may be used for the same purpose in foals and calves. For these purposes it may be given diluted with a little water, or it may be used in the pure state. It is also used as a basis for the compounding of various electuaries for the horse and dog, and it is sometimes incorporated into cough mixtures for the smaller animals. It is used in certain skin dressings when it is desired to soften the skin surface and encourage the absorption of other drugs. It is also used as a diluent for semen. (See under ARTIFICIAL INSEMINATION.)

Glycine
An amino acid that protects the kidneys from overdosing with methionine in the diet.

Glycogen
Glycogen is an animal starch found particularly in the liver as well as in other tissues. It is the form in which carbohydrates taken in the food are stored in the liver and muscles before they are converted into glucose when needed. Glycogen can become depleted when animals are stressed, as by travelling over long periods. If not replaced, animals slaughtered after a long journey may have dry, firm, dark (DFD) meat.

Glycogen Storage Diseases
There is a wide range of problems resulting from defects in the processing and storage of GLYCOGEN in various tissues including liver, muscles etc. They can be either congenital or acquired and include Type IV; seen in humans and cats. PHOSPHOFRUCTOKINASE DEFICIENCY (Glycogen Storage Disease VII).

Glycol, Ethylene
(See under ANTIFREEZE for poisoning in dogs and cats.)

Glycol, Propylene
(See PROPYLENE GLYCOL.)

Glycolysis
The metabolic pathway which converts GLUCOSE to PYRUVATE.

Glyconeogenesis
(See GLUCONEOGENESIS.)

Glycosaminoglycans
Glycosaminoglycans, or mucopolysaccharides, in polysulphated form is used to treat lameness in horses caused by trauma or degenerative joint disease. It can be given by intramuscular injection; or in a high concentration it can be injected into the joint.

Glycosides
Glycosides are potent naturally occurring substances, combining a sugar with a hydroxy compound. Many are found in plants and are of great value in medicine. The cardiac glycoside DIGITALIS, found in the foxglove (*Digitalis purpurea*), is a prime example. Cyanogenetic glycosides are found in linseed and SAPONINS in 'lords and ladies' (*Aurum maculatum*).

Other plants with glycosides are presented under POISONING - POISONOUS PLANTS. (See also DIGITALIS - DIGITALIS POISONING.) GLUCURONIDATION is a process of combining GLUCURONIC ACID with other substances (drugs, pollutants, hormones etc.) to make them more soluble and so allow their excretion as GLUCURONIDES which are then glycosides.

Aminoglycosides are powerful antibacterials; streptomycin was the first widely used aminoglycoside antibiotic.

Glycosuria
(See GLUCOSUREA.)

GM
(See GENETICALLY MODIFIED FEEDS.)

GM1 Gangliosidosis
This is a defect of β-galactosidase which leads to an accumulation of galactosidase GM_1. It has been recorded in Friesian cattle, dogs (PORTUGUESE WATER SPANIEL DOGS; SIBERIAN HUSKIES) (DNA tests available) and cats.

GM2 Gangliosidosis
A defect of hexosaminidase seen in dogs and pigs as A and in cats A and B. There is a deterioration in the skeletal muscles as GM_2 gangliosides. The build-up results in central nervous system including muscular weakness, deafness and seizures. There is a DNA test in BURMESE CATS.

Gnathostoma Spinigerum
A roundworm infecting dogs, cats, wild carnivores, and man. It forms a nodule about 1.5 cm (½ in) in

diameter in the gastric mucosa. In a cat suspected of having rabies it caused anorexia, nausea, and convulsions, coma and death.

Gnotobiotics

Gnotobiotics is the name given to germ-free laboratory animals reared in a 100 per cent sterile environment. Such animals have been used in the investigation of certain diseases. (See also SPF; 'DISEASE-FREE' ANIMALS (IN RESEARCH).)

Goads, Electric

Batons with electrodes at one end which give a mild electric shock when they touch an animal. They are preferable to the use of carelessly or sadistically wielded sticks. The points should be blunt and spring-loaded, as otherwise they can be jabbed into the animal – when the purpose and object of an electric goad are defeated.

It is illegal to use electric goads on calves and piglets. They may only be applied to the hindquarters of cattle over six months of age, and to adult pigs. There must be a way clear for the animals to move forward. The Welfare of Animals (Slaughter or Killing) Regulations 1995 state that electric goads should be applied for no more than two seconds at a time and that there should be adequate time between applications.

Goatling

A female goat between one and two years old.

Goats

Goats are the world's fifth most common farmed species after poultry, sheep, pigs and cattle. It is estimated that there are about 800 million goats in the world of which 85 per cent are in Africa and Asia. World-wide, goat meat production has doubled in the past 20 years and milk production increased 50 per cent. More people in the world are said to eat goat meat than any other, although as most of these consumers eat little meat, the overall proportion of world meat consumption is relatively low. In Europe there are 14 million goats, the majority of which are dairy goats. In the UK there are about 95,000 adult goats with about 45,000 kept for commercial milk production, mainly in large herds. Boer goats imported from South Africa, now amounting with their crosses to about 10,000 are also used for meat, and about 10,000 Angora and Cashmere goats are kept for their fine fibre ('wool'). Many goats are kept as pets.

While cattle and sheep evolved as grazing animals, goats are browsers and are well suited to being kept in dry areas with coarse vegetation rather than lush grass. Thus goats should be kept on diets with a high proportion of coarse, fibrous material to which their digestion is suited. (An exception is the Boer goat, which appears to be able to graze successfully.) As goats are not natural grazers, they have little resistance to parasitic worms and therefore careful pasture management is required to avoid HELMINTH build-up. Wormers should only be used when the level of faecal egg counts indicate their need. Effectiveness of clostridial vaccination is poor in goats and they require more frequent vaccination than sheep or cattle. (See CLOSTRIDIAL ENTERITIS and ENTEROTOXAEMIA.)

In the UK, few medicines have marketing authorisations (MAs) for goats and so products for other farm animal species are used under the 'CASCADE' system. There is a minimum withdrawal period of seven days for milk and 28 days for meat. An exception is vaccines which usually have no withdrawal time specified.

Goats, Disbudding of Kids

This is carried out under general anaesthesia (see ANAESTHESIA, GENERAL; GOATS); and the iron used for disbudding is heated by gas (or electricity) to a 'cherry-red' heat. An oval head is preferable to the round type used for calves. Great care is needed in this operation as the skull is very thin in the area concerned. Disbudding in goats is performed under general anaesthesia as the nerve supply to the goat's horn is more complex than that of calves and the operation less straightforward. In August 2012, the RCVS interpreted the law as saying all UK kids must be disbudded by veterinary surgeons. They stated that an anaesthetic was not required, but in all probability no veterinary surgeon would undertake the procedure without one.

Goats, Diseases of

(See under ACETONAEMIA; AGALACTIA; BRUCELLOSIS; CAPRINE ARTHRITIS-ENCEPHALITIS; CONTAGIOUS CAPRINE PLEURO-PNEUMONIA; CASEOUS LYMPHADENITIS; CHLAMYDOPHILA (for abortion); 'CLOUDBURST'; COCCIDIOSIS; CRYPTOSPORIDIOSIS; CYSTICERCOSIS; ENTEROTOXAEMIA; JOHNE'S DISEASE; MASTITIS; ORF; PARASITIC BRONCHITIS; PARASITIC GASTRO-ENTERITIS OF GOATS; PREGNANCY TOXAEMIA IN EWES; Q FEVER; RICKETS; RINDERPEST; SALMONELLOSIS; SWAYBACK; TUBERCULOSIS; YERSINIOSIS; LOUPING-ILL; SCRAPIE; OSTEODYSTROPHIA FIBROSA; MANNOSIDOSIS; LISTERIOSIS; MYCOPLASMOSIS; RINDERPEST; LIVER-FLUKES; GOITRE; PULPY KIDNEY DISEASE.)

Goats as Grazers with Sheep

(See PASTURE MANAGEMENT.)

Goats' Milk, Cheese

Goat's milk is often substituted for cow's milk for children suffering from a suspected allergy to cow's milk. However, unless the milk is pasteurised, there is a risk of human illness arising; especially

VetBooks.ir

VetBooks.ir

from infection with *Brucella melitensis*, but also from *Yersinia pseudotuberculosis* – one cause of mastitis in goats. Goat's milk may contain louping-ill virus, *staphylococci*, *E. coli*; and, since goats are not immune to tuberculosis, even tubercle bacilli. Goat's milk cheese is also a source of *B. melitensis* infection.

Goat Warble Fly, *Przhevalskiana silenus*

Goat warble fly (*Przhevalskiana silenus*) parasitises goats and horses in many European and eastern countries. *Hypoderma aeratum* and *H. crossi* are other species.

Goblet Cells

Mucus-producing cells found in the large intestine; the mucus acts as a barrier between the digested food and the absorptive system.

Goitre

Goitre is an enlargement of the thyroid gland, associated with an iodine deficiency; rarely, it can be the result of a persistently high intake of iodine by the dam affecting the fetal thyroid. It is seen in puppies, foals and lambs, and also in calves, and it appears to be commoner in some districts than in others. Swellings may appear below the larynx, usually one on either side, and beyond the local enlargements there may be no definite signs shown. Some cases respond to the administration of thyroid extracts, and iodine internally, while some clear up spontaneously without treatment. Goitre is commonly encountered in elderly cats with hyperthyroidism.

(See IODINE; CALCIUM SUPPLEMENTS; THYROID GLAND.)

Lethargy is a notable sign of goitre in the dog, in which the disease often occurs in the three to five year age group, especially in the bigger breeds.

Some pastures and foodstuffs may give rise to goitre. (See GOITROGEN.) Goitre seems particularly common in Dorset Horn sheep.

A number of cases of supposed 'goitre' prove upon careful examination to be tumour growth in some part of the throat, not necessarily in connection with the thyroid gland – though cancer of the thyroid is not uncommon in the dog.

Goitre also occurs when, instead of a deficiency of thyroxin, there is a state of hyperthyroidism, or too much thyroxin. (See THYROID GLAND, DISEASES OF.)

In goat kids, some supposed cases of goitre prove to be hyperplasia of the THYMUS GLAND.

In other animals 'goitre' may be a misdiagnosis for neoplasms in the throat region.

Goitrogen, Goitrogenic Factor

Goitrogen (goitrogenic factor) is one which gives rise to goitre. Both kale and cabbage contain goitrogens (glucosinolates) and must therefore not constitute too large a proportion of an animal's ration over a period. The same applies to turnips. Iodine licks may be advisable. (See IODINE DEFICIENCY ON THE FARM.)

Golden Guernsey Goats

They were imported into Britain (also known as the British Guernsey) in 1965. They are smaller than the British dairy breeds, fine boned and usually docile. They are golden in colour with variable hair length, often with fringing. They are used for milk, producing about 3.2 kg (7 lb) milk daily with 3.7 per cent butterfat and 2.8 per cent protein. The breed was heavily involved in a BOVINE TUBERCULOSIS outbreak in 2008, but it was quickly controlled.

Golden Retriever

Popular dog of medium or larger size with a flat, wavy coat, blonde or gold in colour. CATARACT and ENTROPION are dominant traits; GLAUCOMA, OSTEOCHONDROSIS and retinal pigment epithelial dystrophy have unknown inheritance mechanisms; and PROGRESSIVE RETINAL ATROPHY and multifocal retinal dysplasia are recessives. HIP DYSPLASIA and epilepsy are inherited multifactorially. GONIODYSGENESIS is also seen.

Goldfish, *Carassus auratus*

Coldwater ornamental fish of the carp family, originally domesticated by the Chinese in the Sung dynasty (960–1279). More than 120 breeds are recognised, as well as the common goldfish. They vary in colour and markings, and in conformation of the fin, tail and head. Their life-span can range from 2 years to 25 years. Size may vary from 5 cm (2 in) to 30 cm (12 in) or more. The health of the fish is dependent on good water quality. Diets too rich in oil can result in vitamin E deficiency and cause anaemia, poor growth, muscular dystrophy, exophthalmia and other conditions.

Gonad

Gonad is a sex gland which produces a gamete (the ovary or testis).

Gonadoliberin

(See GONADOTROPHIN-RELEASING FACTOR.)

Gonadorelin

A synthetic compound having gonadotrophic properties.

Gonadotrophic

Gonadotrophic indicates something which stimulates the gonads – testes and ovaries. (See GONADOTROPHINS; HORMONES.)

VetBooks.ir

Gonadotrophin-Releasing Factor (GnRF)

A synonym for GONADOTROPHIN-RELEASING HORMONE. It is also known as GONADOLIBERIN.

Gonadotrophin-Releasing Hormone (GnRH)

A hormone produced in the hypothalamus which passes to the adenohypophysis (anterior lobe of the pituitary) and results in the release of gonadotrophins, especially LUTEINISING HORMONE and FOLLICLE STIMULATING HORMONE.

Gonadotrophins

Gonadotrophins are hormones which have a gonadotrophic effect in the body. (See HORMONES.)

Chorionic gonadotrophin effects luteinisation and is used in the treatment of functional uterine haemorrhage, cases of habitual abortion, and to induce descent of the testes in cases of cryptorchidism.

Serum gonadotrophin contains a follicle-stimulating hormone which affects the gonads of both sexes. It is used in the treatment of sterility, anoestrus, and hypoplasia of the gonads.

Goniodysgenesis

The abnormal development of the angle of filtration in the eye; a congenital problem in dogs. The angle with the pectinate ligament is abnormal and leads to a primary GLAUCOMA later in life. It is particularly seen in BASSET HOUNDS and also DANDIE DINMONT TERRIERS, ELKHOUNDS, ENGLISH SPRINGER SPANIELS, GOLDEN RETRIEVERS, GREAT DANES, HUNGARIAN VISLAS and WELSH TERRIERS.

Gonitis

Inflammation of the hock joint.

Goose Hepatitis

(See GOOSE PARVOVIRUS.)

Goose Influenza

A disease of goslings (and ducklings) caused by *Pasteurella anatipestifer.* Signs include discharge from the nose and eye, and air sacculitis. The liver, heart and central nervous system may also be affected.

Goose Parvovirus

This is also known as DERZSY'S DISEASE, goose hepatitis, infectious myocarditis or 'goose plague'. It mainly affects domestic goslings (up to six weeks) and Muscovy ducklings. Domestic poultry and other waterfowl are not affected. Mortality is very high but depends on any immunity in the egg from the mother.

'Goose Plague'

(See GOOSE PARVOVIRUS.)

'Goose-Stepping'

In the pig this can be a sign of a deficiency of pantothenic acid, one of the B group of vitamins. In cattle it may be a sign of familial ataxia. (See GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS.)

Gordon Setter

A large breed of dog originating from Scotland and the heaviest of the setter breeds with usually a long black coat and chestnut brown lower limbs, paws, throat and muzzle. They are used to hunt game birds and have a good temperament. The males are about 27 in (67.5 cm) at the shoulders and weigh about 80 lb (36 kg). They live about 10 to 12 years but can suffer GASTRIC TORSION, cataracts and PROGRESSIVE RETINAL ATROPHY (DNA test available).

Gorse

(See FURZE.)

Gossypol

Gossypol is a toxic substance present in cottonseed. Cake or meal made from cottonseed is poisonous unless gossypol is removed efficiently before manufacture. It affects fertility in cattle and possibly the human male; in chickens, susceptibility to the toxin is genetic.

Gossypol poisoning gives rise to loss of appetite, gastroenteritis, ascites, pulmonary oedema, convulsions and death. These problems are probably due to lack of VITAMIN A in animals fed gossypol. In poultry, the egg yolks become green.

Contraceptive effect Already in the 1950s it was known that gossypol could impair spermatogenesis, but not ovulation, in rats. In the 1980s research workers in China, in a search for possible male human contraceptives, included gossypol in their list, and sought to enhance the depressive effect on spermatogenesis while at the same time reducing gossypol's toxicity. The World Health Organisation encouraged this research, which led to a highly purified acetic acid preparation of gossypol being offered to scientists in other countries.

Previously, gossypol had been considered as a contraceptive for possible use in dogs and cats.

GOT

Abbreviation of Glutamic Oxalo-Acetate. (See ASPARTATE TRANSFERASE.)

Gout

Gout, the metabolic disorder hyperuricaemia, is associated with an excess of urates in blood and

VetBooks.ir

tissue fluids which can lead to the deposition of crystals of sodium urate in joints. Subsequently an acute gouty arthritis may follow. A genetic factor, associated with an enzyme deficiency, may be involved. Gout has to be distinguished from lead poisoning.

In most animals (except primates), uricase converts urates into allantoin, which is highly soluble and is excreted in the urine. It is therefore extremely rare to find articular gout in domestic mammals, though some breeds of dog can be affected. In Dalmatians the cause is different, being a defect in liver metabolism. Visceral gout in birds and reptiles is usually due to renal failure; in birds, hypovitaminosis A can cause the initial renal dysfunction. (See also 'VISCERAL GOUT' in poultry.)

Calcium gout (*Calcinosis circumscripta*.) This has been recorded in dogs and monkeys as well as in man, and involves the deposition of calcium salts and the appearance of fibrous tissue around the deposits. Firm, painless nodules occur under the skin of the limbs and feet and at the elbow, and may ulcerate. Diagnosis may be assisted by radiography. Calcium gout occurs mainly in large breeds of dog, e.g. Alsatians.

Governing Council of the Cat Fancy (GCCF)

The organisation set up in 1910 to keep registers, to license, and control cat shows, to set up regulations concerning pedigree cats and to ensure that these rules are obeyed.

GPD

(See GUTTURAL POUCH DISEASE.)

Graafian Follicle

The mature ovarian follicle. (See OVARIES.)

Grafts

(See SKIN GRAFTING TRANSPLANTATION; IMMUNITY; H-Y ANTIGEN; MAJOR HISTOCOMPATIBILITY SYSTEM.)

Grains, Brewers'

Brewers' grains are a by-product of brewing, consisting of the exhausted malt, and are used wet in some cases, where they can be easily obtained from a nearby brewery, or as dried grains. They are useful as a feeding-stuff for cattle, pigs, and sheep, providing protein as well as carbohydrate, but must be introduced gradually into the ration. Wet grains must be used fresh as they deteriorate on keeping. Dried grains keep well, and are suitable for horses, about 2.25 kg to 4.5 kg (5 lb to 10 lb) daily, and sheep, up to 225 g (5 lb).

Grains, Distillers'

Distillers' grains are produced as a by-product during the manufacture of whisky in a manner somewhat similar to brewers' grains in the manufacture of beer. They are sold either wet or dry, but are much to be preferred dry, since the wet grains are liable to contain considerable amounts of raw alcohol, which may lead to intoxication of animals eating them. The amounts and uses are similar to those of brewers' grains.

Graminiverous

Animals that feed on grass, grass seeds and other grain.

Gram-Negative

Gram-negative bacteria are those which do not retain the violet of GRAM'S STAINING. Nuclei are stained blue; cytoplasm, red.

Gramoxone

The proprietary name of a herbicide containing PARAQUAT.

Gram-Positive

Gram-positive bacteria are stained purple by GRAM'S STAINING.

Gram's Staining

A method of identifying bacteria in the laboratory. The sample is spread on a microscope slide, heat fixed, and treated with a series of agents (Crystal Violet 0.5 per cent, Gram's iodine, acetone, dilute Carbol Fuschin) and examined under oil immersion using 1250x magnification. Bacteria are described following their retention of crystal violet: those retaining the crystal violet are called GRAM-POSITIVE and those that remain red are GRAM-NEGATIVE. This staining differentiation provides an important means of classifying bacteria into two groups.

Granivorous

Seed-eating. It is usually applied to birds, some of which swallow seeds whole (e.g. GALLINACEOUS BIRDS) and some which dehusk the seed before swallowing only the kernel (e.g. PSITTACINES).

Granular Vulvovaginitis

(See under VULVOVAGINITIS.)

Granulations

Granulations are small masses of cells of a constructive nature containing loops of newly formed blood vessels which spring up over the surfaces of healing wounds (what is commonly called 'proud flesh'). Granulation tissue also occurs internally, forming GRANULOMAS at the site of lesions. (See also WOUNDS - FIRST-AID TREATMENT.)

Granuloma
A tumour composed of granulation tissue. (See EOSINOPHILIC GRANULOMA, and LICK GRANULOMA for important conditions in cats and dogs; also SWAMP CANCER).

Occasionally a granuloma is seen as the result of a *Staphylococcus aureus* infection involving the skin of cats and dogs, or the mammary glands of cattle and goats, or the equine spermatic cord.

Granulomatous
Composed of GRANULOMAS.

Grape
Dogs and cats may experience kidney failure after eating grapes. (See also RAISINS.)

Grass
(See under PASTURE MANAGEMENT; LEYS, NEW; DRIED GRASS; HAY; HAYFLAKES; SILAGE.)

Grass, Turning Out to
(See under YARDED CATTLE.)

Grass Seeds
(See under AWNS.)

Grass Sickness
A DYSAUTONOMIA which occurs in horses usually two to 10 years old after they are put on to the grass between the months of April and September. Practically all breeds of horses and ponies may be affected. A very similar condition occurs in hares, but whether it is the identical disease is not known.

Cause Various theories advanced include: (1) degeneration of certain ganglia of the sympathetic nervous system due to a virus; (2) a fungal toxin; (3) a drastic reduction in peptide-containing autonomic nerves, though what produces this is not known.

Pathognomic lesions in the autonomic nervous system can be experimentally produced by intraperitoneal injection of 500 ml serum from acute cases of grass sickness into normal horses. The serum injections do not, however, cause the stasis of the gastrointestinal tract which is typical of the disease. Examination of sera from acute cases of grass sickness revealed a compound of small molecular weight which does not occur in the serum of normal horses or in cases of colic. This substance may be a neurotoxin but this was not confirmed.

A fourth cause has been suggested, namely overactivity of the sympatho-adrenal system and stress, e.g. sweating, muscle fasciculation, tachycardia and increased plasma catecholamines. It is known that many types of stimuli caused by environmental, emotional or physical (trauma, disease) factors act as stressors and that general arousal will cause a common response in both parts of the sympatho-adrenal system.

Two sets of circumstances are thought to be involved in its aetiology: stress caused by travel to new surroundings, particularly in excitable young thoroughbred mares about to foal; and changes in the external environment such as cold and wet weather following warm and sunny weather. Similar changes are known to cause stress and increases in both plasma catecholamines and corticosteroids in laboratory animals.

Signs The disease may be:

1. Peracute. Death occurs in 8 to 16 hours, and periods of great violence are shown, at which times the animal may be a danger to people looking after it.
2. Subacute. The horse becomes dull and listless and off its food. It may have an anxious expression, and roll from pain. Later there may be a discharge from the nostrils, and an excessive amount of salivation. Swallowing is difficult. There may be localised twitching and sweating. No faeces are passed. Attempts at vomiting are made. Food material becomes impacted in the large intestine. The illness lasts from two to five days, when death or the chronic stage supervenes. The mortality is high.
3. Chronic. The signs are similar, except that constipation is not complete, and also some food may be eaten. The horse becomes progressively thinner, until in the later stages it has a tucked-up 'greyhound' appearance. The horse may live for a variable period in this state; some last only a few weeks, but others linger on for six months or more.

Diagnosis Administration of a barium preparation, followed by radiography, demonstrated serious malfunction of the oesophagus. 'Taken in conjunction with other clinical findings, this evidence was specific enough to confirm the diagnosis, without the need for an exploratory laparotomy, enabling euthanasia to be effected without delay.' (Animal Health Trust.)

Treatment Recovery is uncommon, and seldom complete. Euthanasia is usually indicated. In 2014, a vaccine was being developed and used. (See CONSTIPATIVE MUCOID ENTEROPATHY.)

Grave's Disease
Grave's disease is another name for exophthalmic goitre.

VetBooks.ir

Grayanotoxin
A toxin found in rhododendron and related species such as Pieris. It is a powerful emetic and is the only known compound to produce vomiting in ruminants. It also causes distress, abdominal pain and reluctance to move.

Grazing Behaviour
A study, made at Cornell University, of Aberdeen Angus and Hereford cows at pasture (receiving no supplementary feed) showed that:

1. The average grazing time was seven hours and 32 minutes, of which four hours and 52 minutes were spent in actual eating, and the balance in walking and selecting herbage during the process of grazing. During the hours of darkness the cattle grazed for two hours and 28 minutes.
2. In a pasture of 6 acres the cow travelled 2.45 miles, of which 1.96 were during daylight hours and 0.49 during darkness.
3. The cows lay down for 11 hours and 39 minutes, but this was divided into nine periods ranging from less than one hour to more than six hours. The time spent in chewing the cud averaged six hours and 51 minutes.
4. The calves, which were about three months old, were suckled three times a day at intervals of eight hours, and for 15 minutes at a time.
5. Droppings were deposited on an average 12 times a day and urine, nine times.
6. Under the conditions prevailing, the cows drank water once a day only. This may be accounted for by the luxuriant pasture herbage consisting of Kentucky bluegrass and wild white clover with an average water content of 72 per cent.
7. The cows showed no inclination to extend the grazing period beyond eight hours even when the amount of herbage consumed fell to 20 kg (45 lb) a day. 'It is evident that a mechanical factor is involved in grazing management, and that one of the basic principles of good pasture management is to provide the livestock with pastures in a condition which will permit them to gather the optimum amount of food within a normal period of eight hours' grazing.'

More recently, however, it has been shown that the time dairy cattle graze and ruminate is very flexible, and that the feed intake varies much less from day to day than the time spent in grazing. The cow has, in fact, a capacity to change her grazing habits to suit both her environment and her own bodily needs.

The quartering of a field by horses into parts for grazing and parts for defecation has been described. Cattle avoid the grass in the proximity of faecal pats.

Grazing Management
(See PASTURE MANAGEMENT.)

Greasy Heel
This is a chronic fungal skin infection seen in horses mainly during the winter; with lesions occurring below the fetlock.

Cause *Dermatophilus congolensis*, which invades the epidermis but does not destroy the germinating layer, so that regeneration occurs, to be followed by renewed invasion and desquamation. Lesions extend and there is pus formation; the hair becoming matted and tufted.

Greasy heel occurs in horses with marked feather, such as Shires, stabled in unhygienic, damp stables, or grazing pasture liable to flooding. In ungroomed horses at grass, the tufting may be mistaken for normal coat condition.

First-aid Pending veterinary advice: Clip all the hair away from the affected areas, and thoroughly wash the leg with soap and water containing washing soda. Burn the hair. Wash the hands, as the infection is transmissible to man. Isolate horse under dry conditions. (See also POX; DERMATOPHILUS; 'RAIN SCALD'; STREPTOTHRICOSIS.)

'Greasy Pig Disease'
Also known as exudative epidermitis, this is an infection with *Staphylococcus hiacus*. Bites, abrasions, tattooing and lice infestation may facilitate entry of the organism through the skin.

Often only some piglets in a single litter on the farm are affected. Signs include dullness, loss of bloom, and soft, greasy spots on the reddened skin of the snout, ears, around the eyes, and sometimes on the abdomen. The spots join up and spread, and after a few days the piglet may have a largely greasy and brown body, with thickened and cracking skin. Severely affected cases die within a few days; survivors are seldom an economic proposition as recovery takes several weeks and may be incomplete.

Prevention Clipping the teeth of piglets, boiling tattooing instruments and providing covered, non-abrasive flooring. To be successful, veterinary treatment with a suitable antibiotic has to be undertaken very promptly, together with warm antiseptic skin washes. Long-standing cases are best slaughtered.

Great Dane
A large dog of German origin with broad head, short, folded-over ears, a long neck and tail. The life-span is comparatively short. Ununited

VetBooks.ir

ANCONEAL PROCESS (defective elbow development) CALCINOSIS CIRCUMSCRIPTA, deafness, distortion of the NICTITATING MEMBRANE, glaucoma and OSTEOCHONDROSIS are inherited by unknown mechanisms; HIP DYSPLASIA is of multifactorial origin and 'WOBBLER' SYNDROME (CERVICAL SPONDYLOPATHY) is possibly due to a recessive gene. GONIODYSGENESIS also occurs. As a large breed it is prone to bone tumours and to GASTRIC TORSION. Conditions of the MYOCARDIUM such as CANINE DILATED CARDIOMYOPATHY lead to CONGESTIVE HEART FAILURE. (See MYOCARDIUM.)

'Green-Bottle' Fly

The main one in the UK is LUCILIA SERICATA. (See FLIES.)

Green Muscle Disease

Also known as deep pectoral myopathy or DPM, green muscle disease is seen as necrosis of the breast muscle (pectoralis minor) in muscles of poultry. It is of economic importance as the breast produces about half the total edible protein and a third of the carcase. In turkeys it can be caused by damage to the arterial blood supply to the pectoral muscles. Redesigning the layout of the poultry houses can sometimes avoid this.

Green Slime Disease

(See EPIZOOTIC CATARRHAL ENTERITIS.)

Greenstick Fracture

A greenstick fracture is one in which the bone fractures incompletely somewhat similar to the break of a green stick. They mostly occur in young animals. (See FRACTURES.)

'Green Top' Milk

(See UNPASTEURISED MILK.)

Greyface

The term often applied to a BLUE-FACED LEICESTER or BORDER LEICESTER ram crossed with a SCOTTISH BLACKFACE ewe.

Greyhound

Medium to large dog, bred for racing, with smooth coat, DOLICHOCEPHALIC SKULL, small head and abdomen, long legs and deep chest. It has acute vision but a less good sense of smell than some other breeds. The racing life is short and dogs not selected for breeding may be abandoned or destroyed when comparatively young. Rescued greyhounds make good pets as they do not require more exercise than the average dog; they tire easily after a short burst of speed. HAEMOPHILIA A (Factor VIII deficiency) is sex-linked and CALCINOSIS CIRCUMSCRIPTA may be inherited. They are the breed in the UK most commonly suffering from HOOKWORM DERMATITIS. CANINE HAEMORRHAGIC PNEUMONIA can result in relatively sudden death and STROKES occur.

Griffon Bruxellois

A breed of toy dog with wiry coat, prominent chin, short nose and erect folded-over ears. PATELLAR LUXATION may be inherited. They may also suffer PROGRESSIVE RETINAL ATROPHY, CHIARI-LIKE MALFORMATION and SYRINGOMYELIA.

Griseofulvin

An antibiotic, which can be given by mouth, effective against ringworm and other fungal diseases. Now mainly used in horses and companion animals. (See ITRACONAZOLE, LUFENURON.)

Grit for Poultry

Insoluble grit – sand, flint grit, tiny pebbles – is necessary for the grinding of the food in the gizzard (poultry possessing no teeth). Flint grit should be provided at the rate of 500 g (1 lb) per 100 birds, and is best broadcast with the grain every two or three months; except for battery birds, which require a monthly ration.

Soluble limestone grit is given in order to supply calcium for bone formation and eggshell production, and it dissolves in the gizzard within 48 hours. It is not necessary for chicks, growers or birds in early lay if they are receiving commercial mash or pellets without corn. Too much limestone grit can be harmful.

Caged and aviary GRANIVOROUS birds also require grit, but not in such large quantities as poultry; PISCIVOROUS and CARNIVOROUS birds do not require any grit as their gizzards are not well developed; their high protein diet is digested very efficiently by the PROVENTRICULUS and intestine.

Grooming

The purpose of grooming horses, cattle and dogs, especially when kept shut up in buildings, is fourfold: it is undertaken for the purpose of cleanliness, for the prevention of disease of the skin; to stimulate the skin circulation; and to remove waste products of metabolism.

Horses

Quartering This consists of going over the horse's body with a dandy-brush and removing the coarse adherent particles of bedding, dried dung, etc., as a preliminary before the horse leaves the stable for morning exercise. At the same time a cloth and a pail of water are used to wipe away

VetBooks.ir

discharges from the eyes, nose and dock, in this order, and to remove any urine stains from other parts of the body. Quartering is usually only carried out in high-class stables, where the horses go out for a short walk before the stablehands have had their breakfasts, or when a horse is not going to work but is to be turned out to grass for the day. (See SPONGES.)

Dandy-brushing The dandy-brush is made of stiff, coarse, whisk fibre, generally of the yellow variety, with the bristles not close together. It removes the coarser particles of matter from the coat, and stirs up the finer debris, as well as disentangling matted hairs. Owing to its stiffness it is not used over the head, but each side of the neck, the whole of the body, and the forequarters are well brushed. It should be used in the left hand for the near side of the animal and in the right hand for the off-side. It is advisable to make short, vigorous sweeps, turning the wrist at the end of each sweep, so that the material collected in the bristles is thrown out of the coat. Care is necessary when the undersides of the body and the insides of the legs of thin-skinned or ticklish horses are being groomed with the dandy, for they may kick if this rough brush is used carelessly.

Body-brushing and curry-combing The body-brush is made from finer whisk fibre than the dandy, the bristles are set much closer together, and they are softer and more flexible. There is usually a strap across the back of the brush into which the hand is thrust, so that a better grip can be obtained. The curry-comb is made of metal, either in the form of a square plate with a series of alternately toothed and smooth ridges set across it, or it may be oval with crenated ridges running round it. The former variety is provided with a handle, and the latter has a strap across its back like the body-brush. The body-brush is used all over the horse's body, head and neck. It picks up the finer particles of matter left behind by the dandy-brush and holds them between the fine bristles. To clean the brush it is necessary every three or four sweeps to draw it across the face of the curry-comb and transfer the dirt to the latter. The body-brush should be used in long firm sweeps, without any turn of the wrist. While grooming the near side, the body-brush is held in the left hand and the curry-comb in the right, and for the off-side the positions are reversed.

Wisping A wisp is a small mat of plaited straw or hay, which is used to remove fine dust from the coat, scour and polish the surface hair, and to promote a better skin and superficial circulation. When properly applied it acts as massage to the surface of the body, and gives the coat a fine shine.

Combing the mane and tail For this purpose a bone or metal comb is used, fashioned after the familiar manner of a toilet comb, with stouter teeth. The mane is combed a few strands at a time, both from the outside and also from the inside (with the teeth through the whole thickness of the mane), so that the hair may be laid straight and all tangles removed. Afterwards the tail is treated similarly. When a few unruly strands will not lie in position it is usual to damp the fibres of the water-brush (which is not unlike a small, fine dandy-brush pointed at each end) and lay the strands with the damp brush. Neither the mane nor the tail, however, should be soaked.

Rubbing or shining is carried out either with a stable-rubber, which is a piece of towelling about 45 cm (18 in) square, or with a chamois leather. During this process the hairs of the coat are laid straight all over the body, any loose pieces of hay or straw from the wisp are removed, and the final gloss is put on to the coat.

Cleaning-out of the feet The last operation of grooming consists of picking up each of the feet and removing any adherent dung, etc., by means of a hoof-pick, and brushing out the sole of each foot with the water-brush. If desired, the walls of the hoofs may also be blackened or oiled at this time. This operation should be left till last, just before the horse leaves the stable, for otherwise he may collect fresh dung in his feet. It is an important matter not to neglect this cleaning-out of the feet, for if there is a cake of dung in the soles of each foot, not only is it extremely untidy, but small stones are liable to be picked up and may cause injury to the soles.

Parts often neglected When examining a horse to discover the thoroughness or otherwise of the grooming, it is usual to take a white handkerchief and to rub it along the coat; the size of the particles of grey debris which adhere to its surface are in inverse ratio to the efficiency of the grooming – i.e. the larger the particles, the less efficiently has the horse been groomed. The following parts should be carefully examined: under the forelock, the poll, jowl, under the mane, between the fore-legs, behind the elbows, along the belly, inside the thighs, in the hollows of the heels, and around the dock and between the buttocks.

To dry a wet horse When a horse returns to a stable soaked with rain, snow, or sweat, it is advisable that it be dried to avoid the risk of chill through too-rapid evaporation of the moisture in the coat.

First of all it should be given a warm drink. The harness is next removed and the surface of the body

VetBooks.ir

scraped down with a sweat-scraper. This is a flexible ribbon of copper provided with a handle at either end. The scraper removes the excess water from the coat, and may be used to scrape away adherent mud from the legs and belly, but it should not be used over bony prominences owing to the danger of abrading the skin. Two or three hay wisps are made ready, and the horse is vigorously wisped down all over. As one wisp becomes wet it is discarded and another taken. Sometimes a coarse, rough towel is used instead of a wisp. In about 10 minutes all the moisture that can be removed by this means will have been eliminated, and the rest must be allowed to evaporate. An armful of straw is arranged across the horse's back; a rug is thrown over all, and girthed up. The straw allows a certain amount of ventilation under the rug, and prevents too-rapid cooling and chilling. In about 2 hours' time the rug should be removed, a second wisping should be given, and a new dry rug should be applied. If the feet and legs are very wet, especially if there is much feather, they should be bandaged with woollen stable bandages, and a little bran or sawdust may be sprinkled on to the wet hair below the bandage. Sometimes a horse's feet are washed immediately after coming in from work, especially if they are coated with mud; when this is carried out, care should be taken to see that they are well dried again afterwards, for frequent washing predisposes to grease, eczema, and other skin conditions, through maceration of the surface epithelium.

Dogs When grooming it is always advisable to begin by combing and brushing the coat in the wrong direction (against the lie of the hair), so as to remove pieces of dirt, debris, etc. which have become lodged under a lock of the coat. Finish by brushing and combing in the direction in which it is desired that the hair shall eventually lie.

In the spring, and again in the autumn, when the coat is changing, both dogs and cats require more careful grooming than they do at other times of the year.

Cats benefit from regular grooming. With long-haired breeds, combing is essential. Brush strokes in a cat should be short and brisk, mimicking the action of the cat's own tongue.

Grootlamsiekte

A disease of sheep in SW Africa, associated with a prolonged gestation period, and caused by a poisonous shrub (*Salsola ruberculata*).

Groundnut Meal

Groundnut meal may be infected by a mould, *Aspergillus flavus*, which produces a toxin (AFLATOXIN). In an outbreak of fatalities among turkeys fed in Britain on proprietary feeding-stuffs, the cause was traced to Brazilian groundnut meal (not all samples of which, however, proved harmful). Calves and pigs also died. In calves, groundnut poisoning resembles that of ragwort.

The mould can grow on decorticated groundnuts when their moisture content exceeds about 9 per cent, or on meal at about 16 per cent. It usually develops on the nuts after they are harvested, particularly if drying is delayed and the shells damaged. However, if harvesting is delayed the nuts may become toxic in the ground, and if the nuts are stored at a moisture content in excess of 9 per cent they can also become toxic.

Pigs of from 3 to 12 weeks are particularly susceptible, and pregnant sows to a lesser extent.

It was found that cows fed on hay and a concentrate ration containing 20 per cent toxic groundnut meal excreted a toxin in the milk which produced the same biological effect in ducklings as aflatoxin. There is evidence strongly suggesting that aflatoxin may be a carcinogen, giving rise to cancer of the liver or bile ducts. A 100 per cent incidence of carcinoma of the liver was found in pigs which survived illness following the feeding of a mixture of oil-cakes. The same effect has been observed in rats. Toxicity trials in ducklings produced carcinoma of the bile ducts.

Groundnut meal contains an alkaloid, arachine, which can cause a fatal hepatitis in dogs, and temporary paralysis in frogs and rabbits. (See also AFLATOXINS.)

Grouse

They are wild game birds belonging to the Order *Galliformes* (includes the chicken), although many are bred and reared for shoots. There are two main types in the UK, the black grouse (*Tetrao tetrix*), found in heather, rough grass, rushy areas and woodland, and the red grouse (*Lagopus lagopus scoticus*), associated with heather. Others in the group include capercaillies and ptarmigans. They suffer most of the diseases seen in chickens, but also red grouse can be infected with LOUPING-ILL. 'BULGY EYE' has signs similar to INFECTIOUS SINUSITIS.

Grouse Disease

A wasting disease caused by heavy infestation with *Trichostrongylus tenuis*, a nematode parasite. Grouse tend to remain on the moor where they were hatched and a build-up of the parasite results. If the grouse population increases too much, food may become short. Coupled with the infestation, survival of chicks may become very difficult. Further, an ageing population of birds becomes less fertile. Paradoxically, in the proper management of a moor efficiently regulated shooting maintains the numbers of grouse. (See TRICHOSTRONGYLOSIS.

Growth Hormone
(See SOMATOTROPIN.)

Growth Plates
Growth plates are the epiphyses, the areas of juvenile long bones of mammals capable of growth. (For growth-plate defects, see BONE, DISEASES OF.)

Growth Promoters
Substances which, given in animal feeds, increase feed conversion efficiency or result in better daily liveweight gains, or both. Although very useful when given properly, there have been problems in the past caused by the misuse of some hormonal growth promoters, particularly in Italy, which led to the banning in Europe of some potentially useful products. (For types and examples, see under ADDITIVES; see also SOMATOSTATIN; STILBENES; SURFACTANTS; HORMONES IN MEAT PRODUCTION; CLENBUTEROL HYDROCHLORIDE; WORMS, FARM TREATMENT AGAINST.) Some plant extracts used experimentally are:

Carvacrol an isomer of thymol that can kill certain Gram-negative bacteria and promote *Lactobacillus* spp.

Cinnamaldehyde is the active ingredient from cinnamon and has been shown to produce antioxidant enzymes in the intestine.

Citrus Pomace which is the material after juice extraction and used in ruminant feeds in countries growing the fruit. It is unpalatable unless juice is added to it.

Juniper (*Juniperus communis*) is used as an oil extract combined with thyme oil, tannins, gentian root extract and salinic have given good results.

Oregano produces essential oils and improves production in pigs.

Thyme (*Thymus praecox*) has been combined with other materials to improve growth.

Growths
Areas of tissue which have enlarged without purpose. (See TUMOURS; CANCER; GRANULOMA.)

Guaifenesin
A muscle relaxant that is used in horses with anaesthetics such as DETOMIDINE and KETAMINE to potentiate their action.

Guanacos
A member of the CAMELIDAE (*Lama guanicoe*) from South America. They are smaller than LLAMAS and are about 105 cm to 120 cm (3.5 ft to 4 ft) high at the shoulder and weight about 90 kg (about 200 lb). The hair is brown but can be of various shades and with a white underbelly. It is mainly used for fibre production.

Guanine
A purine which is part of certain genes and controls the formation of amino acids.

Guarnieri Bodies
(See INCLUSION BODIES.)

Guernsey
Cattle originating from the Channel Islands yielding milk of a high butterfat content. The coat is pale brown and white in colour. The females tend to be placid.

Guide Dogs
(See DOGS, WORKING.)

Guinea Fowl
Large bird (50 cm; 20 in long) of the Numidiae family with featherless head and neck. Widely distributed in savannahs of Africa; introduced elsewhere. Used for food, and as an 'intruder alarm' because of the loud gobbling noise it makes if disturbed. There is substantial guinea fowl production in Europe especially in France and Italy. They suffer problems such as HEXAMITIASIS.

Guinea-Pig
Also known as a cavy, the guinea-pig is a rodent, *Cavia porcella*, originating from South America; it is kept as a children's pet, a laboratory animal, and as an animal bred for show purposes.

Breeds include English, Abyssinian and Peruvian.

Diseases include tuberculosis, pseudotuberculosis (yersiniosis), salmonellosis, leptospirosis, streptococcal pneumonia, toxoplasmosis, a viral infection of the salivary glands, and fascioliasis. Mange due to *Trixacarus* and lice infestations also occur. (See PETS, CHILDREN'S AND EXOTIC.)

Guinea-pigs cannot synthesise vitamin C (like people), and their diet can easily be deficient in this vitamin; they frequently show signs of hypovitaminosis C. They practise COPROPHAGY, swallowing the soft brown pellets produced in the caecum, rich in B vitamins and amino acids. (See VITAMINS - VITAMIN C.)

An important characteristic of the female guinea pig is that fusion of the PUBIC SYMPHYSIS BONE is delayed until six months old. This means that sows having their first litter after this time will usually require a Caesarean section and so routinely the aim is to have them give birth before six months old.

VetBooks.ir

Guinea Worm

A nematode parasite (Dracunculus medinensis) which infects man, non-human primates, dogs, cattle and horses. This parasite is found in Africa, the Middle East, India, Pakistan and Iran. The intermediate hosts are several species of the crustacea *Cyclops*, which live in ponds and wells, etc.

D. insignis infects carnivores in the USA and southern Canada.

The pads of a dog's feet may be severely affected by female guinea worms and may ulcerate.

Gular Flutter, Gular Fluttering

The rapid movement of the floor of the mouth and upper throat of birds and lizards as a cooling mechanism.

Gullet

(See OESOPHAGUS.)

Gumboro Disease

Properly called avian infectious necrosis or infectious bursal disease, Gumboro disease takes its name from a town in Delaware, USA. It affects broiler chickens of 1 to 5 weeks of age. The disease has been recorded in Britain since 1962. Because it destroys the cells of the bursa of Fabricius, the immune system of the birds is severely impaired, leaving the birds susceptible to other diseases after recovery from Gumboro disease. For this reason it has been called 'chicken aids' but this is incorrect as the mechanisms of the 2 are quite different. Vaccines are available for its control; administration must be planned strictly in accordance with the manufacturers' schedules. (See INFECTIOUS BURSAL DISEASE.)

Gums

The colour of these is dependent on the blood circulating within them, and provides useful clues to the veterinarian engaged on the detective work which goes into each diagnosis. Very pale gums suggest anaemia or internal haemorrhage. Gum pallor may be seen too in cases of leukaemia, shock after an accident, in warfarin poisoning, or failure of the left side of the heart. A yellowish tinge suggests jaundice. A blue or purple discoloration (CYANOSIS) indicates a shortage of oxygen in the circulating blood. (For inflammation of the gums, see MOUTH, DISEASES OF - GINGIVITIS. For a common tumour of the gum, see EPULIS.)

Gunshot Injuries

Injuries from firearms in free-ranging animals and birds are frequently encountered by the veterinarian. These injuries range from air gun pellet injuries, which often present clinically as a circular hole in the skin with hair driven underneath and protruding from the site. The pellet can be detected by means of a probe or by radiographical examination. Internal wounds are seen in the smaller patient and can include traumatised organs and fractured bones. Wounds from shotguns are usually more serious unless the victim was caught only by the edge of the spray of pellets. Shotgun pellets are easily seen on radiographic examination.

Gut

The intestinal system is used to digest food, starting at the small intestine and ending in the rectum. It is also forms part of the ALIMENTARY CANAL or GASTROINTESTINAL TRACT. (See DIGESTION.)

Gut-Associated Lymphoid Tissue

LYMPHOID tissue on the surface of the gut that assists in removing infections, toxins and other noxious agents. It includes the TONSILS, PEYER'S PATCHES and aggregates of lymphoid tissue of varying size in the oesophagus, stomach, caecum and colon.

'Gut-Tie'

'Gut-tie' is the colloquial name for a type of hernia in which a piece of bowel becomes entangled in the spermatic cord following castration of cattle. It is extremely rare.

Guttural Pouch

A diverticulum of the Eustachian tube developed from the pharynx.

Diseases of the guttural pouch include fungal infections, which may be followed by paralysis of the cranial nerves; and also a haemangioma, which may have a similar result. With both, the signs include difficulty in swallowing and the return of food and water through the nostrils, seen in equines. (See also GUTTURAL POUCH MYCOSIS; EAR Middle.)

Guttural Pouch Disease (GPD)

Sometimes known as guttural pouch diphtheria, GPD is a general term for a number of diseases in horses locating in the guttural pouch. Empyema, mycosis or tympany have all been involved. GPD of one kind or another has been encountered in horses from 2 months to 18 years old – in ponies, cobs, hunters and thoroughbreds. It may prove fatal within a week, or may be chronic, with signs shown over a period of seven months or more.

Signs Clinical signs vary. Epistaxis (nose-bleeding) is often seen. Haemorrhage occurs spontaneously while the horse was at rest in the stable. It is generally recurrent and may be mild, severe or fatal. Other signs may include:

VetBooks.ir

Dysphagia (difficulty in swallowing). Attempts to eat solid food result in coughing and the discharge of food material from mouth and nostrils. Drinking may be difficult. Water is conveyed back into the bucket via the nostrils.

Laryngeal hemiplegia. Paralysis of one side of the larynx, resulting in abnormal inspiratory noise when exercised.

Soft palate paresis. In racehorses this is shown by the sudden onset of respiratory obstruction during a race.

Diagnosis This involves an examination of the guttural pouches by endoscope.

Guttural Pouch Empyema

Caused by bacterial infection of the guttural pouch, empyema produces a painful swelling near the ear. Raised temperature, nasal discharge and anorexia may also be seen. Treatment with antibiotics and lavage of the guttural pouches is often effective; surgical drainage and removal of purulent material may be required in some cases.

Guttural Pouch Mycosis

Guttural pouch mycosis is usually caused by infection with *Aspergillosis* spp. Nose-bleeding, which may be very severe, is common but dysphasia and other signs may be seen. Mycosis can usually be successfully treated with benzimidazole drugs given by mouth. A specially designed catheter has been used for local treatment with antifungal agents. Surgery can be used. Prognosis is very poor in cases where PHARYNGEAL PARALYSIS is present.

Guttural Pouch Tympany

Found mainly in young foals. Usually only 1 guttural pouch is affected, which becomes distended with air, causing a painless swelling near the ear. Breathing may be noisy and in severe cases empyema may develop. Surgical treatment involves an incision in the membrane between the two pouches to release trapped air. Prognosis is usually good.

Gyrodactylus

A fluke living on the skin of freshwater fish. It is viviparous and a developing embryo may be seen within an adult. It can invade the gills and the eyes, causing behavioural changes such as 'flashing' followed by skin erosion and secondary fungal infections. Although apparently harmless to fish stocks in its native habitat, the rivers of the Baltic, *G. salaris* has had severe effects on salmon in Norway. Gryrodactylosis is a NOTIFIABLE DISEASE.

Gyrus

A convolution of the brain.

H

Habib Probe
A device emitting a radio signal that is used in soft tissue surgery. The probe causes COAGULATION NECROSIS of tissues, and can be used to reduce blood loss in the area following surgery such as liver tumour removal.

Habronemiasis
Infection of horses with worms of the genus *Habronema*, the cause of 'summer sores' and a usually mild chronic gastritis. (See ROUNDWORMS – Horses.)

HACCP
(See HAZARD ANALYSIS AND CRITICAL CONTROL POINT.)

Haem
The non-protein, insoluble iron-containing protoporphyrin part which, when combining with protein, makes HAEMOGLOBIN, MYOGLOBIN and various other respiratory pigments in animal and plant cells. It is the iron part of PROTOPORPHYRIN which produces the pigment or colour.

Haemangioma
Haemangioma is a tumour composed of blood vessels. In the liver of adult cattle small haemangiomata are not uncommonly found, but they are seldom of any practical importance. (See also under GUTTURAL POUCH for haemangioma in horses.)

Haemangiosarcoma, Cardiac
A malignant tumour which may give rise to fatal internal haemorrhage, and has been found in the lung, spleen, liver, kidney, brain, etc. of dogs. Metastases are relatively common.

Haemangiothelioma
(See HAEMOSARCOMA.)

Haemarthrosis
Bleeding into a joint or joints. It occurs following trauma or because of other conditions such as HAEMOPHILIA.

Haematemesis
Vomiting blood. When the blood is from a lesion of the stomach or oesophagus it is bright red; but when it has lain in the stomach for some time, and been partly digested, it resembles coffee-grounds.

Haematidrosis
The presence of blood in the sweat.

Haematocele
A haematocele results when blood collects in a body cavity. It often refers to the testicle following an injury which has ruptured the smaller blood vessels. Blood from them then collects in the cavity of the scrotum, in the loose fascia, or in the outer coat of the testicle itself.

Haematochelazia
Blood in the faeces.

Haematocrit Value
This is also referred to as PACKED CELL VOLUME. The percentage by volume of whole blood that is composed of erythrocytes. It is determined by filling a graduated haematocrit tube with blood – treated so that it will not clot – and then centrifuging the tube until the red cells are packed in the lower end. As a rough guide, values are about: sheep, 32 per cent; cow, 40 per cent; horse and pig, 42 per cent; dog, 45 per cent.

Haematoma
A swelling containing clotted blood under the skin, or deeper in the musculature or in VISCERA, following serious bruising; for example, after an animal has been struck by a car. Haematomas also occur in cases of warfarin poisoning and canine haemophilia. They may result from shaking the head or scratching the ear when the ears are inflamed. Aural haematomas are also seen in pigs and sheep. (See also under EAR, DISEASES OF for haematomas in the ear in cats and dogs.)

Haematopedesis
(See HAEMATIDROSIS.)

Haematophagous
This adjective applies to parasites which feed on blood, such as ticks and fleas.

Haematopinus
A genus of sucking lice. (See LICE.)

Haematopoeisis
The formation and development of blood cells; usually takes place in the bone marrow (INTRAMEDULLARY) or in the spleen, thymus and lymph nodes (EXTRAMEDULLARY).

Haematothorax
An effusion of blood into the pleural cavity.

VetBooks.ir

Haematozoon
(plural, Haematozoa)
A general name applied to the various parasites (usually protozoa) living in the blood stream of a host animal.

Haematozoon canis
A coccidia-like parasite found in countries where the tick *Rhipicephalus sanguineus* is present.

Signs Anaemia, fever, hind-leg weakness, dyspnoea; sometimes epistaxis.

Haematuria
Haematuria is any condition in which blood is found in the urine. When urine is allowed to stand, the red cells gravitate to the bottom of the container. (See HAEMOGLOBINURIA; URINE - ABNORMAL CONSTITUENTS OF URINE.)

Haemobartonella
Also known as eperythrozoon, it is a single-celled parasite of the blood. *H. felis* (also known as *Mycoplasma felis*) is the cause of FELINE INFECTIOUS ANAEMIA; *H canis* of the corresponding disease of dogs, in which the parasite complicates many cases of canine parvovirus infections. (See also EPERYTHROZOON PARVUM for the infections in farm animals.) Diagnosis is not easy as the parasites may not be present in the first blood samples examined microscopically. Antibiotic treatment is usually successful; a vitamin B_{12} preparation is often given simultaneously.

Haemochromatosis
A disease of cage birds in which excessive iron is stored in the liver. (See CHELATING AGENTS.)

Haemocyte
A blood cell. Red blood cells are called erythrocytes; white blood cells, leukocytes.

Haemoglobin
Haemoglobin is a complex organic compound containing iron, and gives the red colour to the red blood cells. (See METHAEMOGLOBIN.) Haemoglobin has the function of absorbing oxygen from the air in the lungs and of transporting oxygen to the tissues.

It exists in two forms: carbon dioxide-combined haemoglobin, found in venous blood, and oxyhaemoglobin, found in arterial blood that has been in contact with oxygen. This oxyhaemoglobin, a weak compound of haemoglobin and oxygen, is broken down in the tissues, yielding to the cells its oxygen, and becoming once more haemoglobin.

In some forms of anaemia there is a great deficiency in haemoglobin. Bovine haemoglobin glutamer-200 (an oxygen carrier) has been used on a single occasion to alleviate the effects of certain types of anaemia in dogs. (See BLOOD; ANAEMIA; RESPIRATION.)

Haemoglobinuria
The presence of haemoglobin in the urine, such as occurs in azoturia, red-water fever, leptospirosis of calves and poisoning by an excess of kale or cabbage. When the urine is allowed to stand, the red pigment remains in solution (differentiates from HAEMATURIA).

Haemolymph
In invertebrates, haemolymph is the blood-like fluid that functions as does blood and lymph in vertebrates.

Haemolysis
The breakdown of red blood cells and the consequent release from them of haemoglobin. It occurs gradually in some forms of anaemia and rapidly in poisoning by snake venom. Some chemical and bacterial toxins cause haemolysis.

Haemolytic
Relating to haemolysis. For haemolytic disease of foals, see FOALS, DISEASES OF. Haemolytic disease in pigs and dogs is similar in its effects. In cattle, it may account for some cases of abortion.

Haemolytic Anaemia
The breakdown of red blood cells in haemolysis can lead to anaemia. In such cases there will usually be HAEMOGLOBINURIA and possible jaundice. The cause are many and include excessive breakdown of erythrocytes in the vascular system, monocyte macrophage activity, incompatability of colostrum or blood transfusions, infections, parasites (especially piroplasms), poisoning by kale, rape, etc. CONGENITAL HAEMOLYTIC ANAEMIA occurs in some dog breeds including ALASKAN MALAMUTES, BASENJIS and BEAGLES.

Haemonchosis
Infection of the abomasal wall with *Haemonchus contortus* or *H. placei*. It causes acute anaemia, anasarca and sometimes death in sheep and goats and camelids but is often less severe in cattle. Usually seen in the summer. It is also seen in the CAMELIDAE especially ALPACAS where there is anaemia without diarrhoea.

Haemophilia
A condition in which clotting of the blood is impaired (see CANINE HAEMOPHILIA; FELINE HAEMOPHILIA). Various forms of haemophilia are inherited by various inherited mechanisms. Breeds include AIREDALE TERRIERS (B IX; VII), ALASKAN MALAMUTES (VII), AMERICAN

VetBooks.ir

COCKER SPANIELS (IX, X); BEAGLES (VII, VIII); BULL TERRIERS (IX), CAIRN TERRIERS (IX), CHIHUAHUAS (VII), DEERHOUNDS (VII), ENGLISH SETTERS (VIII), ENGLISH SPRINGER SPANIELS (XI), FRENCH BULLDOGS (VIII, IX), GERMAN SHEPHERD DOGS (VIII), GERMAN WIRE-HAIRED POINTERS (IX), GIANT SCHNAUZERS (VII), GREYHOUNDS (VIII), HUSKIES; IRISH SETTERS, KERRY BLUE TERRIERS (XI), LABRADOR RETRIEVERS (VIII, IX), LHASA APSO (IX), PYRENEAN MOUNTAIN DOGS, SAMOYEDS (VIII), WEIMARANERS.

Haemophilic

Relating or pertaining to HAEMOPHILIA.
In bacteriology, the term relates to organisms that grow well in media containing blood or that require the nutrients that are contained within fresh blood.

Haemophilosis

(See 'SLEEPER' SYNDROME.)

Haemophilus Infections

Haemophilus (GRAM-NEGATIVE; HAEMOPHILIC; BACTERIA) infections include *H. somnus* (now *Histophilus somni*) causing the 'SLEEPER' SYNDROME in feedlot cattle in the USA. The organism has also been isolated from cases of pneumonia, metritis, and abortion in cattle; in Canada it is commonly found in the genital tract of bulls. *H. somnus* has been found in semen samples from Danish bulls. In pigs in the UK, *H. parasuis*, *H. parainfluenzae* and *H. parahaemolyticus* are often associated with chronic respiratory disease, including a painful pleurisy. *H. parahaemolyticus* may also cause an acute illness and sudden death.

Infection with *H. pleuropneumoniae* has been increasingly detected in Britain, as have the reported number of outbreaks of acute PLEUROPNEUMONIA due to this organism.

Haemophilus parasuis

A bacterium formerly linked mainly with GLÄSSER'S DISEASE, a polyserositis, particularly in eight to 10-week-old weaners. Infection has changed to produce respiratory disease with low-grade coughing in sucking pigs, 'fading' and respiratory disease in weaned piglets, acute infections of weaners and growing pigs and, of greatest importance, it is a primary component of PORCINE RESPIRATORY DISEASE COMPLEX in association with PORCINE REPRODUCTIVE RESPIRATORY SYNDROME virus and PORCINE CORONAVIRUS INFECTION Type II. In acutely affected pigs there is typically pneumonia and septicaemia with collapse, dyspnoea, pyrexia, inappetance, coughing and skin discoloration. In some outbreaks there is also meningitis and joint swellings. *H. parasuis* often exacerbates damaged by the latter viruses and is the ultimate cause of death. Diagnosis is by paired serology or cross-sectional herd testing with an ELISA for the presence of intracellular protein released by the organism in the infective stages is helpful and also detects vaccination antibodies. Post mortem examination will show POLYSEROSITIS but the organism is hard to culture. Treatment is based on synthetic PENICILLIN-based products, but often lesions are too severe for the animal to respond. Strategic medication of sows to prevent piglet infection, parenteral treatment of pigs in the farrowing area and water or in-feed mediation of weaned pigs all help. Vaccines are also available.

Haemopoiesis
(adjective, Haemopoietic)

Relating to the formation of red blood cells.

Haemoprotein

(See HAEMPROTEIN.)

Haemoptysis

The expulsion of blood from the lower air passages, generally by coughing. The blood so expelled is bright red in colour and is frothy, as it contains air, thus differing from that which has been expelled from the stomach. It is seen in tuberculosis in cattle and thrombosis of the anterior vena cava.

Haemorrhage
(adjective, Haemorrhagic)

The loss or escape of blood from a blood vessel or from the heart as a result of rupture, erosion or injury. (See BLEEDING; PROTHROMBIN; INTERNAL HAEMORRHAGE; and 'HAEMORRHAGIC DISEASE' OF DOGS.)

Haemorrhagic Bowel Syndrome (HBS)

(See JEJUNAL HAEMORRHAGIC SYNDROME in cattle.)

Haemorrhagic Diathesis

An inherited tendency in dogs, transmissible to either sex, to bleeding from the nasal and other mucosa.

'Haemorrhagic Disease' of Dogs

(See DIARRHOEA; HAEMANGIOSARCOMA, CARDIAC; CANINE HAEMOPHILIA; HAEMORRHAGE.)

Haemorrhagic Enteritis of Turkeys

This acute, often fatal, disease is seen in birds over four weeks old. The droppings are bloody and the disease spreads rapidly through a flock. It has appeared in the UK, the USA, Australia and Southern

Africa. There is an increased incidence during hot weather. An adenovirus is usually the cause.

Haemorrhagic Fever with Renal Syndrome (HFRS)

An important human disease caused by Hantaan or related viruses, and occurring in Europe, the USA and the Far East. Human mortality varies from 0.5 to 18.5 per cent. In Belgium, staff at a research institute were infected by laboratory rats; but voles are the main source. In the USA, urban rats have been implicated (WHO).

Signs These can be like the effects of a mild influenza attack; but in many cases they are those of a serious illness characterised by dizziness, vomiting, back pain, HAEMATURIA, acute kidney failure and shock.

Haemorrhagic Gastroenteritis of Pigs

Haemorrhagic gastroenteritis of pigs can be caused by bacterial infections or parasitic infestations. One syndrome with a non-infectious aetiology involves the sudden death of growing pigs, with autopsy findings of haemorrhage into the small intestine, and sometimes VOLVULUS.

Whey-feeding is especially associated with this syndrome, but it can occur also in meal-fed pigs. It has been suggested that rapid gas production by fermenting whey in the colon leads to distension, displacement and sometimes VOLVULUS. Haemorrhage may result from the twisting and occlusion of the mesenteric veins.

Haemorrhage from the intestine is an important feature of another syndrome seen in Australia. An outbreak involved 372 adult pigs in the breeding units of a minimal-disease piggery; 186 pigs died. Some had been seen to be passing blood; others died without any signs being observed.

This syndrome has the somewhat cumbersome name of PROLIFERATIVE HAEMORRHAGIC ENTEROPATHY (PHE), and has been described also by several research workers in the UK. PHE is associated with adenoma-like changes in the small intestine similar to those seen in necrotic enteritis and inflammation of the ileum, the last part of the small intestine. (See also PORCINE INTESTINAL ADENOMATOSIS.)

Haemorrhagic Gut Syndrome (HGS)

(See JEJUNAL HAEMORRHAGIC SYNDROME in cattle.)

Haemorrhagic Proliferative Proventriculitis and Gizzard Erosion

A disease reported in India which is infectious and probably involves more than one organism and is exacerbated by mycotoxins and diet. It is only recognised at post mortem. The problem is controlled by reducing overcrowding and ensuring the litter is dry.

Haemorrhagic Septicaemia, Pasteurellosis

This is present in most tropical countries, and is especially important in Asia. Outbreaks tend to occur at the beginning of the monsoon rains. Buffaloes and cattle are the animals mainly affected, but the disease occurs also in camels, goats, sheep, pigs and horses.

Cause *Pasteurella multocida* type 1 and possibly other serotypes. Stress due to exhaustion, underfeeding and transport may predispose animals to infection.

Signs After a very short incubation period (two days or less), buffaloes and cattle become dull, lose their appetite, salivate profusely and have a high fever. Visible mucous membranes become dark red. The tongue may swell and protrude from the mouth. Oedema results in hot, painful swellings in the regions of the throat, brisket and dewlap. Death, in this most acute form, usually follows dyspnoea, and occurs in from a few hours to three or four days. Mortality is very high. In less acute cases there may be dysentery or broncho-pneumonia.

Treatment can seldom be carried out in time to save life, but sulfonamide drugs and antibiotics may help if given early.

Control Specific and combined vaccines are available. (See also PASTEURELLOSIS IN CATTLE; 'SHIPPING FEVER'.)

Haemosarcoma

Malignant tumour of the endothelial cells lining the blood vessels. It is relatively common in dogs and incidence levels in cats are increasing. It is also known as ANGIOSARCOMA and HAEMANGIOTHELIOMA.

Haemosiderin

An iron-protein compound. It appears to be the form in which iron is stored in organs such as the spleen until needed for haemoglobin.

Haemosiderosis

A disease characterised by excessive storage of haemosiderin in the viscera. (See IRON STORAGE DISEASE.)

Haemostatics

Haemostatics are means taken to check bleeding, and may be drugs applied to the area, mechanical devices, etc.

Haemotropic Anaemia
A disease in which a micro-organism of the Genus Mycoplasma that is attracted to and invades the red blood cells. (See FELINE INFECTIOUS ANAEMIA.)

Haemprotein, Haemoprotein
A protein in which the non-protein part is HAEM.

Haflinger Horses
Strong horses originating from the Austrian Alps. They can be ridden as well as being small working horses. The breed standard specifies a pale colour, which is termed chestnut, with a flaxen mane and tail.

Hair
(See SKIN - HAIR.)

Hair, Clipping of The
(See CLIPPING OF DOGS; CLIPPING OF HORSES; CLIPPING OF SHEEP.)

Hair, Diseases of
(See ALOPECIA; ATRICHIA; HYPOPIGMENTATION; LEUKOTRICHIA; LEUKODERMA; RINGWORM; DERMATOPHILUS; SKIN, DISEASES OF.)

Hair-Ball
Hair-balls (also called trichobezoars) are masses of impacted hair or fur caused by animals licking their own or other animals' coats. They sometimes cause indigestion in calves, especially those aged about six weeks to four months. The hair may be in the form of a ball or in loose masses, sometimes mixed with milk curds, sand, binder twine, etc. Bad management encourages calves to lick their own or other animals' hair. The condition rarely proves fatal either in calves or in pigs. (However, the owner of an animal, on finding a hair-ball, may erroneously decide that this is the cause of death, which may in fact have been caused by some infection.) Note: a certain amount of hair in the stomach of rabbits is a normal finding, but sometimes hair causes impaction in the small intestine with serious consequences.

Signs in calves are usually vague, but may include grinding of the teeth, an unnatural gait, and in chronic cases a general loss of condition, although the appetite remains fairly good. Convulsions may also occur.

Prevention Ensure a well-balanced diet, adequate minerals and roughage, and attend to any skin disease. (See SALT – Salt licks.)

Treatment in calves is surgical and often successful if carried out early.

In rabbits an obstructing intestinal hair-ball may move to the large intestine after the administration of opiates. If not it may have to be "milked through" or be removed surgically following laparotomy.

Cats Particularly in long-haired varieties, hair/fur-balls sometimes result in impaction of the intestine. This also occurs in the dog, but less commonly.

Hair Dryers
Hot air from these has been used for removal of maggots from wounds following any necessary debridement.

'Hairy Shaker' Disease
'Hairy shaker' disease, or border disease, is a transmissible disease of lambs (See 'BORDER DISEASE' OF SHEEP.)

Halal Food
Food that has been prepared and is acceptable to Islamic law. It refers to a way of life rather than to food. It is estimated that about 88 per cent of Halal meat slaughtered in Britain is pre-stunned. All animals killed must be healthy.

Halal Slaughter
The slaughter of animals according to Islamic law which is undertaken by cutting the throat with a very sharp knife without stunning. About 90 per cent of cattle and about 88 per cent of all Halal meat are pre-stunned before slaughter. (See also RELIGIOUS SLAUGHTER.)

Half-Bred
In sheep, this term is used for the following crosses: a BORDER LEICESTER ram crossed with a CHEVIOT ewe is a Scottish half-bred; a BORDER LEICESTER ram crossed with a WELSH MOUNTAIN ewe is a Welsh half-bred; and a BORDER LEICESTER ram with a CLUN FOREST is an English half-bred.

Half-Life
The time taken for the concentration of a drug in the animal's body (or circulation) to be reduced by 50 per cent. It is also used to describe the rate of decay of radioactivity.

Halitosis
Bad breath may be indicative of a number of disease conditions. Checking for offensive odour in the breath is routine in the clinical examination of many animals, particularly dogs and cats.

Halofuginone
A coccidiostat for the prevention of coccidiosis in turkeys and chickens reared for meat. It is also used for the treatment of *Cryptosporidium parvum* infection in calves.

VetBooks.ir

VetBooks.ir

Halothane, Fluothane

A potent, non-irritant inhalation anaesthetic that was until recently used widely in horses, dogs, cats, laboratory animals and, to a lesser extent, in cattle. It has been largely superseded by ISOFLURANE. It offers smooth induction, and gives moderate to good analgesia and muscle relaxation. Side-effects are usually dose-dependent and can include cardio-respiratory depression, vasodilation, hypotension, cardiac arrhythmias and hypothermia. Halothane was usually administered in oxygen or a mixture of oxygen and nitrous oxide but it is no longer available in the UK.

Halothane Test

The ability of halothane to detect a single gene affecting stress susceptibility and production traits can be used to identify animals susceptible to PORCINE STRESS SYNDROME.

Pigs of around eight weeks of age are made to breathe the anaesthetic through a face mask for a total of three minutes. If they remain relaxed throughout this period, they are scored as negative, or stress-resistant. If the muscles of the hind leg become rigid during the three minutes, the pigs are scored as positive, or stress susceptible. In this case the halothane must be turned off immediately, or the reaction may reach an irreversible stage which can kill the pig. Positive and negative reactors normally recover fully within five minutes of the test.

Ham

(See GLUTEAL, MUSCLES *and*, for abscesses, INJECTIONS.)

Hamartoma

A tumour-like malformation composed of an abnormal mixture of the normal tissue components of the organ from which the hamartoma arises. Pulmonary hamartomas have been found in animals, with either vascular or cartilaginous tissue predominating. It is a relatively rare congenital defect of the skin and other organs.

Hammondia hammondi

A coccidian parasite, antigenically related to *Toxoplasma gondii*, of cats. The parasite has a two-host life-cycle. Hosts also include rodents and dogs.

Hampshire Down Sheep

Arose in 1829 as a cross of the Southdown breed with the Old Hampshire breed, the Wiltshire Horn and the Berkshire Nott, all horned, white-faced breeds. A short-wooled polled breed of sheep with brown/black face and legs used for meat production. Rams weigh up to 140 kg (305 lb), ewes up to 90 kg (200 lb) with a fleece of 2.9 kg to 4.5 kg (6.25 lb to 10 lb).

Hampshire Pig

A black pig with a white belt, from Kentucky, USA. The origins of the breed were probably 19th-century Old English.

Hamsters

Small rodents popular as domestic pets: the dwarf Russian (*Phodopus sungorus*), the Chinese (*Cricetulus griseus*) and the golden (*Mesocricetus auratus)* hamsters. Hamsters are nocturnal and are therefore very active at night. When they are kept as pets this characteristic may upset their owners. They are capable of escaping from their cages and containers. They store feed, which may lead to inefficiency of oral medication. They have large cheek pouches in which to store food and a fore-stomach which is acidic and contains micro-organisms. Aggression is common, especially in females, who may bite other hamsters or humans.

Common clinical problems include injuries after falls, entanglement in synthetic bedding (natural paper is safest), impacted and/or everted cheek pouches and skin diseases, especially mite infestation (*Demodex creteci* and *D. aurati*). Often owners are concerned about the appearance of normal sebaceous glands on the flanks of males and the testes which are very large and look cancerous. Often the incisor teeth are overgrown, usually after trauma to the jaw following a fall. As hamsters are often kept as pets by children inadvertent negligence can lead to husbandry-related disorders, the most common of which is water deprivation due to a blocked sipper bottle nozzle, especially in areas in which tap water is very hard.

Synthetic-fibre bedding material sold for hamsters has caused severe injury, sometimes necessitating euthanasia.

In the *M. auratus* species, the main health problem is 'wet tail'. The cause is a combination of infection and stress resulting in terminal ILEITIS leading to diarrhoea and consequent staining of the tail – hence the name. This may culminate in prolapses or intussusception.

Hamsters and human health They occasionally carry the virus of cymphocytic choriomeningitis (LCM) which can infect humans.

(See also under LYMPHOCYTIC CHORIOMENINGITIS, and PETS, CHILDREN'S AND EXOTIC.)

Restraint As hamsters are quite liable to bite, restraint is best achieved by cupping the animal between the palms of the hands and rolling it over to expose of the area requiring inspection.

Anaesthesia ISOFLURANE is well tolerated, with rapid recovery.

VetBooks.ir

Hand
A unit of measurement for the height of a horse, as measured at the withers. A hand is 4 inches. Under 1981 UK legislation, metrication was officially introduced, resulting in rounded equivalents, e.g. 12 hands = 122 cm, 10½ hands = 107 cm. (See HORSES, MEASUREMENT OF.)

Hand, Foot and Mouth Disease
A disease of man, first described in 1957, which has to be differentiated from rare human infection with foot-and-mouth disease. The cause is Coxsackie A9 virus (or A5, A10 or A16).

Handling Veterinary Waste
Waste generated through veterinary treatment of animals, whether at a veterinary premises or on a farm, needs to be separated according to the available methods of disposal. The current regulations are Waste (England and Wales) Regulations 2011. The main classes of waste are:

Waste which is cytotoxic, cytostatic, carcinogenic, mutagenic and teratogenic. This category includes anti-cancer drugs, hormone products, including used intravaginal devices. These must be segregated into purple-lidded containers along with any empty vials of the products and any empty syringes, drip bags, etc. which may have been used to administer the products. Needles that are contaminated are disposed of via purple-lidded sharps bins along with syringes attached to them. The material is always incinerated at a suitably licensed plant.

Infectious Clinical Waste This is waste which has been generated by treating infectious animals. It will include such materials as soiled bandages and dressings. Also animal bedding and blood from infectious animals and associated cleaning materials, swabs, gloves, disposable clothing, etc. used in the treatment of infectious animals is also included. These materials are all disposed of in yellow bags and go for high temperature incineration.

Offensive Waste Waste that is not a risk, but can be unpleasant to handle. This includes bodily fluids.

Other Veterinary Waste This includes most waste medicines and cartons that have contained medicines, that are not cytotoxic, etc. Most of these medicinal wastes, when generated on farm, will be classified as needing to be disposed of by incineration.

Sharps These are mainly hypodermic needles, and any used syringes attached to them. It also includes used vials as opposed to bottles.

Hantavirus
A genus containing the Hantaan and related viruses. (See HAEMORRHAGIC FEVER WITH RENAL SYNDROME.)

Hantavirus infection in animals A single feline case in the UK was recorded in 1983 and subsequent antibody surveys on randomly selected cats have indicated an exposure to the virus in the order of 10 to 15 per cent.

The virus can cause chronic illness in cats, especially in those infected also with the feline leukaemia virus or the feline immunodeficiency virus.

Sources of infection Voles and rats.

Human hantavirus infection In many parts of Europe a mild form, *Nephropathia epidemica*, has been recorded; but a severe form appeared in Greece and Bulgaria. There may be internal haemorrhage and kidney disease in some cases.

Sources possibly include exposure to saliva, urine, faeces, and lung secretions; also bites by rodents.

Infections from laboratory rats, and from Hantaan tissue culture, are a recognised hazard.

Farm workers, water sports enthusiasts, sewage farm workers, and laboratory personnel have seropositivity rates of up to 21 per cent.

Signs, appearing two or three weeks after exposure, comprise conjunctivitis, with erythema of face, neck and upper chest. In the severe form, fever, headache, nausea and vomiting are typical; with moderate or severe kidney disease.

It has been suggested that people with suspected LEPTOSPIROSIS should have their blood tested also for *Hantavirus*.

Haploid
Haploid refers to the reduced number of chromosomes in the ovum and sperm – half the (diploid) number in the somatic cells. (See MEIOSIS.)

Hapten
A small molecule that cannot by itself initiate an immune response, but which can do so when linked to a 'carrier', e.g. a protein such as albumin. (See IMMUNE RESPONSE; B CELLS.)

Harderian Gland
The third eyelid or nictitans gland, first described by Johann Jacob Harder (16561711) which, in some animals, secretes serous fluid or mucus, the amount and appearance of which varies between different animal groups. In the dog it secretes around one third of the tear production of the eye

VetBooks.ir

and therefore, if prolapsed, should be surgically reduced rather than removed, as removal can lead to KERATOCONJUNCTIVITIS SICCA (DRY EYE). The same gland is often prolapsed in adult buck rabbits after a period of sexual arousal. (See also NICTITATING MEMBRANE and EYE, DISEASES AND INJURIES OF.)

Hard Palate

(See PALATE.)

'Hardware Disease'

The colloquial American name for traumatic pericarditis of cattle caused by metal objects, such as nails or pieces of baling wire. (See under HEART DISEASES.)

Hare-Lip

This deformity (often called 'split lip') is seen in puppies of the toy breeds, and in sheep. When the cleft in the lip is wide, sucking is impossible and the young puppies often die from starvation. In less severe cases they obtain some nourishment, but never thrive as well as the others in a litter. The malformation is generally associated with CLEFT PALATE. (See LIPS; PHILTRUM.)

Hares

(*Lepus* spp.) may harbour the liver fluke of sheep, *Fasciola hepatica*, and the cystic stage of the tapeworm *Taenia multiceps packi* of the dog, and of *T. pisiformis*. In some countries (e.g. Denmark), hares are a source of *Brucella abortus suis* infection to pigs. Some European hares also harbour *B. melitensis*.

In the UK, orf-like lesions have been seen (and confused with myxomatosis, which can also occur occasionally). Other diseases include aspergillosis, streptococcal endocarditis, toxoplasmosis, and coccidiosis. Louping-ill virus and/or antibody has been found in English hares, and also Q fever antibody. Avian tuberculosis is another occasional finding. European brown hare syndrome (leporine dysautonomia), a disease similar to grass sickness, has been diagnosed in East Anglia. Its cause is not yet known.

In order to prevent the introduction of *B. suis* and also of *Pasteurella tularensis* infections, the Hares (Control of Importation) Order 1965 was enacted in the UK. (See TULARAEMIA.)

Harvest Mites

(See under MITES, PARASITIC.)

Hassall's Corpuscles

(See THYMUS GLAND.)

Havana Cat

A medium-sized oriental breed of cat with a dark brown coat.

Havana Rabbit

A medium-sized self-coloured breed of rabbit. Various colours are seen.

Haverhill Fever

The name given in human medicine to sporadic cases of rat-bite fever resulting from contamination of food. The causal bacteria are *Streptobacillus moniliformis* and *Spirillum minus*. Rats are usually subclinical carriers.

Haw

A colloquial term used for the third eyelid, particularly in breeds such as the St. Bernard, where a prominent haw was considered desirable. Also a number of eye conditions in dogs and cats may be called by this name. They include drooping of the lower eyelid, and protrusion of the third eyelid (See NICTITATING MEMBRANE).

Hawks

In the UK, hawks and falcons are different, but in other anglophone countries the terms overlap. (See FALCONS.)

Hawks, Diseases of

These birds suffer similar conditions to falcons, but BUMBLE-FOOT is more serious. (See FALCONS, DISEASES OF.)

Hay

There are two general classes of hay: that from grasses only; and that containing leguminous plants such as clover and lucerne. (See LEYS, NEW; PASTURE MANAGEMENT.) Hay is a very important, but perhaps a somewhat underrated, article of diet for cattle. (See under DIET AND DIETETICS - FIBRE.) Hay is sometimes put down on very lush pasture where BLOAT is anticipated. As well as assisting in bloat prevention, it will help to obviate hypomagnesaemia and acetonaemia. The feeding of hay together with green fodder crops is also said to reduce the risk of scouring in ruminants, especially when large quantities, of the fodder are being eaten and during wet weather. When kale or rape are being fed in quantity, hay is most necessary in the diet. Hay made from NEW LEYS is less palatable than that made from old pasture.

The composition of the end-product varies depending on the method used to make the hay and the weather. Grass dried on tripods has four to five times the CAROTENE content of that dried on the ground (swathe hay). Swathe hay has a greater vitamin D content than other types. However, damage causes a reduction in the vitamin D and carotene content than would otherwise be expected. Soaking hay for 14.5 hours reduced carbohydrate content.

VetBooks.ir

There would certainly seem to be more scope now for barn hay-drying, though the relatively high costs of this and also of hay-towers are likely to limit wide application of these two methods. The first essential, in any event, is of course high-quality grass to make into hay.

The nutritional quality of hay can vary widely, depending on management and weather. A study showed that, for hay made in England 'Average quality is inadequate for the bare maintenance of an average Friesian cow, which will require 0.9 kg (2 lb) of cereal supplement. At the other extreme hay with a high crude protein content of 20 per cent can produce a daily liveweight gain of 1 kg (2.14 1b) daily in bullocks fed hay only.'

Usually in hay there are many different grass species as the same field contains many species and so the hay is often named after the predominant species present.

TIMOTHY GRASS is a coarse species yielding only one crop per year, but it is a valuable feedstuff for horses and rabbits and is particularly favoured by owners of horses with laminitis.

Mouldy hay can be dangerous. (See ASPERGILLOSIS and 'FARMER'S LUNG'.) Hay which contains sweet clovers, or vernal, and has become overheated or mouldy, may have a dangerously high DICOUMAROL content. Fatal poisoning has also occurred in stock fed hay containing RAGWORTPOISONING or FOXGLOVES.

Hay, soaking Contrary to popular belief, dampening hay does not control mould and fungal spores. However, it reduces the amount of dust produced and thus may help respiratory conditions in horses fed hay. The hay is netted, then soaked for about 15 minutes; longer soaking is of no benefit and may be detrimental to the quality of the hay.

Hay Fever

(See ATOPIC DISEASE.)

Hayflakes

In appearance, hayflakes resemble chopped hay but retain the quality of dried grass. They are not chopped so short that the fibrous quality of grass is destroyed, nor so long that storage space becomes difficult. They can be stored loose in the barn for self- or easy feeding; alternatively they can be baled.

Haylage

Haylage is a registered trade name for material which has been wilted down to 40 to 50 per cent dry matter, precision-chopped to 1.2 cm (½ in) nominal length, and processed through a Harvestore tower silo.

Hazard Analysis and Critical Control Point (HACCP)

A method used to analyse the main areas of danger and thereby provide a preventive approach to food safety and pharmaceutical safety. It identifies the physical, chemical, allergenic and biological hazards during the production which might make the end product unsafe or endanger those producing the product. The aim is to reduce the hazards to a safe level rather than just inspect the finished product. It has been used extensively in all parts of the food industry especially in the area of MEAT-HYGIENE REGULATIONS.

Hazardous Waste

(See HANDLING VETERINARY WASTE.)

HBS

Abbreviation for HAEMORRHAGIC BOWEL SYNDROME. (See JEJUNAL HAEMORRHAGIC SYNDROME in cattle.)

HCC

(See HYBU CIG CYMRU.)

HCH

Hexachlorocyclohexane. (See BHC, which consists of five isomers of HCH.) In Britain HCH-containing sheep dips have been withdrawn from the approved list.

HCT, hct

(See HAEMATOCRIT VALUE.)

Headfly

(See under FLIES.)

Head Injuries

These may result in concussion (See under BRAIN DISEASES) or secondary EPILEPSY in the dog. Lesions may include an intracranial haematoma, a depressed fracture of the skull, scar tissue, etc.

Head Shaking

Seen in some horses. It can be caused by trigeminal nerve neuritis, allergies which may coincide with certain seasons and pollens, volatile plant products and other irritants. Environmental influences may also be involved such as sunlight, cold water, etc. Surgery called caudal compression of the infraorbital nerve, involving placing platinum coils in the infraorbital canal, has resulted in a 50 per cent long-term success rate.

Head-Tilting

This occurs in all species from various causes. The head is held on one side so that the ear on that side is closer to the ground. It indicates damage to the

VetBooks.ir

vestibular system, part of the nervous system concerned with balance. The vestibular system includes parts of the inner ear, the vestibular nerve that travels from the ear to the base of the brain, the medulla oblongata (part of the brain stem) and the cerebellum. It is frequently caused by ear disease. In cats and dogs this sign occasionally occurs in cases of a foreign body present in an ear. (See EAR, DISEASES OF; also FELINE VESTIBULAR SYNDROME, IDIOPATHIC.)

In rabbits it can be a sign of serious cerebral infection (PASTEURELLA or ENCEPHALITOZOON CUNICULI), which can lead to TORTICOLLIS.

Healing of Wounds

(See WOUNDS.)

Health-Related Quality of Life (HRQL)

This is associated with the quality of life following a problem which has resulted in chronic PAIN.

Health Schemes for Farm Animals

Private or officially run programmes by which the veterinary surgeon is closely involved in the health and productivity of livestock. In consultation with the farmer, all aspects of health and nutrition are monitored and medication prescribed on the basis of preventing disease, rather than curing it after an outbreak. Such schemes can lead to increased profitability, especially in the large units which are commonplace today.

Currently on farms in the UK a variety of health schemes are in operation, either private, government, or operated in conjunction with large retailing groups. For example, many large dairy units receive routine weekly or fortnightly visits, when cows are presented to the veterinary surgeon for pregnancy diagnosis and treatment of disease or advice on preventive measures, and testing and certification of freedom from infectious bovine rhinotracheitis (IBR), bovine viral diarrhoea (BVD), *Leptospirosis hardjo* and *Mycobacterium paratuberculosis* (as well as officially NOTIFIABLE DISEASES).

In sheep, testing is possible for enzootic (chlamydial) abortion, maedi/visna, ovine pulmonary adenomatosis. Advice on management and nutrition, worming programmes and disease prevention can be routinely part of any health programme.

Pigs had the first official health scheme. The pig health scheme evolved into Farm Assured British (FAB) pigs, in which private and ministry veterinarians visit farms quarterly to assess the health status and welfare of pigs.

The importance of maintaining good health in their flocks has long been recognised by poultry farmers. Routine visits are the norm and some large producers employ their own veterinarians to produce protocols for maintaining the health of their flocks.

In the USA, Canada and other parts of the world where large-scale farming is practised, many dairy, poultry and pig farmers have produced, with their veterinarians, management and health protocols for their stock. These set out in detail how the animals are to be looked after and treated, and when veterinary assistance has to be sought.

Hearing

(See EAR – The act of hearing; see also ULTRASOUND.)

Heart

This organ is in the THORAX; it is a muscular pump which circulates the blood around the body. It is made up of a special muscle called cardiac muscle and hence the adjective relating to the heart is cardiac. Lack of heart function rapidly results in death. In mammals the heart comprises four compartments, two AURICLES and two VENTRICLES. One of each is on the right and one on the left. Blood enters the auricles and is passed to the ventricles. The right side receives blood from the body after oxygen removal via the anterior and posterior VENAE CAVAE and pumps it to the LUNGS where it is oxygenated. It then goes to the left side of the heart which pumps it around the body via the AORTA. The left side compartments are thicker than the right and there are valves between the auricles and ventricles (bicuspid on the left and tricuspid on the right). (See also CIRCULATION OF BLOOD.)

Heartbeat

(See PULSE.)

Heart Diseases

As in man, heart disease in animals is frequently encountered in companion animal medicine where animals are more commonly allowed to live to old age. Thus they are more likely to acquire heart disease and succumb to heart failure. Congenital heart disease is also relatively common. Many animals with congenital heart lesions may live well into old age without showing any clinical signs, while others may develop heart failure and others show signs at a young age.

Signs Signs of heart disease are many and varied and include heart murmurs, irregularity in the heart rhythm (DYSRHYTHMIA or ARRHYTHMIA), and/or an abnormal heart rate (BRADYCARDIA or TACHYCARDIA) which may be detected by stethoscopy, electrocardiography or simply palpating the pulse. In heart failure, visible signs include

VetBooks.ir

pallor and/or discoloration of the mucous membranes (CYANOSIS), increased respiratory effort, coughing, poor exercise tolerance, abdominal distension and SYNCOPE.

Congestive heart failure This refers to the situation when the heart is no longer acting as an effective pump. Blood normally propelled around the body from the left of the heart backs up into the pulmonary circulation and lungs and eventually fluid accumulates into the air-filled lung causing pulmonary oedema ('fluid in the lungs'). This is known as left-sided heart failure and is associated with breathing difficulties and coughing. The right side of the heart receives blood from the large veins of the body before pumping it into the lung circulation. Right-sided heart failure leads to blood backing up into the large veins. The resultant venous congestion can result in fluid in the body cavities, causing ASCITES, or under the skin leading to swelling of one or more limbs. Engorgement of the veins often occurs, with enlargement of the liver. In companion animals, treatment usually consists of reducing exercise and giving DIURETICS and other drugs to support cardiac function, such as PIMOBENDAN.

A common cause of heart failure in dogs is degeneration of a MITRAL VALVE.

Pericarditis is an inflammation of the membrane covering the exterior of the heart. It may be 'idiopathic', when its cause is not known; it may be 'traumatic', when it is due to a wound; or it may follow a general infection (e.g. 'heartwater') or a local infection (e.g. pleurisy) or an abscess in a remote part of the body. Pericarditis may be 'dry', in which case the two opposing surfaces of the membrane are covered by a layer of fibrin; or oedema may accompany this condition, in which case fluid fills up the PERICARDIAL sac and, when no more distension of the sac can occur, presses upon the outside of the heart itself.

Pericarditis has been reported in very young pigs at grass. The piglet, often in good condition and not anaemic, dies suddenly at about two to three weeks of age. (See also 'MULBERRY HEART'.)

Cardiac Tamponade describes the situation where the pressure in the PERICARDIAL sac rises and exceeds that in the right side of the heart. The result is failure of the right side of the heart and right-sided congestive heart failure. (See CONGESTIVE HEART FAILURE.)

The commonest cause is PERICARDIAL effusion (fluid accumulation within the PERICARDIAL sac), but less commonly inflammation can produce minimal fluid and the sac itself constricts the heart (restrictive pericarditis).

Tamponade can be managed by drainage of the fluid, but if the effusion is recurrent or if there is restrictive pericarditis the PERICARDIAL sac can be removed surgically (PERICARDIECTOMY).

Congenital heart disease in dogs and cats is usually indicated by a cardiac murmur, the site and nature of which can provide clues as to the cause, such as an abnormal heart valve, narrowing of outflow routes from the heart (STENOSIS), abnormal connections between heart chambers ('hole in the heart') and anomalous connections between vessels ('shunting'). Defects may be simple (a single defect) or combined or complex, e.g. TETRALOGY OF FALLOT shows whether a valve or a SHUNT is involved.

(See also HEARTWORM.)

Deficiency of vitamin E is one cause of sudden cardiac arrest in cattle.

Signs These are not always characteristic, but they include breathlessness, pain on pressure of the left side of the chest, a jugular pulse (seen along the jugular furrow with each heartbeat) and oedema. On listening to the heart a variation in the normal sounds may be heard, or they may be altogether masked by the presence of the fluid. A tinkle is sometimes audible over the region of the heart; friction sounds indicate the presence of dry pericarditis; and irregularity or even palpitation may be noticed.

Traumatic pericarditis of cattle Sometimes when the animal is thought to be suffering from simple digestive disturbance, it is found that a nail or piece of wire has been swallowed and arrives in the reticulum.

A distance of about only 5 cm separates the heart from the reticulum, so that sharp metal objects can easily penetrate the PERICARDIUM.

Attacks of pain may occur and the appetite is irregular, but after a time the animal regains its normal health, since an adhesion has occurred around the hole in the reticulum wall, and the inflammation subsides. A cow may die suddenly before signs of pericarditis appear, or soon afterwards.

Treatment is sometimes feasible by surgically opening the rumen and removing the piece of metal.

Prevention In Switzerland the percentage of cows slaughtered on account of traumatic pericarditis was reduced following the use of magnets for the treatment of traumatic reticulitis. Magnets weighing 114 g (nearly 4 oz) and measuring 90 mm (3.5 in) long and 15 mm (0.6

VetBooks.ir

in) in diameter were used orally 10 minutes after a subcutaneous injection of atropine sulphate. Without this it was found that only 53 per cent of the magnets dropped at once into the reticulum. The correct siting of the magnets was checked with a compass.

Myocarditis is inflammation of the heart muscle. In the pig it is seen in HERZTOD DISEASE, for example; in cattle it is seen in MUSCULAR DYSTROPHY and can be encountered in rabbits with ENCEPHALITOZOONOSIS. In the dog, epidemics of myocarditis have been seen in puppies 5 to 16 weeks old in Britain, Australia and the USA. Spaniels, boxer crosses, Alsatians, Scottish terriers and poodles are breeds in which sudden death has occurred – puppies dropping dead a moment after eating or playing, no premonitory signs having been noticed (See also CANINE PARVOVIRUS; MYOCARDIUM.)

Endocarditis is inflammation of the membrane lining the heart. It frequently leads to the development of nodules on the valves.

The nodules result in an incomplete closing of the valves, and since the fibrin deposited upon them tends to become converted into fibrous tissue ('organised'), these vegetative growths slowly increase in size and are common in pigs. (See SWINE ERYSIPELAS.)

The valvular insufficiency can be diagnosed by auscultation. Congestive heart failure may be the outcome (sometimes embolism); but compensation takes place, and the animal may live a long time with faulty valves.

Bacterial endocarditis is a cause of death in cattle, especially in South Wales. (See HEARTWORM for another cause of endocarditis in the dog.)

Valvular diseases form a most important and common group of heart disorders, and although many animals can compensate for narrow or leaking valves, others will progress to show signs of heart failure over a period of time. Although animals may have congenital defects, vulvular disease is more commonly acquired. Infections can damage valves e.g. bacterial endocarditis. In dogs the most common cause of valvular disease is MYXOMATOUS VALVULAR DISEASE, where the valves thicken and elongate. (See also CHRONIC DEGENERATIVE VALVULAR HEART DISEASE.)

Hypertrophy, or enlargement of the heart, has two forms, with very different causes. In one form the heart muscle (wall) thickens. In trained athletic animals such as racehorses, hunters, and sporting dogs this cardiac hypertrophy is normal. However, this thickening can arise when the pumping chambers or ventricles are forced to work harder by pumping against a raised pressure (sustained high blood pressure) or against a narrowed outlet flow of blood flow such as a STENOTIC valve. Thickening can also be a consequence of defects within the heart muscle, a common scenario in cats (hypertrophic CARDIOMYOPATHY). In this second form of hypertrophy, the ventricles are dilated and enlarged, but wall thickness is not greatly increased. This occurs when the heart starts to fail and tries to compensate for this failure and also in diseases of the heart muscle itself (dilated CARDIOMYOPATHY)

Congenital defects These include a patent *ductus arteriosus*. (See diagram of fetal circulation under CIRCULATION OF BLOOD; also LIGAMENTUM ARTERIOSUM; ECTOPIA CORDIS.) Tetralogy of Fallot consists of: (1) stenosis of the pulmonary valve; (2) a defect in the septum which separates the two ventricles; (3) the aorta overriding both ventricles; (4) marked hypertrophy of the right ventricle.

The signs are often vague: in kittens, for example, these may be a failure to thrive, and inability to cope with exercise. More serious defects result in the death of newborn kittens.

Functional disorders Palpitation is a condition in which the heart beats fast and strongly due, for example, to fright. (See TACHYCARDIA.)

BRADYCARDIA is a condition of unusually slow action of the heart. Intermittency or irregularity is an exceedingly common condition among animals, and as a rule appears to cause them no inconvenience whatever. In some horses at rest in the stable the heart constantly misses every third, fourth or fifth beat, a long pause taking the place of the pulsation, but when at exercise or work the normal rhythm is restored.

Heart-block is a condition in which the conducting mechanism between atrium and ventricle (atrio-ventricular bundle of His) is damaged in whole or part, so that the two beat independently of each other.

Rapid heart action (TACHYCARDIA) may have a number of causes including exertion or excitement. It is normally harmless in such cases. It is also seen in diseases which affect the transmission of the heartbeat stimulus.

Cardiac flutter and fibrillation are conditions of great irregularity in the pulse, due to the atria emptying themselves, not by a series of regular waves, but by an irregular series of flutters or twitches instead, which fail to stimulate the ventricles properly.

Five cases of atrial fibrillation were described in horses after racing. In four of them, which had performed poorly during their races, the arrhyth-

VetBooks.ir

mias disappeared spontaneously within 24 hours; these cases were regarded as paroxysmal. In the fifth horse, which won its race, the arrhythmia persisted for at least 45 hours after the race and it was regarded as an example of persistent atrial fibrillation. Treatment with quinidine sulphate restored the sinus rhythm. Paroxysmal atrial fibrillation may cause a sudden decrease in racing performance.

Diagnosis of heart disease is based largely on the character of the pulse and heart sounds. Murmurs, for example, indicate valvular incompetence, cardiac dilatation, or congenital lesions. Muffled sounds may indicate fluid in the PERICARDIUM (or PLEURISY).

Additionally, radiography and cardiography are used in diagnosis. (See PACEMAKERS as a possible treatment of some canine patients.)

Heart Stimulants

The concept of 'heart stimulants' is no longer used but referred to the use of drugs such as theophylline, adrenaline, isoprenaline and dobutamine.

Heartwater

Heartwater, also known as BUSH SICKNESS (Boschziekte), VELD SICKNESS, and INAPUNGA, is a specific disease of cattle, sheep, and goats transmitted by the bont-tick (*Amblyomma hebraeum*) in South Africa, and *A. variegatum* in Kenya. The disease is characterised by the accumulation of a large amount of fluid in the PERICARDIAL sac and nervous signs.

In 1980 the existence of heartwater in many islands of the Caribbean was discovered; previously the disease had been known only in Africa. The tick involved is *A. variegatum*, introduced into Guadeloupe with cattle from Senegal.

Cause Infection of the nymphal or larval stages of the bont-tick with *Rickettsia ruminantium* (*Cowdria ruminantium*) which is transmitted to other animals upon which the tick feeds at a later state of its life-history.

Incubation After sheep and goats have been bitten by infected ticks, a period of between 11 and 18 days elapses before any signs are shown; in cattle the disease appears between 20 and 25 days after infestation with ticks. These periods are influenced by the stage of the disease in the animal supplying the infected blood to the ticks, and also by individual susceptibility, which is less in native-bred cattle than in those imported from other countries, and especially those brought from Britain.

Signs

Sheep and goats Sheep and goats at first show nothing more than a rise in temperature (which gradually increases to 41.7° C (107° F), falling each evening a few degrees lower), a general dullness, prostration, and lack of appetite. As these conditions are common to many other diseases, the difficulty of diagnosis is great. The affected animals isolate themselves from the rest of the flock, lie about in secluded spots, cease to ruminate and, when handled or driven, are very easily tired and lie down.

Many animals show peculiar nervous signs, which vary in different individuals; some may bleat almost continuously; others champ the jaws as if feeding, moving the tongue backward and forward between the lips; others lick the ground; some turn in circles until they finally fall to the ground and lie prostrate or perform galloping movements with their limbs; while others show profuse salivation. Convulsions are not uncommon, especially when the animals are handled. Death usually follows soon after convulsions make their appearance.

Cattle The signs in cattle are very similar to those seen in sheep. The nervous form in which peculiar masticatory movements are made by the mouth is common. Animals show a tendency to bite at their feet or legs, especially when lying on the ground, and biting the ground is also seen. A number of animals in the early stages may show a dangerous tendency to charge any human being approaching them. In cattle the disease is usually at its height about the fourth day after the first rise in temperature, and death usually occurs about the sixth day. Hyperacute cases occur in cattle, and the animal is found dead on the veld.

Autopsy Fluid in the PERICARDIAL sac surrounding the heart (hence the name 'heartwater'); but while this is usually found in sheep and goats, it may be absent in the case of cattle. In typical instances there is also a collection of similar fluid in the thoracic and abdominal cavities. Both the PERICARDIUM and the ENDOCARDIUM which lines the heart may show several small or a few large 'petechiae', i.e. areas where a slight amount of haemorrhage has taken place.

Prevention Entirely successful results have followed measures taken against the ticks which transmit the disease. These consist in '5-day dippings'.

Antibiotics and sulfonamides are used in treatment.

Heartworm, Dirofilariasis

Dirofilaria immitis is a common parasite of dogs in Central Europe, Russia, Australia, America and

VetBooks.ir

Asia. It has been moving steadily northwards and has been increasingly seen in the UK in dogs returning from travel in mainland Europe via the PET TRAVEL SCHEME. Foxes are reservoir hosts. The worm larvae are transmitted by various mosquitoes that carry infective larval stages known as microfilariae, and they also are present in the bloodstream of infected animals. The adult worms reach a length of up to 30.5 cm (12 in) (females) and inhabit the pulmonary arteries in the lungs. If the worm burden is high they extend to the right side of the heart and even into the vena cava. Within the pulmonary vessels the worms induce blood clot formation and thickening of the vessel walls increasing the resistance to blood flow and leading to raised blood pressure (pulmonary hypertension). Large numbers of worms in the heart can obstruct blood flow, induce liver congestion and damage, and cause a massive immune response. The worms can also damage the kidneys.

Diagnosis Microfilariae may be seen in blood smears, but the standard screening tests used are immunoassays, often ELISAs that detect a protein found in the female worm. Radiography has also been recommended as a diagnostic aid and ultrasound scans of the heart can be useful.

Treatment and control Heartworm can be treated with drugs targeted at the adult and immature worms, but it is not without risks. Prevention, using drugs that prevent development of the immature stages, is strongly recommended in heartworm endemic areas and in dogs travelling to such areas.

Typical signs of Heartworm infection exercise intolerance, cough, HAEMOPTYSIS, weight loss and signs of right-sided congestive heart failure.

The presence of worms in atypical sites such as the brain and eyes can cause other signs and the THROMBUS formation in the pulmonary arteries can cause generalised bleeding tendencies.

Heartworm in cats can cause sudden death, SYNCOPE, severe breathing difficulties, vomiting and a cough.

Angiostrongylus vasorum sometimes known as the French heartworm, is another worm found in the UK and elsewhere that inhabits the pulmonary artery and the right ventricle of the heart. Signs associated with it include coughing and breathing difficulties as well as excessive bleeding. Slugs and snails may act as the intermediate hosts.

Heat

A female animal is said to be on heat when she is sexually receptive to a male (See OESTRUS; for the suppression of 'heat' in the bitch, see OESTRUS, SUPPRESSION OF.)

Heat Detection in Cows

(See under OESTRUS, DETECTION OF, IN COWS.)

Heat Exhaustion

A syndrome in which the body's core temperature is grossly elevated and in which there is a depletion of electrolytes and water in the body. (See HEAT-STROKE.)

Heather Blindness

Infectious ovine keratoconjunctivitis or contagious ophthalmia in sheep. (See EYE, DISEASES AND INJURIES OF - BLINDNESS - CATTLE AND SHEEP; EYE, DISEASES AND INJURIES OF - OVINE INFECTIOUS KERATOCONJUNCTIVITIS.)

Heat Loss

Heat loss from the body occurs by radiation, and by conduction from the skin, by convection in evaporated sweat from the skin and moisture from the lungs. The normal body temperature is maintained and controlled partly by alteration of the rate of metabolism, and partly by constriction of the surface blood vessels when the animal is exposed to cold, as well as by shivering which generates heat. There comes a point, however, as body temperature falls still further, at which shivering ceases. Then the danger of hypothermia may not be recognised. (See BEDDING - PIGS for pigs; also HYPOTHERMIA.)

Sensible loss of heat This is the heat which animals lose under normal conditions of consciousness by convection, conduction, and radiation. It does not include heat lost by vaporising water from the skin and respiratory passages.

Heat Stress

This occurs when hot blood is directed away from the intestines to the skin to aid heat loss. This can lead to reduced oxygen levels at the intestinal wall, allowing ENDOTOXIN absorption. In poultry the effect can be reduced by adding extra arginine, threonine and tryptophan to the diet, as well as adding betaine.

Heat-Stroke

Heat-stroke is a condition associated with excessively hot weather, and especially under conditions of stress. It occurs in farm animals when taken to tropical countries from temperate countries, especially when recently unloaded from transport ships and subjected to great excitement in unfamiliar surroundings; it is seen in cattle, sheep and swine travelling by road or rail, and it frequently occurs at agricultural shows. Dogs may be affected when they have been left in a car

VetBooks.ir

parked in the sun, and with windows closed or almost closed. Affected animals fail to lower their body temperatures. (See CAR, PARKED IN THE SUN; also HYPERTHERMIA; TROPICS, LIVESTOCK PRODUCTION IN THE.)

Signs The animal is usually suddenly overcome by a great lethargy and inability to work or move. The gait is staggering, and if the animal is made to move it falls to the ground. Convulsions may occur, the temperature is very high, perhaps as much as 42.2° C (108° F) in the horse. Death often takes place in a few hours, but some cases last as long as three days. If recovery occurs, great dullness for a number of weeks is liable to follow.

Treatment Removal to a cool place; douching the head and neck with cold water from a hosepipe. Immersion in water containing ice cubes may be used to cool smaller animals.

An animal may die as a result of combined heat-stroke and heat exhaustion, or either separately. (See also HEAT EXHAUSTION.)

Heaves

Former common name for RECURRENT AIRWAY OBSTRUCTION in horses, it was previously called CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) and 'BROKEN WIND'.

Heavy Horses

These are also called draught horses in Britain, draft horses in America; historically, dray horses. They are large horses, used to haul loads, carts, carriages, etc. as well as for ploughing. They are often used to cross breed especially with light riding horses such as THOROUGHBREDS to produce sports horses. Many are used for showing, demonstrations, etc. and for driving. Breeds of heavy horse include the CLYDESDALE, PERCHERON, SHIRE HORSE and SUFFOLK PUNCH.

Heavy Metal Poisoning

Poisoning with heavy metals, especially zinc and lead. (See CADMIUM (Cd); CHROMIUM; LEAD POISONING; 'NEW WIRE DISEASE'; ZINC POISONING.)

Hebdomadis Serogroup

(See LEPTOSPIROSIS.)

Hedgehogs

Hedgehogs (*Erinaceus europaeus*) are of veterinary interest in that they are susceptible to natural infection with foot-and-mouth disease, which they transmit to other animals.

Hedgehogs, like horses, are the natural hosts for *Leptospira bratislava*, anecdotally assumed to infect dogs.

Probably the most common cause of death in wild adult hedgehogs in the UK is road traffic accidents, but badgers are a predator. Other zoonoses in hedgehogs include SALMONELLOSIS, RINGWORM, (*Trichophyton erinacei*) and YERSINIOSIS. They are hosts to lungworms (*Crenosoma striatum*), flukes (*Brachylaemus erinacei*), tapeworms (*Rodentolepsis erinacei*), ticks, fleas, and mange mites (*Caparinia tripilis*) were other parasites found. Deaths have been recorded after hedgehogs ingested slug bait (See METALDEHYDE POISONING). Oral CANDIDIASIS has been found in hoglets with severe mouth lesions.

A safe, simple method of dealing with 'rolled-up' hedgehogs is to catch them by their hind legs and uncurl them; or injection with ketamine is a common approach.

Anaesthesia Fentanyl citrate + fluanisone (Hypnorm; VetaPharma), KETAMINE, medetomidine and DIAZEPAM by subcutaneous or intramuscular injection is suitable separately or in various combinations for anaesthetising hedgehogs. ISOFLURANE can administered by inhalation both for induction and maintenance.

Heifer

A year-old female up to her first calving.

Heinz Bodies

Heinz bodies in red cells are seen in cases of haemolytic anaemia caused by e.g. an excess of kale in dairy cattle. Heinz-body anaemia has also been seen in cats as a result of poisoning by methylene blue (formerly used in America as a urinary antiseptic) and those poisoned by paracetamol. This form of anaemia has been linked with onions, and a case was reported in a puppy which preferred raw onions and other vegetables to conventional dog foods. After a change of diet the puppy became well, and no longer tended to collapse after exercise. Heinz bodies are present in cats.

Helicobacter Gastritis

This results in stomach ulcers in dogs, pigs and ferrets as well as humans. The organism may be found in the stomach but numbers are higher in illness and often stress-induced. There may be vomiting, loss of condition and abdominal pain and, in some cases, melaena (dark faeces) and anaemia. Antibiotics and bismuth subsalicylate can be used to treat the infection.

Hellebores

There are four hellebores toxic to animals. *Black hellebore* is the dried rhizome and rootlets of the Christmas rose, or bear's-foot, *Helleborus niger*. It may be eaten by livestock when garden trimmings

VetBooks.ir

are thrown out on to fields to which livestock have access. It contains two very irritant glycosides – *helleborin* and *helleborein*. *Stinking hellebore* (*H. fetidus*) and *green hellebore* (*H. viridis* or *Veratrum viride*) are sometimes the cause of livestock poisoning. The latter, along with *white hellebore* (*V. album*), contain several alkaloids. They are depressants of the motor nervous centres.

Poisoning by hellebores occurs in cattle and sheep in which clinical signs can include stupor, convulsions and death when large amounts have been taken, and purgation, salivation, excessive urination, attempts to vomit, great straining and the evacuation of a frothy mucus when smaller amounts have been eaten. Cows give milk which has a bitter taste and which is liable to induce diarrhoea or purgation in animals and people drinking it. Rumenotomy in cattle and sheep may be indicated, in order to remove parts of the swallowed plant.

'Western false hellebore' (*Veratrum californicum*) is teratogenic, due to the presence of cyclopamine in its roots and leaves. It causes the deformity known as 'monkey face lamb disease', which can be avoided by preventing pregnant ewes from foraging on the plant. The foetus is also at risk on days 19 to 21 from early embryonic death, and between days 28 and 33 when stenosis of the trachea may result, together with shortening of metacarpal and metatarsal bones. Sheep should be prevented from feeding on the plant until 33 days after the rams have been removed from the flock.

In Idaho, USA, ewes eating 'Western false hellebore' gave birth to lambs with harelip and hydrocephalus.

Helminths

(See ROUNDWORMS; TAPEWORMS; FLUKES AND FLUKE DISEASE.)

Hemangiothelioma

American spelling of HEMANGIOTHELIOMA (See HAEMOSARCOMA.)

Hematuria

American spelling of HAEMATURIA.

Heme

American spelling of HAEM.

Hemeralopia

Defective vision in bright light caused by degeneration of the retina; it is often called 'Day Blindness'. Hemeralopia is stated to be due to an autosomal recessive gene. This eye disease is common in the Alaskan malamute dog, and has been reported also in miniature poodles. The blindness occurs during bright light, although the animal can see in dim light. (See EYE, DISEASES AND INJURIES OF).

Hemicrania

Incomplete ANENCEPHALY.

Hemimelia

Congenital absence of some or all of the distal part of a limb.

Hemipenis
(plural, Hemipenes)

The paired sexual organ of snakes, lizards and crocodiles. Normally within the cloaca, it becomes erect and extended during copulation and is often subject to prolapse in snakes and lizards in captivity.

Hemiplegia

Hemiplegia means paralysis limited to one side of the body only. (See under GUTTURAL POUCH DISEASE for facial and laryngeal hemiplegia in horses.)

In the cat (and dog), one-sided paralysis may be the result of cerebral thrombosis, haemorrhage, or embolism – plugging of an artery in the brain. The affected cat may fall over (always to the same side), or move in a circle. A tilting of the head and nystagmus (a jerky involuntary movement of the eyeball) have also been recorded. The condition is rare.

Hemivertebrae

Hemivertebrae ('wedge-shaped' vertebrae) are inherited in some breeds of dog and also occur in calves. The mechanism of inheritance is not yet known. (See SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Hemlock Poisoning

As a rule animals will not eat hemlock on account of the mousy odour and disagreeable taste, but in the spring, when green herbage is scarce and when the fresh shoots of the plant are plentiful, young cattle are sometimes affected.

The toxic principles of hemlock are a group of volatile alkaloids, the most important being coniine. Others include N-methyloconiine, coniceine, and conhydrine. They are present in the flowers, fruits, and leaves.

Hay containing hemlock is not likely to cause poisoning, owing to the volatility of the alkaloids.

Signs Initial stimulation and then depression of the central nervous system. Dilation of the pupils, weakness and a staggering gait are seen first; later breathing becomes slow and laboured. Before death the animal may be paralysed and unable to

Hemlock (*Conium maculatum*). The flowers are creamy white, and the stem is distinguished by purplish spots. Height: 1.3 to 2 m (4 to 6 ft).

rise from the ground, though consciousness usually remains.

The mousy odour, detectable in the breath and urine of poisoned animals, assists diagnosis.

Hemlock poisoning in the pregnant cow can result in deformity in the calf, and the same cause was suspected in piglet deformities where the sow had access to rough grazing.

First-aid (See ALKALOIDS.)

Hemoglobin
American spelling of HAEMOGLOBIN.

Hemophilia
American spelling of HAEMOPHILIA.

Hemorrhage
American spelling of HAEMORRHAGE.

Hemosarcoma
American spelling of HAEMOSARCOMA.

Hemprotein, Hemoprotein
American spelling of HAEMPROTEIN.

Hendra Virus (HeV)
First reported in 1994 in Brisbane, Australia. Found in pteropid flying bats (flying foxes) and has been transmitted to horses and humans. Transmission is suspected to occur from consumption of pasture or feed contaminated with bat urine, food spillage or reproductive fluids. In man, infection is probably from direct contact with secretions and body fluids of horses, and it can cause respiratory and neurological signs and often death. It has been reported in 2012 in Yosemite, USA possibly from dust containing dried mice droppings. In Australia, a vaccine is being used in horses, apparently successfully against it.

Henle, Loop of
The U-shaped loop connecting the ascending and descending tubules in the kidneys.

Henneguya
A group of parasites found in the skin and muscles of fish, notably sea trout and salmon. The parasites are seen as tadpole-shaped cysts containing two 'eye-spots'. They cause 'milky flesh disease'. This is seen in fish, apparently healthy, which on being cut into are found to have areas of muscle replaced by a milky fluid.

Hen Yards
(See under POULTRY AND POULTRY KEEPING.)

Heparin
A naturally occurring anticoagulant.

Hepatic
Pertaining to, or relating to, the liver.

Hepatic Cutaneous Disease
(See HEPATOCUTANEOUS SYNDROME.)

Hepatic Encephalopathy
A disease of the brain caused by cirrhosis of the liver; or it may result from a congenital portosystemic shunt. It is usually seen in dogs and cats but can occur in other animals. It occurs when the normal blood supply from the bowel to the liver is disrupted, and substances absorbed from the bowel can enter the general circulation. This can result in neurological signs such as depression, circling, apparent blindness and even coma. The signs can be lessened by reducing protein in the animal's diet, administering antibiotics and the laxative, lactulose. In the case of PORTOSYSTEMIC SHUNTS surgery may be indicated to correct the abnormal blood flow. (See PORTAL VEIN.)

Hepatisation
Hepatisation means the solidified state of the lung that is seen in pneumonia, which gives it the appearance and consistence of the liver.

Hepatitis
Inflammation of the LIVER.

Hepatitis in the horse occurs after infectious equine encephalomyelitis, especially where vaccines or sera have been used. In cattle and sheep, it can occur after liver fluke, ragwort poisoning and aflatoxicosis.

For hepatitis in dogs, see CANINE VIRAL HEPATITIS. See also under DUCK VIRUS HEPATITIS.

Hepatitis Contagiosa Canis
(See RUBARTH'S DISEASE.)

Hepatocutaneous Syndrome, Necrotic Migratory Erythema
A severe, uncommon skin condition usually in older dogs and cats associated with internal disorders (hepatopathy and/or pancreatitis) usually with serious gastroenteritis and manifested by sudden painful skin erosions, ulcerations and exudate on the pad and lips of dogs; it is more widespread in cats. Prognosis is guarded; corticosteroids can alleviate but the underlying cause needs to be addressed. It has been reported in the rhinoceros in zoological collections. (See LIVER, DISEASES OF; PANCREAS, DISEASES OF.)

Hepatocyte
A liver cell. (See LIVER.)

Hepatozoon, Hepatozoonosis
A single-celled parasite transmitted by the tick *Rhipicephalus sanguineus*. *Heptazoon canis* infects both dogs and cats, often causing anaemia, fever, and occasionally paraplegia. Other species infect rodents.

Heptachlor
A constituent of chlordane, a chlorinated hydrocarbon, and used also as an insecticide on its own. It is not used on animals but they may be exposed to the substance in the environment. It is stored in the body fat, and in the tissues is converted into heptachlorepoxide, four times as toxic to birds as heptachlor itself.

Heracleum Mantegazzianum
(See GIANT HOGWEED.)

Herbalism, Herbal Medicine, Herbal Therapy
The study and use of plants in the treatment of animals and man. Many plants contain within them substances to deter their predation or eating by HERBIVOROUS or OMNIVOROUS animals, man, fungi, insects and are known as PHYTOCHEMICALS. Some of these substances can result in POISONING but many have medicinal properties. They were used in the past and today in many Asian and African countries. There is a whole industry looking for chemicals in plants that can be adapted for human and animal use. Many CONVENTIONAL MEDICINES were originally produced from plants including ASPIRIN, DIGITALIS, QUININE, etc. However usually in modern times, it means the use of preparations and products from plants that have not been through the procedures of the MEDICINES ACT 1968 or VETERINARY MEDICINES REGULATIONS. Many herbal products are sold as supplements or nutritional additives and are not able to make specific medicinal claims, although often they are implied. The preparation's content may not be well standardised.

Herbicides
(See PARAQUAT; DIQUAT; MONOCHLOROACETATE POISONING; WEEDKILLERS; POISONING.)

Herbivorous (noun, Herbivore)
Plant-eating. The term is applied to animals that eat plants or products derived from plants.

Herding Dogs
The term is particularly used in Australia and New Zealand; they are used for stock handling.

Herdsmen
Occupational hazards of those looking after cattle include BRUCELLOSIS; Q FEVER; TUBERCULOSIS; COWPOX; MILKER'S NODULE; SALMONELLOSIS; SPOROTRICHOSIS; BUBONIC PLAGUE (not in the UK).

Herdwick
A hardy breed of hill sheep originating in Scandinavia. They have a grey face with white ears, the body is covered by grey coarse wool and the rams have cream horns. It is used for meat, and its fleece is used for carpet making. Relatively rare, it is found particularly in the Lake District in England.

Hereditary Nephritis
A condition is seen in SAMOYEDS (DNA test available). Signs normally occur at two to three months with, in males, a severe loss of weight and nephritic signs and death by about a year. In females the signs are less severe, with some loss of weight and proteinuria but there is no kidney failure. It is an inherited X-linked problem.

Heredity
The transfer of genetic traits from parent to offspring (See GENETICS, HEREDITY AND BREEDING.)

Hereford Cattle
The breed has a white face and red-brown coat, with white along the back and on the tail. It was a major breed used for crossing with dairy breeds to produce white-faced cattle which could be reared successfully for beef. They are able to fatten with

VetBooks.ir

little or no concentrates. The breed is susceptible to 'cancer eye' (squamous cell carcinoma).

In 2009 the Hereford cow was the first bovine to have its GENOME completely sequenced.

Hereford Disease

The name used locally for HYPOMAGNESAEMIA in cattle.

Hermaphrodite, Hermaphroditism

An animal in which reproductive tissue of both sexes is present. A lateral hermaphrodite has an ovary on one side, and a testicle on the other; whereas a bilateral hermaphrodite has an ovary and testicle (or a combined ovary-testis) on each side. (See also INTERSEX.)

Hernia

The protrusion of all or part of an organ through the membrane or surrounding tissue which contain it. In a typical abdominal hernia there are always the following parts: a 'ring', or opening in the muscular wall of the abdomen, which may have been brought about as the result of an accident or may have been present at birth; and a swelling appearing below the skin, composed of the 'hernial sac' and its contents.

The contents vary according to the situation, size, and nature of the hernia, but the following organs or parts of them are most commonly herniated: a loop of bowel with its attached mesentery OMENTUM, either the whole or a part (very common in dogs); the stomach; the urinary bladder; the spleen or liver (through the diaphragm); the uterus, either when non-pregnant or with its contained fetus or fetuses; and sometimes a kidney in the cat.

(For strangulated hernia, see under 'Signs', below.)

Umbilical hernia The opening in the abdominal wall is a natural one which should have closed at birth. If given time, it may still do so. In the puppy, for example, only a persistent or irreducible umbilical hernia will need surgical intervention owing to the risk of a piece of omentum having its blood circulation interfered with, or bowel becoming obstructed or strangulated – both serious conditions requiring immediate surgery.

Inguinal hernia, which is practically the same as SCROTAL hernia, but at a less advanced stage, is almost wholly confined to the male sex in all animals, except the bitch, where a horn of the uterus may, rarely, come down through the inguinal canal. Inguinal and scrotal forms of hernia may be either congenital or acquired; congenital forms (most common in young animals) result through some failure of the inguinal canal, through which the testicle descends, to close properly; while acquired forms (commoner in adults) result from such accidents as slipping sideways with the hind-feet, injuries to the abdomen from falls, blows and kicks.

Femoral hernia is very rare, but sometimes occurs in performing dogs which have been trained to walk upon their hind-legs for considerable periods of time. Usually there is prolapse of intestines into the femoral canal which takes blood vessels and nerves to the thigh. The vertical position of the body imposes an unusual strain upon the muscles at the fold of the thigh, and they give way. It is always an acquired condition.

Perineal hernia occurs lateral to the anus and can be unilateral or bilateral. It is almost exclusively confined to the dog. It may occur in either sex, usually as the result of much straining occasioned by constipation or diarrhoea, chronic coughing or asthma, bronchitis, etc., and in old male dogs suffering from enlarged prostate glands.

Ventral hernia is almost invariably the result of a serious injury to the muscular portion of the abdominal wall. It is commonest in mares, especially those used for breeding purposes. Very often there is little or nothing to be noticed if the mare is injured when non-pregnant, but when pregnancy follows and the tension upon the abdominal wall increases, the muscular part gives way and a large mass appears along the lower line of the abdomen. In cows it very often results from horn-gores from neighbours; in such, the skin remains intact but the muscle is torn and a swelling appears at the seat of the injury. Hernia due to a gore is probably commonest in the region of the flank, where the muscle is naturally thin.

Mesenteric hernia is rare in cattle ('probably because of the thickness of the mesentery') but not in horses. In a case involving a cow, intestine was herniated through a tear or defect in the mesentery, resulting in incarceration. A laparotomy was performed, and the defect enlarged to permit extrication of the intestine. The cow recovered.

Diaphragmatic hernia may occur in any animal, but is commonest in the dog and the cat. It usually results from road accidents.

The rent may be in the muscular or tendinous portion of the diaphragm, but it very frequently involves one or other of the natural openings (*hiati*), giving passage to the oesophagus, the vena cava, or the aorta, (although a hernia through an enlarged aortic hiatus is very rare on account of the powerful nature of the diaphragm in its upper parts).

VetBooks.ir

Signs The signs of hernia vary greatly, depending upon the site of the hernias, the particular organ which is herniated, the size of the opening, which may or may not compress the hernia and dictates whether it is reducible or not, and upon the condition of the herniated organ. In very many cases a hernia contains either omentum or a loop of bowel, or both. The swelling may be present at birth, or it may appear suddenly or gradually at almost any time during life. To the touch it may present one of several sensations: (1) in the simple form it feels soft, fluctuating (as if it contained fluid), painless, neither hot nor cold, and causes no discomfort to the animal when being handled. If pressed upon, it can usually be returned to the abdominal cavity, though it will reappear as soon as the pressure is released. This is referred to as 'reducible'. In a small animal the hernia may disappear when it is laid on its back, and remain out of sight until it stands up; (2) when the structures are adherent to the skin which covers them, return to the abdomen is impossible, no reduction can be achieved by manipulation, no definite ring can be determined as a rule, and there is no increase in size with exertion, but otherwise an adherent or 'irreducible' hernia presents the same appearances as a simple one; (3) in the strangulated form the ring is tightened around the herniated organ. This may supervene upon a hitherto simple hernia. There are very definite and serious signs of general disturbance: breathing is fast and distressed, an anxious expression is visible on the face, and the swelling shows a marked tenseness and pain when being handled. It may be red and inflamed-looking at first, but later it frequently becomes bluish. After about 12 to 24 hours gangrene sets in; the swelling becomes cold and painless to the touch; the temperature falls subnormal, and the animal becomes alarmingly weak. Death usually follows shortly after, unless the strangulation is relieved by operation and perhaps amputation of the strangulated portion of herniated organ. An **obstructed hernia** is usually merely the preliminary of strangulation.

Treatment Palliative treatment, common in human beings consisting in the application of trusses, bandages, etc., is of no use whatever where animals are concerned. In the case of an umbilical hernia in a young animal of any species it is usual to leave the hernia alone provided that it is not acute (strangulated), for often during growth and development the hernia disappears of its own accord, and the hole in the abdominal wall heals over. There is, however, always a danger that, as the result of some extra exertion, heavy feeding, boisterous playfulness, fighting, etc., strangulation may occur.

The most rational method of repair is one in which the animal is anaesthetised, the skin is incised, the contents are returned to the abdomen, the peritoneal sac is removed if it is present, the edges of the ring are debrided and carefully sutured so that they will form a strong union, and finally the skin wound closed. (See also under DEBRIDEMENT.)

The operation for a strangulated hernia differs from that for a simple one in that it is necessary to enlarge the tight ring, to allow restoration of the circulation.

Repair of perineal hernias in dogs involves restoration of the pelvic diaphragm by apposing the internal obturator, coccygeal and external anal sphincter muscles and the sacrotuberous ligament.

Heroin

(See DIAMORPHINE.)

Herpesviruses

Herpesviruses are a family of viruses which contains double-stranded DNA and cause, for example, AUJESZKY'S DISEASE, jaagsiekte, feline rhinotracheitis. (See the table on next page; also under MONKEYS and 'FADING' PUPPY SYNDROME.)

Herztod Disease

A heart condition in pigs, it has similarities to 'MULBERRY HEART'. (See PORCINE STRESS SYNDROME.)

Heterokaryon

A cell containing nuclei of 2 different species (an example of genetic engineering). (See GENETICS, HEREDITY AND BREEDING.)

Heterologous

Derived from a different species or from a different part of the body. The term is applied to vaccines made from related but not identical micro-organisms against which protection is required – for example, the myxomatosis vaccine used in the UK is derived from SHOPE RABBIT FIBROMA virus. A heterologous graft is produced from a tissue other than that in which the part is transplanted. (See also HOMOLOGOUS.)

Heterophil

The LEUKOCYTE of birds, reptiles, and lagomorphs equivalent to the polymorphonuclear leukocyte of mammals, but of a different morphology in that its cytoplasma is organised in granules that stain pink with routine laboratory blood stains. The heterophil contains less lysozyme than its mammalian counterpart, which is one of the factors contributing to the solid nature of pus in the species. (See BLOOD, POLYMORPH.)

Heteroplastic Tissue

Heteroplastic tissue is that which is abnormal, i.e. different in structure from the adjacent tissue in

VetBooks.ir

Some of the herpesviruses of man, domestic animals and poultry*

Recommended label	Traditional name	Associated disease
Asinine herpesvirus 1	Equid herpesvirus 6	Genital problems
Asinine herpesvirus 2	Equid herpesvirus 7	Unknown
Asinine herpesvirus 3	Equid herpesvirus 8	Nasal inflammation
Asinine herpesvirus 4	Equid herpesvirus 9	Interstitial pneumonia
Asinine herpesvirus 5	Equid herpesvirus 5	Interstitial pneumonia
Human herpesvirus 1	Herpes simplex type 1	Herpetic sores, etc.
Human herpesvirus 2	Herpes simplex type 2	Genital herpes and cervical cancer
Human herpesvirus 3	Varicella-zoster	Chicken pox and shingles
Human herpesvirus 4	Epstein-Barr virus	Burkitt's lymphoma and infectious mononucleosis (glandular fever)
Canine herpesvirus 1	Canine herpesvirus	Herpes of dogs (neonatal deaths, respiratory infection, genital lesions)
Feline herpesvirus 1	Feline rhinotracheitis virus	Respiratory disease
Equid herpesvirus 1	Equine abortion virus	Abortion
Equid herpesvirus 2	Cytomegalovirus	Nothing or respiratory disease
Equid herpesvirus 3	Coital exanthema virus	Coital exanthema
Equid herpesvirus 4		Respiratory disease
Bovid herpesvirus 1	Infectious bovine rhinotracheitis/ infectious pustular vulvo-vaginitis	Upper respiratory tract infection; vaginitis, abortion, etc.
Bovid herpesvirus 2	Bovine mamillitis virus	Mamillitis and pseudo-lumpy skin disease
Bovid herpesvirus 3	Malignant catarrhal fever virus (wildebeeste herpesvirus)	Malignant catarrhal fever in cattle (Africa)
Bovid herpesvirus 4	Jaagsiekte virus pulmonary adenomatosis	Metritis, abortion, respiratory disease
Bovid herpesvirus 5		Encephalitis
Pig herpesvirus 1	Pseudorabies virus	Aujeszky's disease
Pig herpesvirus 2	Inclusion body rhinitis (cytomegalo) virus	Rhinitis
Phasianid herpesvirus 1	Infectious laryngotracheitis virus	Laryngotracheitis in poultry
Phasianid herpesvirus 2	Marek's disease virus	Marek's disease (fowl paralysis)

*Based on the recommendations of the Herpesvirus Study Group, International Committee for the Nomenclature of Viruses, and updated.

the same organ. Heteroplastic bones are those which are not parts of the skeleton, e.g. the *Os penis* in the dog and some rodents, and the *Os cordis* (one of two small bones in the cow's heart). Heteroplasm is normal tissue found in an abnormal situation e.g. a graft (heteroplasmid - a supply of normal tissue, even from other species).

Heterosis
Hybrid vigour – the improved vigour of the first generation progeny by crossing two breeds which is better than the average of the two parents.

Heterotopic
Wrongly positioned – refers to organs and parts of an organ.

Heterozygous
Relating to a heterozygote, which is produced from unlike GAMETES and has 1 gene (see ALLELES) dominant and the other recessive for a particular characteristic.

Hetp
An organophosphorus insecticide used in agriculture and horticulture. Similar to TEPP.

HeV
(See HENDRA VIRUS.)

Hexachlorobenzene
A fungistat used as a seed-dressing, it has given rise to a form of PORPHYRIA in children in Turkey, and might similarly affect livestock.

Hexachlorocyclohexane
The group name for several isomers each having the formula $C_6H_6Cl_6$. The most important of them is BENZENE HEXACHLORIDE. (See HCH; BHC.)

Hexachlorophane
An antiseptic used as an ingredient of medicated soap to kill bacteria on the skin.

Hexadactyly
The possession of six fingers or toes (in those animals which have fingers and toes).

Hexametaphosphate
When added to dog kibble diets it reduces tartar and plaque formation.

VetBooks.ir

Hexamine
Also called methenamine. It is excreted by the kidneys and as it liberates formalin in an acid medium it has antiseptic qualities when the urine is acid. In the past it has been combined with sodium acid phosphate for this purpose in a tablet as treatment of mild cystitis in dogs.

Hexamitiasis
An infectious enteritis of turkeys occurring in the USA and Britain. It is also seen in pheasants, quails, peafowl, etc.

Cause *Hexamita meleagridis*.

Signs Day-old poults may be affected, but more commonly the disease attacks turkeys a few weeks old. The feathers become ruffled, the birds are listless with drooping wings. The droppings become liquid and frothy. Birds stand silent and motionless with eyes closed. Loss of condition is rapid, with marked dehydration. In young birds mortality may reach 100 per cent. Recovered birds may act as carriers.

Treatment Antibiotics (especially tetracyclines) and furazolidone.

Hexoestrol
A synthetic oestrogen banned from use in animals in the EU. (See STILBOESTROL; HORMONES IN MEAT PRODUCTION; STILBENES; CAPONISATION.)

Hexoses
Hexoses are monosaccharide carbohydrates and include GLUCOSE, fructose, galactose, and mannose. Monosaccharides also include the pentoses, e.g. arabinose, ribose. (See SUGAR, PENTOSES.)

Hexylresorcinol
Formerly used as an anthelmintic for roundworms and for fluke.

HGS
Abbreviation for HAEMORRHAGIC GUT SYNDROME (See JEJUNAL HAEMORRHAGIC SYNDROME in cattle.)

Hiatus Hernia
Protrusion of (usually) part of the stomach through the diaphragm at the oesophageal hiatus (see under HERNIA).

Hibitane
Chlorhexidine, a valuable disinfectant effective against some bacteria which cause mastitis in cattle. It is often combined with detergent and used as a pre-surgical scrub.

Hiccoughs, Hiccups
It is seen in dogs, particularly puppies under eight months old, and follows the ingestion of large quantities of air with food or liquids. It is relatively common and does not need treatment.

Hide
1. The skin of cattle after its removal at the abattoir.
2. Ways of studying wildlife without the animals or birds being aware of human presence; a structure used to conceal the observer. Occasionally it is used to determine the abnormal signs present in an animal which might otherwise not be seen.

Hidrosis
Sweat secretion, either normal or abnormally profuse.

Highland Cattle
Also known as the Kyloe. It is an ancient Scottish breed with long hair, usually coloured red, yellow or dun, and long horns tending to grow sideways. The animals are very hardy and can forage well. They are used for beef. In Scotland, a group of Highland cattle is known as a fold rather than a herd.

Highland Ponies
Ponies were bred in the Highlands of Scotland. It is thought that they may contain Spanish genes from ponies released from Spanish galleons wrecked on the coast during the Armada. They are good, strong ponies and must be less than 14.2 HANDS (1.42 m) high. They are usually dun or grey and have a dorsal stripe but they must not have any white on their legs. They breed standard allows a small star on their heads but no other white or flesh marks.

High-Rise Syndrome
(See FALLS FROM HIGH BUILDINGS.)

Hill Radnor Sheep
Another name for the RADNOR SHEEP.

Hilum, (incorrectly, Hilus)
Hilum (incorrectly, hilus) is a term applied to the depression on organs such as the lung, kidney, and spleen, at which the vessels and nerves enter or leave, and round which the lymph nodes cluster.

Himalayan Rabbit
A medium-sized breed, white with dark points on the nose, ears, tail and feet. The Himalayan is born white, but the points develop as it grows.

Hinny
The offspring of a stallion and a female ass.

VetBooks.ir

Hip Dysplasia in Cats

Hip dysplasia occurs in cats but less frequently than dogs. It is seen in ABYSSINIAN, MAINE COON and PERSIAN breeds.

Hip Dysplasia in Dogs

This term covers a number of abnormal conditions of the hip joint (acetabulum and head of the femur). Hip dysplasia is a developmental disorder shown by variable degrees of joint laxity, malformation of the acetabulum and femoral head and osteoarthritis.

There are many causes; some hip conditions are hereditary, others can be result from management (e.g. excessive exercise before the joint is fully formed). The clinical signs include a reluctance to rise from the sitting position, and a sawing gait, observed when the puppy is four to five months old, and hopping like a rabbit when running may be observed.

The condition typically affects larger dogs, most often a GERMAN SHEPHERD DOG, sometimes a GOLDEN RETRIEVER. It is also recorded in AFFENPINSCHERS, ALASKAN MALAMUTES, BELGIAN SHEPHERD DOGS, BORDER TERRIERS, BOXERS, BRIARDS, BULL MASTIFFS, DOBERMANN PINSCHERS, ELKHOUNDS, ENTLEBUCHER MOUNTAIN DOGS, GREAT DANES, ITALIAN SPINONES, KEESHONDS, NEWFOUNDLANDS, OLD ENGLISH SHEEPDOGS, PHARAOH HOUNDS, PYRENEAN MOUNTAIN DOGS, RHODESIAN RIDGEBACKS, ROTTWEILERS), WELSH SPRINGER SPANIELS.

Abnormalities of the joint include:

1. Subluxation, in which the head of the femur is no longer firmly seated within the acetabulum. Deformity of the head of the femur gradually develops.
2. OSTEOCHONDRITIS DISSECANS is seen in terriers with short legs, poodles, and Pekingese. It is possibly identical with PERTHES DISEASE. Muscular wasting and lameness are observed, usually in one limb.
3. Slipped EPIPHYSIS. This also causes pain and lameness at four to six months, but is difficult to distinguish from (2).
4. Congenital dislocation, in which the acetabula are too shallow to retain the heads of the femurs in position. Reported in the Black Labrador. A false joint forms in time. (See also PERTHES DISEASE.)

The BVA and the Kennel Club jointly run a scheme whereby X-rays of a dog's hip-joint are examined by a panel of experts and given a score according to the condition of the joint. The intention is that dogs showing a tendency to dysplasia will not be used for breeding in an attempt to address the inherited part of the problem.

Hip-Joint

The joint formed between the head of the femur, or thigh-bone, and the depression on the side of the pelvis called the acetabulum.

Hippocampal Necrosis

(See FELINE HIPPOCAMPAL NECROSIS.)

Hirsute

Literally, hairy.

Hirsutism

The condition of abnormal hairiness. Seen in horses with Cushing's disease.

Histaminase

An enzyme obtained from extracts of kidney and intestinal mucosa, capable of inactivating histamine and other diamines. It has been used in treating anaphylactic shock and other allergic conditions due to, or accompanied by, the liberation of histamine in the body.

Histamine

(Compare ANTIHISTAMINES.)

An amine occurring as a decomposition product of histidine (see AMINO ACIDS) and prepared synthetically from it. Histamine is widely distributed in an inactive compound form in the body, particularly in the lungs, liver, and to a lesser extent in blood and muscle. As a result of trauma, burns, or infection, it may be liberated from the skin, lungs, and other tissues. Histamine dilates capillaries, reduces blood pressure, increases any tendency to oedema, stimulates visceral muscles and gastric and pancreatic secretions. Histamine toxicity is shown by engorgement of the liver, shock, and a tendency to urticaria-like skin lesions. (See also ANTIHISTAMINES; ALLERGY; MAST CELLS.)

Histidine

An amino acid from which histamine is derived by bacterial decomposition. It is important in the diet of young animals but not essential for adults.

Histiocytes

Another name for macrophages. (See under BLOOD – Leukocytes.)

Histiocytosis A condition resulting from an excess of histiocytes in the bloodstream. It affects some breeds of dog, e.g. Bernese mountain dogs. Clinical signs vary from anaemia and respiratory disease in the malignant form to itchy skin patches.

VetBooks.ir

Histiocytic Ulcerative Colitis
An uncommon disease resulting in inflammation and ulceration of the large bowel with signs of bloody mucoid diarrhoea, frequent straining and loss of weight. It is relatively common in young BOXER DOGS.

Histocompatibility
The ability of a cell or tissue transplant to be accepted by a different animal. Histocompatible antigens are present in most tissue cells. They are the cause of the rejection of transplants. (See MAJOR HISTOCOMPATIBILITY SYSTEM.)

Histocytoma
A benign skin tumour common in dogs. Rarely, malignant histocytomas occur.

Histomoniasis, Histomoniosis
(See BLACKHEAD OF TURKEYS.)

Histophilus somni
This was formerly *Haemophilus somnus* and causes THROMBOEMBOLIC MENINGOENCEPHALITIS in calves.

Histoplasmosis
A fungal disease, caused by *Histoplasma capsulata*, which gives rise to loss of appetite, diarrhoea, emaciation and liver enlargement. It occurs chiefly in dogs and man. In man, infection often occurs following time spent in bat-infested caves in Central and South America, and in Africa. Lesions first occur in the lungs, but – in serious cases – other organs may be affected.

The mycelial phase, found in soil, produces two kinds of spore: *microconidia* and *macronidia*. The latter enter the body by inhalation.

Hock
Hock is the tarsus, a joint composed of six or seven bones, between the tibia and the cannon bone of the hind-limb. (See under BONE.)

Hodgkin's Disease
Hodgkin's disease is a form of cancer involving the lymph nodes, bone marrow and sometimes other tissues.

Hog
A male pig after being castrated.

Hog Cholera
(See SWINE FEVER.)

Hogg
Sheep up to the first shearing. (See also under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC..)

Hogget
(See under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC..)

Hogweed
(See under GIANT HOGWEED.)

Holly, Ilex
Holly leaves eaten by lambs when grazing under holly trees have caused deaths by obstructing the pharynx and larynx.

Holoprosencephaly
A rare congenital brain malformation, accompanied by various facial deformities including a deficit of midline facial development; CYCLOPIA occurs in the severe form. The condition appears to be inherited in an autosomal recessive manner.

Holorrachischisis
A rare congenital condition where there is a fissure of the entire spinal cord.

Holstein Cattle
The breed is a high-performance milking cow. Most black and white dairy cattle in the United Kingdom contain some Holstein blood, being HOLSTEIN-FRIESIAN, but many are now purebred. They tend to be taller and thinner than FRIESIAN CATTLE and so the males are less useful for beef. They tend to be more susceptible to problems such as lameness, poor fertility and have a short life in the dairy herd averaging three to four lactations.

Holstein-Friesian Cattle
This breed of cattle in the USA and Canada has its origin in animals imported from the Netherlands mostly between 1857 and 1887. They are also known as American or Canadian Holsteins or Friesians. They are black and white, often mainly white. They have been bred for high milk production and the male calves are poorer as beef fatteners than Friesian. Holstein-Friesians tend to be susceptible to poor environmental or management conditions, which can result in poor fertility, resistance to disease etc.

Homatropine
Homatropine is an artificial alkaloid prepared from atropine. It is used to dilate the pupil of the eye for careful examination of the deeper parts of that structure. It does not interfere with vision for as long as does atropine.

Homeostasis
Maintenance of the body fluids (as opposed to fluid within cells) at the correct pH and chemical composition.

VetBooks.ir

Homoeopathy, Homeopathy

A treatment method used in human medicine and sometimes in veterinary medicine. It is based on the principle of Samuel Hahnemann who, from his studies on quinine, considered that 'like cures like'. It is based on a detailed consideration of the patient, its environment and management. Treatment is based on medicines produced from the serial dilutions of a substance, often natural, in water or alcohol and then performing succussion (hitting the container on a surface such as a book). Usually dilutions are sufficient to mean no molecule of the original substance is present. There is considerable controversy over the validity of this form of medicine and treatment in conventional medical and veterinary circles. It is recognised in EU law.

Homograft Reaction

The process by which an animal rejects grafts of another's tissue. (See IMMUNE RESPONSE and KIDNEYS – Function.) The term 'allograft' is now regarded as preferable to 'homograft'.

Homologous

Derived from the same species or the same part of the body. The term is applied to vaccines made from the same, usually attenuated, micro-organism against which protection is required. A homologous graft is derived from the same tissue as that to which the part is implanted. (See also HETEROLOGOUS.)

Homozygous

The characteristic of having identical alleles, usually of a particular characteristic or characteristics or IDENTICAL TWINS.

(See GENETICS, HEREDITY AND BREEDING.)

Honey

This appears to have an antibiotic effect and to be a successful dressing for bed sores in human patients. Some honeys contain PYRROLIZIDINE ALKALOIDS. (See BEES.)

Hoof

(See FOOT OF THE HORSE.)

Hoof-Prints

Hoof-prints, and other places where the soil is exposed below the turf, are on wet pastures a common habitat of the snails which act as intermediate hosts of the liver-fluke. Dressing with 12.5 kg (28 1b) of finely powdered bluestone (copper sulphate), mixed with 50 kg (1 cwt) of dry sand, to the acre (0.4 hectare), will reduce the snail population if done each year in June and repeated in August.

Hoof Repair with Plastics

Plastic material, consisting of acrylic resin with a filler, can be bonded with the horn, so that this can be built up. Cracks, deformities and cavities can be repaired, using one or other of the proprietary preparations marketed. With one type, the acrylic becomes in about five minutes as hard as wall horn; with the other, that of the frog tissue. The former can be rasped and nailed; the latter rasped or trimmed with a knife. Large defects should be repaired with a series of layers in order to avoid damage from heat generated by the process.

Hookworm Dermatitis

A condition that mainly occurs in wet areas and is most often seen in GREYHOUNDS, foxhounds and country dogs. It results in small, raised papular areas with later loss of hair and skin thickening. It can result in self trauma when lesions are on the pads of the feet, and in the nail bed. It is more common in other countries than the UK.

Hookworms

These include *Uncinaria stenocephala*, present in temperate regions (including the UK), and the more pathogenic *Ancylostoma caninum* in warmer climates. Infestation occurs either through skin penetration or by ingestion of larvae in bitch's milk, etc. (See also ROUNDWORMS.)

Hoose

(See PARASITIC BRONCHITIS.)

Hordeolum

A stye. Inflammation of one or more of the sebaceous glands of the eyelid Inflammation of one or more of the sebaceous glands of the eyelid. (See EYE, DISEASES AND INJURIES OF.)

Hormones

Hormones are substances which upon absorption into the bloodstream influence the action of tissues or organs other than those in which they were produced. The internal secretions of the ovary, testicles, thyroid, parathyroid, adrenal, pituitary body, and the pancreas are examples of hormones. (See ENDOCRINE GLANDS.) The placenta is also a source of one or more hormones.

Most animal hormones are either polypeptides (small proteins) or steroids, and the 2 groups have different modes of action.

The interaction of the hormones is far-reaching and complex. In health, a delicate balance – the 'endocrine balance' – is maintained. In ill-health this balance may be disturbed by an insufficiency of a particular hormone or by excess of another. Some hormones are antagonistic to each other, so that an excess of one amounts to much the same

VetBooks.ir

thing as too little of another. In some conditions, such as 'milk fever' in the cow, a number of endocrine glands are believed to be involved – the imbalance being far from a simple one. The thyroid might be regarded as the 'master gland'; its secretion profoundly influences growth, sexual development, immunity, and the rate of metabolism. Yet the thyroid is itself stimulated by a hormone secreted by the anterior pituitary gland – an example which illustrates the interdependence of the whole endocrine system.

An animal's disposition and its hormone secretions are closely linked. Fear or anger, for example, will cause an outpouring of adrenaline – the 'fight or flee' hormone. And, probably, the animal's 'endocrine make-up' determines to some extent its capacity for, or tendency to, anger, fear, etc., as it does for sexual appetite.

Insulin (see PANCREAS; DIABETES MELLITUS; HORMONE THERAPY).

Glucagon (see PANCREAS).

Thyroxine (see under this heading and THYROID GLAND).

Adrenaline (see under this heading and ADRENAL GLANDS).

Aldosterone (see under this heading and ADRENAL GLANDS). (See also GLUCOCORTICOIDS.)

Hormones of the anterior pituitary lobe stimulate the gonads (gonadotrophin), thyroid, adrenals, the skeleton, milk secretion, etc.

Pituitary gonadotrophin influences both the ovary and the testis. In the latter it stimulates development of the sperm-secreting tissue and of actual sperm production, and of the interstitial tissue and the secretion of male sex hormones. In the ovary it stimulates growth of the ovarian follicles and development of corpora lutea. Pituitary gonadotrophin is thus considered as having two parts or principles: FSH (follicle stimulating hormone) and LH (luteinising hormone).

Chorionic gonadotrophin. This is a hormone resembling that of the anterior pituitary, but formed in the placenta and excreted in the urine of pregnant women. The action of this hormone is predominantly luteinising.

Serum gonadotrophin (PREGNANT MARE'S SERUM) is a hormone similar to the above but predominantly follicle-stimulating, obtained from the serum of pregnant mares.

Pituitrin is the hormone from the posterior lobe of the pituitary, and comprises a pressor principle (vasopressin), which acts upon the heart and circulation, causing a rise in blood pressure, and an oxytocic principle (oxytocin) which stimulates involuntary muscles such as those of the intestines and of the uterus (when pregnant). (See also under ANTIDIURETIC HORMONE.)

Natural oestrogens are hormones obtained from the follicles of the ovary and include oestrin and its chemical variants oestrone, oestriol, oestradiol, etc. At puberty oestrin brings about development of the teats, udder, vagina, etc. Oestrin is, to some extent, antagonistic to luteal hormone and the parathyroid secretion.

Synthetic oestrogens have a similar effect to the above. They include STILBOESTROL, hexoestrol and dienoestrol.

Progestin, progesterone, or the luteal hormone is produced by the corpus luteum. This hormone, stimulates preparation of the lining of the uterus for pregnancy, and by counteracting other hormones ensures the undisturbed maintenance of the gravid uterus; meanwhile suppressing oestrus, and – with the oestrogens – stimulates development of the udder and onset of lactation.

Androgens are sex hormones, e.g. testosterone secreted by the testes, and hormone(s) secreted by the adrenal supplementing, it seems, the action of testosterone. The latter is responsible for the development of secondary sexual characters, is capable of counteracting the female sex hormones, and apparently inhibits the deposition of fat.

Hormones in Meat Production

Hormonal preparations, such as stilboestrol, were formerly used to improve meat production. Often administered in unauthorised doses, serious health problems resulted in the animals and in the humans consuming the meat produced. The use of stilboestrol and similar hormones was consequently banned.

ANABOLIC steroids such as trenbolone became popular in the 1970s. They were claimed to have only slight side-effects, and improved food-conversion efficiency. However, their use as growth promoters is banned in livestock in the EU. They are used clinically in debilitating diseases, anaemia, renal failure and to promote tissue repair.

(See GROWTH PROMOTERS.)

Hormone Therapy

Hormone therapy is of value in cases where a true endocrine failure or imbalance is at fault, but it is obviously not a panacea. Moreover, the indiscriminate use of hormones is fraught with danger, and if persisted with may give rise to the production of ANTIHORMONES. Therapy should be carried out by a veterinary surgeon only.

The uses of insulin, thyroxine, adrenaline and pituitrin are described under these headings, and extracts of thyroid and parathyroid gland are similarly dealt with. Apart from these, considerable use is made in veterinary practice of the sex hormones. (See HORMONES.)

Chorionic gonadotrophin is used in the treatment of nymphomania due to cystic ovaries, of

VetBooks.ir

CRYPTORCHID, and also of pyometra and of some cases of infertility due to a deficiency of luteinising hormone. In the mare and cow a single dose given intramuscularly will usually correct nymphomania.

Serum gonadotrophin (PREGNANT MARE'S SERUM) is used in cases of anoestrus and infertility, and to obtain an extra crop of lambs. (PMS = pregnant mare's serum.)

Progesterone is used to prevent abortion or resorption of the fetus occurring as a result of luteal deficiency. It is also used to treat cases of cystic ovaries, and may be tried to relieve uterine haemorrhage. Luteal hormone preparations are given either intramuscularly (if in oil) or by implantation (if in tablet or pellet form).

Synthetic oestrogens were formerly used in cases of retention of the afterbirth, in some cases of pyometra, uterine inertia and dystokia, and in order to cut short lactation. Some synthetic oestrogens can be given by the mouth. In the dog, stilboestrol was used in treating enlarged prostate; in the bitch stilboestrol diproprionate may be used by intramuscular injection after mating to prevent conception.

Testosterone propionate is of use in sexually underdeveloped young males, and in adult males it may be given to improve fertility or to overcome impotence. In castrated or androgen-deficient males it may be of service in obesity, alopecia, and possibly eczema. In the female it may be used to cut short oestrus in racing bitches and mares, to suppress lactation, and in the treatment of pyometra. It has been used with success in the treatment of alopecia (baldness) in spayed cats and also in the bitch (non-spayed). (See CORTICOSTEROIDS; SYNCHRONISATION OF OESTRUS.)

Horner's Syndrome

A denervation of the sympathetic nerve supply to the eye which can occur following middle ear infections, cervical injuries and spinal cord lesions as well as idiopathically in GOLDEN RETRIEVER dogs. It is seen in most mammalian species. The classic triad of signs is MIOSIS (constricted pupil), PTOSIS (drooping upper eyelid) and ENOPHTHALMUS (sunken eyeball) with third eyelid protrusion. Diagnosis can be confirmed as signs resolve with PHENYLEPHRINE drops. No treatment is required as most cases resolve spontaneously in one to three months.

Horn Fly

Lyperosia irritans is a parasite of cattle in America, Hawaii, and Europe. Heavy infestations of cattle have been reported in the UK. (See FLIES.)

Horns, Injuries to

In the horned breeds of cattle, sheep, and goats, injuries to the horns are not uncommon. In spite of the great strength of the horns of cattle, fracture of the horn cores, from fighting, collision, etc., may arise with comparative ease when the force has been applied in a lateral or transverse manner. Frequently the horn itself remains apparently intact, but the bony core is fractured, and the injury is not suspected until it is noticed that the animal is bleeding profusely from 1 nostril, i.e. that on the same side as the injured horn. Sometimes the tip of a horn may be broken clean off, and the external haemorrhage is liable to be alarming.

Horse Bots

Maggots of the common horse bot fly. Horse bots have been known to infect the liver, causing hepatitis and jaundice.

As bot flies have only one generation per year, it has been suggested that a single annual treatment of horses, preferably during early winter, would remove most, if not all, the bots. (See under FLIES.)

Haloxon in the feed or paste preparations of IVERMECTIN are used for the control of bots.

A survey carried out in Ireland showed that during the months of October to May (inclusive), 90 per cent of horses slaughtered at an abattoir near Dublin, and just under 67 per cent of those at an abattoir near Belfast, were infected with *Gastrophilus intestinalis*. Over 28 per cent of horses at the former abattoir harboured *G. nasalis*; but none of those in the Ulster abattoir.

Horse-Meat

Uncooked liver, lungs, etc. may be a source of the hydatid cysts of the tapeworm *Echinococcus granulosus* of the dog. The diaphragm may harbour *Trichinella spiralis* and, though this parasite is unknown in the UK, horse-meat may have to be examined for it. It is possible to use a DNA probe to detect horse muscle and detect if it has adulterated other meats. (See MEAT DNA TESTING.)

Dogs and cats have occasionally been poisoned, some fatally, after being fed horse-meat containing barbiturates or chloral hydrate (administered to the horse for euthanasia). Signs include drowsiness and muscular incoordination.

Human cases of TRICHINOSIS have followed the eating of horse-meat served rare.

Horse Passports

(See HORSES, IDENTIFICATION OF.)

Horse-Pox

(See POX.)

Horseradish

It contains a natural decongestant and may be included in herbal remedies for dogs and cats.

Horses, Back Troubles in

A deterioration in a horse's performance or ability to jump may be the result of chronic back pain or discomfort. This may alter the animal's behaviour or temperament. Some may become fractious when handled or worked; some may resent any weight on their backs at all. When investigating back problems, it is essential for a complete history of the animal to be taken, since problems in schooling and equitation may be the real trouble, and to rule these out details of management, tack, performance and previous temperament need to be studied.

The thoracic and lumbar regions of the spine are commonly involved. Lesions may be grouped as shown in the table.

In one study, three types of ACUPUNCTURE were found to be equally useful in the treatment of horses with chronic back pain. Three groups of 15 horses suffering from this condition for between

Major causes of back troubles in horses. (With acknowledgements to Professor L. Jeffcott.)

DEFORMITY OF VERTEBRAL COLUMN	Scoliosis, lordosis, kyphosis, synostosis (congenital vertebral fusion).
SOFT-TISSUE INJURIES	Strain/damage to supraspinous ligament of the back; myositis; or cramp; sacroiliac strain.
FRACTURES	Dorsal spinous processes – single or multiple; bodies of vertebrae and neural arch.
OTHER BONE DAMAGE	Ossifying spondylosis; crowding or overriding of the dorsal spinous processes; osteoarthritis and fusing of the dorsal spines, transverse and articular processes.
MISCELLANEOUS	Skin lesions – sitfasts; warbles beneath saddle area.

two and 108 months were treated by: (1) needle acupuncture (once a week for eight weeks); or (2) laser acupuncture (once a week for 11 weeks); or (3) injection acupuncture (once a week for nine weeks). Pain was reduced in 13 horses in group l; in 11 in group 2; and in 13 in group 3; they were able to resume training and competition work.

Horses, Common Causes of Death in

Records of consecutive post-mortem examinations, carried out at the University of Liverpool Veterinary Field Station, showed that in 480 horses the following conditions accounted for 10 or more deaths:

Alimentary system. Perforations, 21; specific and non-specific enteritis, 21; volvuli, 18; strangulated HERNIAS, 15; malabsorption due to atrophic enteropathy (intestinal disease), 14; intestinal obstructions, 13; parasitic enteritis, 12; infestation by small strongyles (e.g. cyathostome larvae).

Nervous system. Grass sickness, 51.

Cardiovascular system. VERMINOUS ARTERITIS, 14; haemorrhage, 13.

Haematopoietic system. Lymphosarcoma, 12.

Miscellaneous. Pyaemia or septicaemia, 14.

The following conditions were not considered to have caused death in the 480 horses, but were found 30 times or more:

Alimentary system. Parasitic peritonitis, 93; gastrophilus larval infestation, 82; parasitic enteritis, 54; hepatic hydatidosis, 44; gastric ulceration with no gastrophilus present, 37.

Cardiovascular system. VERMINOUS ARTERITIS, 146.

Respiratory system. Pneumonia, 31.

Diseases of the equine liver (See RAGWORT POISONING; LIVER-FLUKES; AFLATOXINS; HYDATID DISEASE.)

Horses, Feeding of

Horses at grass are likely to be contented, for they can feed at intervals during both day and night (as they do in the wild state), with exercise as an appetizer. A stabled horse is denied these opportunities. (However, horses do need shelter in winter – or at least they should be rugged.)

Horses are fussy feeders, and this can be affected by the age, composition and type of pasture – all of which influence dry matter intake. (For grasses most suitable for horses, see PASTURE MANAGEMENT – Grass varieties.)

With concentrate feed, the aroma, freshness, and physical characteristics influence both initial acceptance and continued consumption.

(See DIET AND DIETETICS for preparation of feeds, palatability and deterioration in storage, etc.; also LUCERNE; LINSEED; HAY; HYDROPONIC GRASS.)

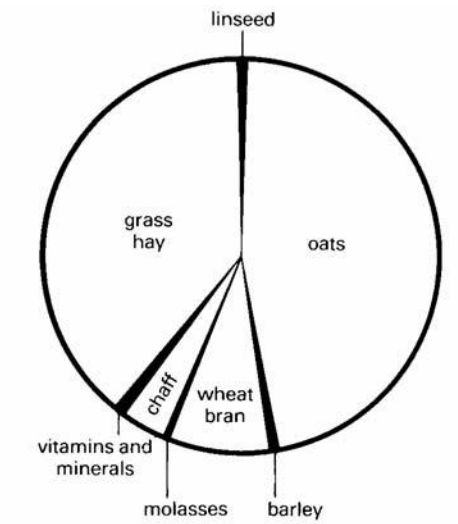
The horse can eat only relatively small quantities of feed at a time because of its relatively small stomach size. The number of feeding times per day should therefore be increased with increasing workload because otherwise the horse cannot get enough feed to cover requirements. In addition, the horse chews its feed thoroughly and therefore requires relatively long feeding times (about an hour). A horse under an average workload requires per day about 2 kg feed (air-dry weight) per 100 kg (4 lb 6 oz per 220 lb) bodyweight.

Horses in all phases of life can largely cover their nutrient requirements by sufficiently long daily grazing on a good pasture. If the pasture is of poor quality then the nutrition of horses will be deficient unless supplemented.

Oats are the most widely used cereal for feeding horses; they do not need processing for adults, but should be crimped or rolled for foals. Barley, wheat

VetBooks.ir

and maize are used to a lesser extent. Barley should be crimped or rolled, wheat should be rolled, and maize cracked. If included in horse feeds, beans should be split or kibbled.



Cereals are rich in starch, comparatively poor in protein, and mostly provide too little calcium but too much phosphorus. This mineral imbalance is also found in bran, which should not form a significant proportion of the ration.

Hay and oats feed rations are sufficient to cover the requirements of adult horses both for maintenance and for work, gestation and lactation, only if the feed rations are of good quality. If of poor quality, mares in the late phase of gestation may suffer from a deficiency in minerals, whereas lactating mares and young horses may suffer from a deficiency not only in minerals but also in energy and in high-grade digestible crude protein.

For safety reasons (as a safeguard against undetected poor quality of feed rations) it is therefore advisable to supplement both grazing and hay and oats feeding of horses in all phases of life with minerals and trace elements (mineral supplement feed).

Mares at the peak of lactation and young horses up to six months after weaning, if they are fed on hay and oats, require feed supplementation with high-energy low-fibre concentrate feed containing high-grade protein, e.g. dried skimmed milk.

Regardless of the stage of life and of performance requirements, all horses should be given all necessary vitamins as a supplement to the feed. This is the only way to avoid uncertainties or actual deficiencies in vitamin supply which may arise owing to the variability of vitamin contents of feedstuffs. In addition, over and above a sufficient supply of minerals, all horses should have free access to common salt in the form of mineral licks.

Average weekly composition of traditional feed given to thoroughbreds in training – percentage by weight. (With acknowledgements to David Frape in *In Practice*.)

A way to avoid deficiency situations when feeding horses on hay and oats rations is to replace the oats partly or entirely by a compound feed for horses. With such hay/oats/compound feed rations or hay/compound feed rations, no further supplementation is required provided the compound feed contains the necessary ingredients.

Maintenance rations Crude protein requirements are relatively low, and can be met by cereal grains. More than half the diet can be hay. Horse hays in the UK average between 4 and 7 per cent crude protein. Energy requirements can be met by good-quality hay.

Growth, lactation and work each have different nutrient requirements. For a horse in work, or lactation, gut capacity is insufficient for energy requirements to be met from bulky, but good-quality, hay.

For growth The protein requirements of a young, growing horse are much greater than those referred to under 'maintenance rations' above. Both digestibility and amino-acid content are important. Diets containing only poor-quality protein should be supplemented with LYSINE, or some soya could be substituted for linseed.

Pregnant/lactating mares In America under poor range conditions, where grazing provides inadequate protein, feed blocks supplying 50 g (1 ⅔ oz) urea daily improve a pregnant mare's condition.

During the last third of pregnancy, energy requirements increase above those of maintenance. The mare should still be able to consume daily 1 kg (2.2 lb) of hay and 0.25 kg (0.6 lb) to 0.5 kg (1.1 lb) cubes per 100 kg (220 lb) of bodyweight. (Levels of feed for thoroughbreds need to be 30 per cent higher than those for pleasure horses.)

During peak lactation a 500 kg (1,100 lb) mare may produce over 13.5 l (3 gal) of milk daily and, if she is also undertaking some work, her energy demands are considerable. Requirements for concentrate cubes during the third month of lactation may reach 250 g (about 8 oz) to 500 g (1.1 lb) per 100 kg bodyweight.

Proprietary concentrates are widely used. For novices, these concentrates are a boon, since they are likely to be well balanced. Some concentrates contain soya-bean meal, which is a good source of lysine in which home-mixed rations are often deficient.

Horses do need some long hay in addition to concentrates to provide bulk, assist PERISTALSIS, and mitigate the boredom which can lead to habits such as crib-biting.

VetBooks.ir

In recent years silage has, to a very limited extent, become an item of horses' diet. Care must be taken to avoid any mouldy samples, and it may take a week for a horse to accept silage.

Food preferences of ponies Studies of the feed preferences of ponies should help to predict the acceptability and intake of rations containing sucrose, grains or by-product feedstuffs. Given a choice between oats, maize, barley, rye and wheat, six mature pony mares preferred oats, with maize ranking second and barley third. Wheat and barley were liked least, but when the choice was restricted to these two grains the ponies' feed intake was not greatly depressed. Given oats or oats plus 2 per cent or 10 per cent sucrose, four of six pony geldings selected the sweetened oats but one disliked sucrose and the other selected from one feed bucket regardless of its content. The six pony mares preferred a basal diet containing 54 per cent maize, 20 per cent whole oats, 10 per cent wheat bran, 8 per cent soya-bean meal, 7 per cent molasses and 1 per cent limestone when it was supplemented with 20 per cent of distillers' grain, but not when it was supplemented with 20 per cent beet pulp, 20 per cent blood meal or 20 per cent meat and bone-meal.

The following rules should be adhered to as far as the feeding of horses in Britain is concerned:

1. Water before feeding (see WATER AND WATERING OF ANIMALS).
2. Feed in small amounts and as often as the nature of the work or other circumstances will allow.
3. Do not work immediately after the horse finishes feeding. An hour should be given for a full feed.
4. Give the first feed of the day early, and give the majority of the bulky food at the last feed of the day, so that the horse can eat it at its leisure.
5. Always buy the best quality of food obtainable; it is false economy to use inferior food-stuffs.
6. Inspect the teeth periodically, and have any errors corrected at once.

Horses, Identification of

Under the Horse Passports Order 1997, the keeper of any horse born in the UK after January 1, 1998 must have the horse registered with an authorised organisation and receive a passport for it. This has to accompany the animal when it is moved in or out of Great Britain, when it goes to competitions, when it is moved for veterinary treatment, when it is moved to new premises, or for any other purpose. The passport contains an outline silhouette of the animal properly filled in and details of all vaccinations it has been given.

From 1999 it became a requirement of entry into the *General Stud Book* and *Weatherbys Non-Thoroughbred Register* that foals had to be identifiable by means of a microchip implanted in the neck at the same time that the blood sample (for typing) was taken and marking recorded for the animal's passport.

Freeze branding or hoof branding are also used for identification. Semi-feral equines, such as Dartmoor ponies, must be registered on capture.

Currently horse identification comes under the Horse Passport Regulations 2009, Horse Identification (Scotland) Regulations and the Horse Passport Regulations (Northern Ireland) 2010. Under these the keeper of any horse must have a passport for that horse and the document should pass to new owners. The veterinary surgeon has a legal responsibility to ensure treatment with PHENYLBUTAZONE is properly recorded on the HORSE PASSPORT.

Horses, Import Controls

There is free movement of horses throughout the EU. Importation of horses into Great Britain is allowed only through one of four Border Inspection Posts: Heathrow Airport, Immingham Port, Luton Airport and Tilbury Port. Unregistered equidae can be imported through Bristol. Importing a horse elsewhere is an offence, but factors such as the designated airport being fogbound and the aircraft diverted will be taken into account. Each animal is examined, and if found clinically free from evidence of infectious or contagious disease, is free to travel anywhere in the EU. Each horse has to be accompanied by a health certificate. The health certificate accompanying competition horses is valid for 90 days' stay in the EU and does not require proof of freedom from venereal disease, whereas the certificate for permanent residency does.

Horses from the USA must have been tested for evidence of NOTIFIABLE DISEASE. Restrictions may be applied in the case of a new equine disease being identified. For example, in 1996 a respiratory disease was linked to certain race meetings in New England. No horse which had been in contact with any horse involved in those meetings was allowed into the UK until the matter had been cleared up.

The Animals and Animal Products (Import and Export) Regulations 1998 specify the terms of importation.

Horses, Infectious Diseases of

(See HORSES, IMPORT CONTROLS.)

Horses, Infertility in

(See CONTAGIOUS EQUINE METRITIS; UTERINE INFECTIONS.)

Horses, Loss of Condition in

When ponies and other riding horses lose condition, a veterinary surgeon should be consulted, for

VetBooks.ir

the possible causes are many and a professional diagnosis is important. Some pony-owners, inexperienced or otherwise, may be underfeeding their animals, not supplying enough drinking water, or overworking them. Appetite may be depressed because of pain – perhaps in the joints or feet, perhaps associated with brucellosis. The teeth may need attention. Chronic grass disease will result in loss of condition. Migrating red worm larvae may be causing circulatory disturbance, or the animal may have a severe infestation of worms in the intestine. Bots may be present in the stomach. Chronic disease of liver or kidneys may be present; or cancer or tuberculosis. These and many other conditions may be causing the pony to be unthrifty.

A scheme of regular visits by a veterinary surgeon (often on a contract basis) can help to keep horses and ponies in good condition. (See HORSES, DISEASES OF.)

Horses, Lung Haemorrhage

A study carried out at the Animal Health Trust's equine research station confirmed the high incidence of blood pigment present in tracheal washes from 'normal' racehorses, and indicated that exercise-induced subclinical bleeding from the lungs occurs in British as in other racehorses. (See RACEHORSES, EXERCISE.)

Horses, Measurement of

As equine veterinarian D. F. Oliver has pointed out, the precise height of a horse may determine whether it is worth thousands of pounds or only hundreds. 'The value of a horse which "measures in" may well be in the order of £35,000; if "measured out" only £500,' he said. Consequently, there is great pressure on the measurer. The use of a spirit level, to check the level of the ground, is now required in the UK. The horse must be measured from both sides, and the mean taken. Some horses resent the slightest pressure on their withers; others are taught to crouch at such pressure – both making accurate measurement extremely difficult. Horses should be familiarised with the measuring standard. (See HAND.)

Horses should be examined for 'over-preparation of the foot' and measuring postponed if they are found in this condition.

In one study, the heights of 89 horses were measured at the withers before and after half a furlong of trotting exercise. The average height-increase after the exercise was 1.75cm; the horses returning to their 'resting height' within seven minutes.

Horses, Motor Neuron Disease

This is characterised by a considerable loss of weight, trembling, sweating and a stiff gait.

Horses, Shoeing

In the UK, horses may only be shod by a farrier registered with the Farriers Registration Council after completing an approved apprenticeship and passing the examination for the Diploma of the Worshipful Company of Farriers.

Horses, Spinal Cord Diseases in

A survey based on 81 horses examined at the New York State College of Veterinary Medicine, Cornell University, revealed 20 (25 per cent) cases of injury including cervical vertebral stenotic myelopathy (CSM – 11 cases), compressive myelopathy (4), occipitoatlantoaxial malformation (2), cervical vertebral osteomyelitis (2) and cervical injury (1). Of the 37 (45 per cent) inflammatory lesions, equine protozoal myeloencephalitis (EPM) was the most common. Organisms were seen in 16 of the 32 cases. There were also 23 (28 per cent) cases of equine degenerative myeloencephalopathy (EDM).

CSM occurred particularly in young male thoroughbreds and horses that were large for their age and breed. They were identified accurately by measuring (on radiographs) the minimum sagittal diameter at the level of each vertebra (it should exceed 16 mm [0.6 in]) and also between adjacent vertebrae in the flexed position (it should exceed 13 mm [0.5 in]).

EDM was characterised by the onset of progressive symmetric ataxia, spasticity and paresis in animals, particularly Arabs, under two years of age. EDM was distinguished from CSM and other conditions with focal lesions because of differences in the patterns of pelvic and thoracic limb gait deficits.

EPM was most frequent in young mature standardbred and thoroughbred horses in the spring and summer. In addition to ataxia and paresis there is frequently acute to chronic progressive asymmetrical defects in the gait and evidence of sensory deficits, loss of reflexes and muscle atrophy. Tetraplegia was associated with severe lesions in the spinal cord or brain stem. The protozoon parasite involved is probably a coccidian; morphological and serological evidence mitigates against the suggestion that EPM is a form of toxoplasmosis.

Horses, Worms in

The following list shows those adult worms regarded as of most importance.

Adult worms in the intestines:
Strongylus edentatus
S. equinus
S. vulgaris
Triodontophorus spp.
Oesophagodontus robustus

Adult worms mainly in other tissues:
Echinococcus granulosus (larval stage)
Dracunculus medinensis
*Draschia megastoma** (larval stages in the skin)
Dictyocaulus arnfieldi
Fasciola spp.
Habronema spp. (larval stages in the skin)

(See ROUNDWORMS; IVERMECTIN; FLUKES AND FLUKE DISEASE; TAPEWORMS.)

* Frequently, but incorrectly, called *Habronema megastoma*.

Horse-Sickness, African (AHS)

This is a NOTIFIABLE DISEASE throughout the EU. It is a viral disease transmitted by midges. In Africa, the species is *Culicoides imicola*; with climate changes, this midge has expanded northwards and the disease is present along the north African coast. *Culicoides nubeculosus* can also transmit the disease, but not so successfully; however, it is able to spread into more temperate areas. It appears likely that the infection could also be spread by local strains of Culicoides. Europe is at risk via the Straits of Gibraltar, the Middle East or the Balkans.

Signs The acute form of the disease is a severe respiratory condition with the horses literally 'drowning in their own juices'. A chronic form is seen as a cardiovascular problem. Subacute forms show both cardiac and respiratory signs.

Treatment All that can be done is to treat the signs.

Prevention Horses must be protected against night-flying insects. Vaccines can be used but they must be prepared from local strains of virus. **NB The statutory surveillance zone around an infected horse is 150 km (about 94 miles): it follows that disease does not have to reach the UK before a surveillance zone has to be established there.**

Horse-Tails, Poisoning by

In different localities and under different conditions there may be considerable variation in the chemical composition of species of *Equisetum*, with results accordingly. It would appear that on the continent of Europe and in Britain, *E. palustre* and *E. sylvaticum* are the most dangerous, and that in America *E. arvense* is most to be feared, particularly when they are fed among hay. (See also BRACKEN POISONING; THIAMIN.)

Hospital-Acquired Disease

(See NOSOCOMIAL; IATROGENIC DISEASE; ANTS (Pharaoh's); SALMONELLOSIS.)

Hounds

(See MEAT, KNACKERS; HOOKWORMS; ORF; BOTULISM; HORSE-MEAT; SALMONELLOSIS; AUJESZKY'S DISEASE.)

House Decorating, Poisoning

Old lead primer can be exposed when woodwork is stripped and this disperses particles of the primer so that the air can become toxic with lead. This can affect all species. Parrots allowed free range in old houses can strip paintwork and ingest toxic amounts of lead. Wood preservatives and woodworm treatments are toxic and can be harmful to pets.

House Fly

(*Musca domestica*) can be a nuisance in animal houses.

House Plants

Poisoning in cats and dogs may be caused by the needles from Christmas trees, holly, mistletoe, laurel, oleander, azalea, lilies, lily-of-the-valley, rhododendron, honeysuckle and hydrangea. Ingestion of dumb cane (*Dieffenbachia* spp.) causes swelling of the mouth and throat and difficulty in breathing.

Housing of Animals

The housing of farm animals is a complex subject. The following is only a synopsis and for detailed information reference should be made to specialist texts. (See also TROPICS, LIVESTOCK PRODUCTION IN THE.)

Two things must be said at the outset. Generally speaking unless housing is excellent, when animals are housed for long periods they are less healthy than those kept outside – when given windbreaks, the possibility of shelter in inclement weather and of shade in summer, the avoidance of muddy conditions and of overstocking. Housing of animals in the past (less so today) can mean overcrowding in dark, damp, draughty or ill-ventilated buildings. Under such conditions disease is almost inevitable – pneumonia or scours in calves; infertility in the bull; agalactia in the sow; mastitis in the dairy cow; respiratory disease in poultry. Parasitic skin conditions such as lice and mange tend to spread in housed animals, as does ringworm in cattle and horses. Some modern and costly buildings still have ventilation defects, leading to condensation inside, which results in ill-health of the housed stock. The use of Yorkshire boarding or gap boarding can obviate both the condensation problem and much of the pneumonia.

The second thing is that, from a health point of view, not every 'development' is an advance. In the past, commercial competition resulted in the overcrowding of chickens to the point where feather-picking has to be counteracted by red lighting or de-beaking. This is being controlled by law.

VetBooks.ir

VetBooks.ir

Conversely the dairy cow has undoubtedly benefited from another dictate of economy – the change from cowshed to the yard-and-parlour system – for instead of being yoked or closely chained for long periods, she is free to move around; and such exercise is in itself important. (See CUBICLES FOR COWS.)

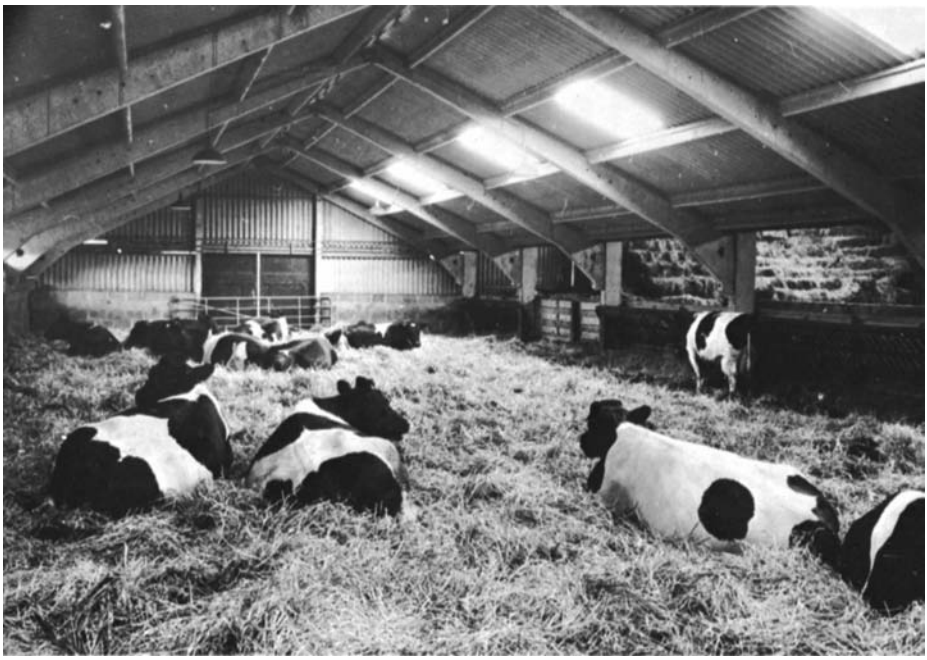
Cattle were housed on slatted floors in England in 1860 – with straw. Their use without straw may lead to welfare problems such as HYGROMATA, damaged teats or injured legs, housing on wholly slatted floors is not recommended and must not be used for dairy cows.

Intensive housing methods have led to development in forced-draught ventilation, and to the efficient insulation of the walls and roof of animal houses. Insulated roofs are not usually used for cattle or calves. Housing for poultry and pigs, however, should have roof insulation as well as wall insulation as these animals have a higher critical temperature than ruminants. (See under CONTROLLED ENVIRONMENT HOUSING.)

It costs over four times as much to keep an animal warm by feeding concentrates – 'an internal fuel' – when compared with warming the livestock house. Minimum economic temperatures are given below.

Housing has an important bearing upon the feeding of animals. Pigs, for instance, confined on concrete have no opportunity for the normal scavenging which can obviate mineral or vitamin deficiencies, and special rations accordingly become necessary for such housed animals. Vitamin A and E deficiencies are particularly likely to occur under these circumstances.

Residual infection is obviously important when considering the housing of animals, and advice is given on this under SALMONELLOSIS and DISINFECTION. In a building used, successively, for calves and pigs, or pigs and turkeys, for example, a cross-infection between the species may arise with a particular strain of *E. coli*. Buildings in which pigs and sheep are housed may harbour ERYSIPELAS; RINGWORM can pass from cattle to sheep, pigs or horses via an infected building. On land surrounding buildings it is worth remembering that the worm *Trichostrongylus axei* is common to cattle, sheep, horses, and goats.



Cattle An open-ridge method of ventilation is still recommended as the best for cowsheds. In winter, the optimum temperature inside appears to be within 6° C and 13° C (44° F and 55° F). Milk yields are said to be depressed when the temperature falls below freezing point. In summer, there is an upper limit of about 25°C (77°F), at which point cattle begin showing distress. High humidity at a temperature above 15.5° C (60° F) appears to diminish milk yield.

For covered yards, ventilators should be provided at the highest point, with a gap of 60 cm (2 ft) between the top of the walls and the eaves.

A dairy unit, with lying area, parlour and dairy under one roof. Note the Yorkshire boarding to the left of the picture — a means of ensuring good ventilation and an absence of condensation.

VetBooks.ir

Cattle on deep litter in a covered yard.

Open-fronted covered yards should not have a gap. About 2 tonnes of straw per cow is required for straw yards in winter.

Pigs Given adequate straw, the most primitive arks on range will yield better results than a cold, damp house. A warm environment will reduce the risk of OVERLYING by the sow. While different optimum temperatures have been given by different research workers, it seems that 21° C (70° F) is about the figure to aim at in the farrowing house. For artificial rearing, a temperature of 30° C (86° F) has been recommended for the first four days. Cold, damp floors result in liver disorders which do not appear in buildings where the pigs have a warm, dry bed. Pregnant sows are better not housed. (See CONCRETE; HYPOTHERMIA.)

For fattening pigs, an optimum temperature would appear to be about 18° C (65° F); 15.5° C (60° F) should be the minimum. Humidity does not appear to have an adverse effect, though few authorities recommend it. Good ventilation is advocated.

Sheep In general, the disease problems associated with the housing of sheep have been less serious than might have been expected, and there is a credit side as well as a debit side. For example, if lambs are born and reared to market weight indoors, there is far less risk of worm infestation causing trouble. It is recommended that pens should not contain more than 15 to 25 ewes, grouped according to lambing dates.

Ewes and hogs housed for the winter after grazing should be wormed during the first week. If it is a liver-fluke area, dosing against flukes is advisable six weeks after housing.

Lambs must be protected against lamb dysentery, and any from unvaccinated ewes should be given antiserum.

Infestation with lice may be aggravated by housing and spread more rapidly. Since it can cause serious loss of condition, dipping or spraying before housing is recommended.

E. coli infections are as much a threat to the housed lamb as to the housed calf. Overcrowding and dirty conditions at lambing predispose to *coli* septicaemia, which is usually a sequel to navel infection. In early weaned lambs, the quality of the milk substitute is important if scouring is to be avoided; measures should be taken to minimise contact between housed sheep and their dung. Slatted floors, regular cleaning, copious use of bedding material and periodical disinfection all help in this direction.

Good ventilation can go a long way towards reducing the risk of acute pneumonia. In lambs and older sheep this is often associated with *Pasteurella* infection, sometimes aggravated by lungworm infestation. *Pasteurella* pneumonia vaccine may be

effective in prevention, but is useless against other forms of pneumonia – which can be caused by other bacteria, moulds and viruses.

Infections which give rise to abortion may prove more troublesome indoors than out, and vaccination against enzootic (*chlamydial*) abortion seems worthwhile. (See also COPPER, POISONING BY and under SHEEP BREEDING AND MANAGEMENT and INTENSIVE LIVESTOCK PRODUCTION.)

Poultry Chickens probably do best at temperatures between 13° C and 18° C (55° F and 65° F). Egg-production declines at temperatures below 5° C (40° F) or above 23° C (75° F). A relative humidity of 50 per cent is considered the optimum for grown birds. A cold, dry house is better than a warm, wet one. Ventilation requirements vary; for example, a bird may need as much as 300 cm^3 (1 cubic ft) per minute per 450 g (1 lb) bodyweight in the hottest weather, but only one-sixth of this in the coldest weather. (See also under CHICKS; NIGHT LIGHTING.)

For other aspects of housing, see under CONCRETE; LEAD POISONING; WOOD PRESERVATIVES; CUBICLES FOR COWS; BULL HOUSING; LOOSE-BOXES; DEEP LITTER FOR POULTRY; INTENSIVE LIVESTOCK PRODUCTION; YORKSHIRE BOARDING; WATER AND WATERING OF ANIMALS.

Exotic Animals Wherever possible housing should mimic their natural habitat.

Rabbits are kept for different purposes: for commercial meat and pelt production; for research purposes; and as pets. Different breeds and strains of breeds are selected for each purpose and their longevity is usually not important if for meat. The keeping of rabbits in laboratories is controlled by legislation. Rabbits kept as pets may create welfare issues as the traditional hutch is often too small to allow proper exercise, skeletal development and health. The aim is to allow plenty of room for exercise and safety from predators (cats, foxes, stoats, weasels and birds of prey). Water should be available in utensils that the rabbit can recognise and operate – some individuals are accustomed to sipper bottles; some to bowls, the latter should be well secured to prevent spillage. The ambient temperature is extremely important — above 25° C is deleterious. Litter is important as unabsorbed urine ferments and produces ammonia to which rabbits are extremely susceptible – odours of ammonia undetected by humans can produce diseases in rabbits. Access to fresh vegetation is necessary, both as a source of nutrition and as environment enrichment.

Reptiles are usually kept as pets and require different facilities, depending on the climate of the regions of origin. This means that they have to be housed in restricted environments – usually purpose-built vivaria, although those from temperate climate zones (e.g. tortoises of the *Testudo* genus) often do well in British gardens, especially those in the south of the country. Facilities in vivaria should include heaters, humidifiers and sources of ultraviolet and/or broad spectrum light. Siting of the vivarium is important as, for example, one placed in direct sunlight may overheat with fatal consequences for the inmate. Hygiene is of paramount importance as the temperature of a vivarium is often the same as that of a bacterial incubator so pathogens can breed in close proximity to the animals and infect them. Prospective reptile owners should make themselves aware of the requirements for keeping them before acquiring a specimen, as the housing facilities and equipment often cost more than the animals themselves and inadequate facilities can lead to disease, fatalities and wasted outlay.

HRQL
(See HEALTH-RELATED QUALITY OF LIFE.)

HSA
(See HUMANE SLAUGHTER ASSOCIATION.)

Huarizo
A cross between a LLAMA and an ALPACA.

Huckleberry Poisoning
(See GARDEN NIGHTSHADE POISONING.)

Humane Destruction of Animals
(See EUTHANASIA.)

Humane Slaughter Association (HSA)
The charity that works in the UK and internationally provides educational, scientific and technical advances on the welfare of farm animals in transport, markets, slaughter and killing for disease control or welfare reasons. Address: The Old School, Brewhouse Hill, Wheathampstead, Hertfordshire, AL4 8AN. Telephone: 01582 831919.

Humerus
Humerus is the bone of the foreleg between the shoulder-joint and the elbow-joint. It has a rounded head which, with the corresponding depression of the scapula, forms the 'ball-and-socket' shoulder-joint. At the opposite extremity it forms with the radius and ulna the hinged elbow-joint.

Humoral Immunity
Humoral immunity is that conferred by the immunoglobulins derived from the B-cells of the

VetBooks.ir

RETICULO-ENDOTHELIAL SYSTEM and is differentiated from cell-mediated immunity associated with T CELLS. (See also IMMUNE RESPONSE; COLOSTRUM; IMMUNOGLOBULINS.)

Humour
Humour is a term applied to any fluid or semi-fluid tissue of the body, e.g. the aqueous and vitreous humours in the eye.

Hungarian Kuvasz
A dog originating in Hungary to guard livestock. It is a strong large (40 kg 50 kg; 90 lb to 110 lb) dog with a thick white coat, small pendulous ears, dark eyes and a medium-sized tail. It is prone to PROGRESSIVE RETINAL ATROPHY (DNA test available).

Hungarian Puli
A breed developed as a sheepdog, which because of the structure of its coat somewhat resembles a long-woolled sheep. RETINAL DYSPLASIA is inherited as a recessive trait. Their registrations in Britain are increasing.

Hungarian Visla
A medium-sized hunting dog with short, reddish-brown coat and pendulous ears. Few genetic defects are known other than haemophilia A which is sex-linked. Congenital GONIODYSGENESIS occurs. (See HAEMOPHILIA; CANINE HAEMOPHILIA.)

Huntaway Dogs
These are large dogs mainly found in New Zealand that have a loud bark and are used for driving sheep and cattle. They are usually black and tan but can be black and weigh 18 kg to 30 kg (40 lb to 65 lb) and about 50 cm to 60 cm (20 in to 24 Iin) high at the shoulder. They are a friendly intelligent dog.

Husk
Husk is a disease of cattle, sheep, and goats characterised by bronchitis, which is caused by lungworms. (See PARASITIC BRONCHITIS.)

Husky
A general name for a dog type which pull sleds and includes the SIBERIAN HUSKY. A muscular, medium-sized dog with a thick double coat. They work in teams and pull sleds in Polar regions and carts in warmer climes. Cart-racing is quite popular; it must not take place on public roads as this would contravene the Protection of Animals Act 1911. Huskies are prone to corneal dystrophy, glaucoma and ventricular heart defects. HAEMOPHILIA and CORNEAL LIPIDOSIS have been recorded.

Hyaline Membranes
A fibrinous exudate from the epithelium which lines the alveoli of the bronchioles, found in stillborn animals and those dying soon after birth. It is also referred to as hyaline membrane disease.

Hyalomma Ticks
A Genus of ticks. Some species have several stages which transmit diseases including *Babesia caballi*, *B. equi*, *Rickettsia bovis*, CONGO VIRUS DISEASE, Crimean Haemorrhagic Disease, and Q FEVER.

Hyaluronate
A mucopolysaccharide used as an injection into the joint to treat arthritis.

Hyaluronidase
An enzyme which breaks down the hyaluronic acid forming part of the material in the interstices of tissue, and so facilitates the rapid distribution and absorption of fluids following a SUBCUTANEOUS or INTRAMUSCULAR injection. It has been used in the treatment of urinary calculi.

H-Y Antigen
This histocompatability antigen is present in the gonads of the bovine freemartin. It causes XX cells in the female gonad to assume testicular organisation. It is responsible for the rejection of male grafts by females of the same species.

Hybrid
At one time this word meant a cross between two inbred lines; now it is used to describe a simple cross between 2 different strains or breeds.

For a comparison between a hybrid and a chimera (with reference to fertile mules), see CHIMERA.

Hybridisation
The production of a HYBRID.

Hybridoma
(See GENETIC ENGINEERING; also under RABIES – Diagnosis.)

Hybrid Vigour
The improved performance produced in the offspring by mating 2 breeds. (See GENETICS, HEREDITY AND BREEDING; BLOOD TYPING, CATTLE; T CELLS.)

Hybu Cig Cymru HCC
The Welsh organisation responsible for the development, promotion and marketing of red meat (beef, lamb, pigs) in Wales. It is supported by a levy on animals killed for meat. It evolved from the MEAT AND LIVESTOCK COMMISSION and is the equivalent of EBLEX and QMS. (See also

ENGLISH BEEF AND LAMB EXECUTIVE; QUALITY MEAT SCOTLAND.)

Hydatid Disease

Hydatid disease is caused by the cystic larval stage of the tapeworm *Echinococcus granulosus*, of which the dog and fox are the usual definitive hosts. Eggs released from tapeworm segments passed in the faeces by these animals are later swallowed by the intermediate hosts, grazing cattle, sheep and horses, which may become infested also through drinking water contaminated by wind-blown eggs.

In Australia an anti-hydatid disease campaign has proved successful; though in New South Wales there is a sylvatic strain which circulates predominantly between wild dogs and wallabies.

Swallowed eggs hatch in the intestines and are carried via the portal vein to the liver. Some remain there, developing into hydatid cysts; others may form cysts in the lungs or occasionally elsewhere, e.g. spleen, kidney, bone marrow cavity, or brain. Inside the cysts, brood capsules, containing the infective stage of the tapeworm, develop, and after five or six months these can infest dog or fox.

People become infested through swallowing eggs attached to inadequately washed vegetables; eggs may possibly be inhaled in dust or carried by flies to uncovered food. The handling of infested dogs is an important source of infection.

In Wales, where the incidence of hydatid disease is relatively high, farm dogs and to some extent foxhounds are important in its spread.

About seven people are known to die from this disease in England and Wales each year – a figure which would probably be higher were diagnosis less difficult. Condemnation of sheep and cattle offal from this cause runs into hundreds of thousands of pounds annually. Routine worming of dogs is essential for control. *E. granulosus* is far from being a typical tapeworm, as it has only three or segments and a total length of a mere 3 mm to 9 mm, so that the dog-owner will not notice the voided segments.

A problem of diagnosis also arises, in that this worm's eggs are indistinguishable from those of *Taenia* tapeworms. Previously, one could dose dogs with arecoline hydrochloride and examine the faeces for the presence of the intact tapeworm, but in Britain this anthelmintic is no longer obtainable, having been replaced by more modern drugs which destroy the tapeworm but leave it unrecognisable.

Equine hydatidosis in Britain is caused by a strain of *E. granulosus* which has become specifically adapted to the horse as its intermediate host, and is often referred to now as *E. granulosus equinus*. This apparently is of low pathenogenicity for man.

In a survey covering 1388 horses and ponies examined at two abattoirs in the north of England, 8.7 per cent were infected. Prevalence of infection was closely related to age – rising from zero in animals up to two years old to over 20 per cent of those over eight years old.

Sixty-six per cent of the infected animals had viable cysts. Prevalence appeared to be greatest in central and north-west England.

Treatment of human patients Hydatid disease has been said to be one of the rare parasitic conditions that can be treated only by surgery. However, the result is often incomplete, with frequent local recurrences or accidents of secondary dissemination. Repeated interventions are often mutilating and do not guarantee a definite cure. Mebendazole has been used successfully in some patients, but is not always effective.

Hydralazine

An arterial dilator, useful in treating dogs with failing heart due to MITRAL REGURGITATION (usually caused by fibrosis of the valve) and left-sided congestive heart failure.

Hydranencephaly

The absence of most or all the cerebral hemispheres in the brain (See BRAIN - PARTS OF THE BRAIN). This can occur in all species and is present at birth. The animals often also have no PITUITARY GLAND and this can lead to an increase in duration of pregnancy. The animal, if born alive, may appear very dull and probably recumbent. They often show the DUMMY syndrome. In cattle it can occur in with AKABANE VIRUS, BLUETONGUE, BOVINE VIRAL DIARRHOEA, SCHMALLENBERG VIRUS. It is rare in dogs and cats.

Hydrargyrum

(See MERCURY.)

Hydraulic Fluid

Intense generalised pruritus was suffered by animals grazing in a field beneath the flight path to an airfield after they ate grass contaminated by hydraulic fluid leaked from an aircraft.

Hydroallantois

An abnormally large accumulation of fluid in the uterus, usually in the last third of pregnancy. The cause is not known but the condition occurs in cows, especially the JERSEY breed, but rarely in mares. Fluid accumulates in the allantoic sac. It results in uterine inertia, DYSTOKIA and usually death or abortion of the fetus.

Hydrocele
The collection of fluid present within the outer proper coat of the testicle (tunica vaginalis) or within the spermatic cord.

Hydrocephalus
Hydrocephalus is a condition in which a large amount of fluid collects within the brain cavity of the skull. It may be present before birth (congenital hydrocephalus), in which case the large size of the head may present an obstruction to parturition. In the congenital form, which is met with in foals, calves and puppies, there is a large prominent swelling over the forehead, and a rounded dome-like cranium. Animals born with this condition are usually dead, or if they are living they die soon after birth. It may become necessary to puncture the swollen skull and evacuate the fluid before delivery can be effected.

In the acquired form, the type usually encountered in the horse and dog, the fluid collects in the ventricles of the brain, or under the meninges, as the result of meningitis, or as an exudate from blood vessels engorged due to a tumour interfering with circulation of cerebrospinal fluid.

When due to meningitis, hydrocephalus is usually an acute condition, and its signs are masked by those of the meningitis. When due to other causes in which there is obstruction to the flow of cerebrospinal fluid it is usually chronic, and the signs are those of pressure on the brain. The animal becomes gradually dull, sleepy, and insensitive to its surroundings. Convulsions may occur, and during one of these death is liable to take place. (See under HELLEBORES.)

Hydrochloric Acid (HCl)
Hydrochloric acid (HCl) is normally present in the gastric juices, usually at about 0.2 per cent. (See DIGESTION, ABSORPTION AND ASSIMILATION.) Concentrated, commercially available HCl is a corrosive poison.

Hydrocyanic Acid (HCN)
Hydrocyanic acid (HCN) and its salts – sodium and potassium cyanide – are among the most deadly poisons, and very rapid in their effects.

Signs If taken by mouth, or given by injection, there is a rapid acceleration of the breathing (and occasionally coughing). A poisoned dog or cat will utter a cry and collapse, the limbs extended fully. There is an odour of bitter almonds on the breath. There may be convulsions. Respiratory failure ensues, and death may occur within seconds.

Hydrocyanic poisoning may occur from the ingestion by grazing animals of plants containing a cyanogenetic glycoside. (See GLYCOSIDES; JAVA BEAN POISONING; LAUREL POISONING.) Poisoning is then less acute, and signs are not always indicative of the cause.

Treatment In acute cases, death occurs in dogs and cats before treatment can begin. If a smaller quantity of the poison has entered the body, or if poisoning is the result of the cyanogenetic glycosides (and this is known in time), an intravenous injection of a 1 per cent solution of sodium nitrite, followed by 25 per cent sodium thiosulphate, has been recommended for the dog and large animals. Repeat doses at half that rate as required.

Hydrogen Peroxide
An antiseptic, with some effect against viruses, due to the release of oxygen. Available as a 3 per cent (10 volume) or 6 per cent (20 volume) solution, it is used, usually diluted, for cleansing the skin and disinfecting wounds. It is unsuitable for the irrigation of cavities or deep wounds. (See OXYGEN - OXYGEN EMBOLISM.)

Hydrolysis
The division of a compound by the addition of water.

Hydromeningocele
A congenital protrusion of the meninges or spinal cord in a sac of fluid through a defect in the skull or spine.

Hydrometra
Another name for pseudopregnancy, it is the accumulation of a watery fluid within the uterus, sometimes sufficient to push other organs aside and to cause swelling of the abdomen of rabbits. This idiopathic condition has also been seen in cats.

Hydromyelocele
A congenital protrusion of a sac containing cerebrospinal fluid and tissue of the spinal cord through a defect in the spine such as a HYDROMYELOMENINGOCELE.

Hydromyelomeningocele
A congenital protrusion of a sac containing cerebrospinal fluid, meninges and tissue of the spinal cord through a defect in the spine.

Hydronephrosis
Hydronephrosis is a condition in which the capsule of the kidney, or even the kidney itself, becomes greatly distended with urine which is unable to pass along the ureter into the urinary bladder owing to some obstruction in that channel, such as calculus, a twist, or owing to the pressure of some organ, tumour or internal abscess, nearby. The kidney swells

VetBooks.ir

in size, and causes pressure upon the surrounding organs with pain over the lumbar region, and in severe cases a bulging of the muscles just behind the last rib. It is treated by either the removal of the whole kidney (provided the other one is healthy), or else by the removal of the obstruction.

Hydropericardium

The accumulation of clear, straw-coloured fluid in the pericardial sac, a swollen and discoloured liver and enlarged kidneys with distended tubules. It can occur in all species, especially small ruminants. In poultry this syndrome (Angaria disease) had a devastating effect on the broiler poultry (three to six weeks old) of Pakistan, with up to 60 per cent mortality.

Cause In poultry an unidentified infectious agent which appears to require the presence of an adenovirus to produce the lesions.

Hydrophobia

RABIES.

Hydroponic Grass

Grass can also be grown artificially in sheds, often with artificial light and in tiered shelving, and is fed to cattle and sheep. It can be used where grazing is limited. Hydroponic grass can also consist of a mat of barley seedlings harvested at the eight-day stage. It has been used for horse feeding, and is usually eaten with relish. It is highly nutritious, very digestible and parasite-free.

Hydrops amnii and Hydrops uteri

(See UTERUS, DISEASES OF.)

Hydrosalpinx

An accumulation of serous fluid in the Fallopian tube. It has been stated to be a common cause of sterility in gilts in America.

Hydrotherapy

It involves baths usually containing warm water and is used for dogs and horses following various musculoskeletal conditions or following surgery. It provides support for the animal whilst allowing movement of the animal and improving circulation. It has been used in cattle with the 'DOWNER COW' SYNDROME.

Hydrothorax

Hydrothorax means a collection of fluid in the chest, i.e. in the pleural cavity. This is one of the results of certain forms of pleurisy or a thoracic tumour.

L-2-Hydroxyglutaric Aciduria

An inherited recessive condition, mainly affecting the central nervous system, present in STAFFORDSHIRE BULL TERRIERS (DNA test available). It is seen as seizures, ataxia, dementia and tremors.

'Hyena Disease'

A condition in cattle in which the hind part of the animal grows more slowly than the fore part, producing a silhouette said to resemble that of a hyena. The cause is unknown but bovine virus diarrhoea has been suggested. It has not been reported in the UK.

Hygiene

(See INFECTION; VENTILATION; HOUSING OF ANIMALS; WATER AND WATERING OF ANIMALS; DIET AND DIETETICS; DISINFECTION; SLURRY.)

Hygroma

(plural, Hygromata)

Hygroma is a swelling occurring in connection with a joint, usually the knee or hock, and mainly the result of repeated bruising against a hard surface. (See CAPPED HOCK.)

Hygroma in cattle may arise through an insufficiency of bedding, or through faulty building design. (See also CALLOSITY.)

Hygroma of the elbow in large dogs can be successfully treated by insertion of a 6 mm diameter Penrose drain passed through incisions made dorsally and ventrally into the hygroma, and secured firmly to the skin at each end. Dressings are changed every four to five days, and the drain taken out after two or three weeks.

Hygromycin B

An antibiotic used in the USA as an anthelmintic, and claimed to be effective against large roundworms and whipworms.

Hymen, Imperforate

Imperforate hymen in thoroughbred fillies, with consequent accumulation of fluid in the uterus, has led to signs varying from acute abdominal pain, sweating, and attempts to lie down and roll, to discomfort when urinating. Immediate relief followed necessary surgery in the more serious cases. Pulse and respiration rates returned to normal within 10 minutes, with feeding resumed. (See also 'WHITE HEIFER DISEASE'.)

Hymenolepis nana

(See 'DWARF TAPEWORM'.)

Hyoid

Hyoid is the name of the bone which gives support to the root of the tongue and to the larynx. It has some similarity to the letter 'U'.

Hyostrongylus rubidus
A parasitic worm of pigs.

Hyper-
Hyper- is a prefix indicating excess.

Hyperadrenocorticism
The condition is seen in humans, dogs (common) and cats; cortisol has an important role in the cause. It is also a common condition in ferrets, where the adrenocortical sex hormones are involved. (See CUSHING'S SYNDROME.)

Hyperaemia
Congestion. An excessive amount of blood in a part of the body.

Hyperaesthesia
Oversensitivity to bright light, sudden noise or touch. It occurs in diseases such as rabies, tetanus, feline HYPERTHYROIDISM and hypomagnesaemia. It is the main consistent clinical sign in bovine spongiform encephalopathy (BSE).

Feline hyperaesthesia may result also from poisoning by, for example, benzoic acid.

Signs Aggressiveness, excitement.

Hyperbaric
(See OXYGEN.)

Hypercalcaemia
An excess of calcium in the blood.

Causes In dogs these include cancer, an excess of vitamin D, destructive bone (osteolytic) lesions, kidney failure, excess parathyroid hormone and Addison's disease. Less common diseases are associated with chronic inflammatory (granulomatous) conditions e.g. blastomycosis are associated with hypercalcaemia.

Clinical signs Typically increased thirst, but signs associated with the underlying disease may predominate.

Hypercapnia
The presence in the blood of a raised level of carbon dioxide.

Hyperchlorhydria
Hyperchlorhydria is a form of indigestion associated with excessive secretion of hydrochloric acid.

Hyperchromatism, Hyperchromatosis; (adjective, Hyperchromatic)
This has several definitions, including excessive pigmentation; a degeneration of the nuclei of cells which then become filled with particles of pigment or chromatin; increased staining capacity. An excess of iron in the liver of certain birds, especially mynahs and toucans results in hyperchromatism.

Hyperchylomicronaemia-Associated Neuropathy
An autosomal recessive trait seen in cats usually over eight years old. Affected animals have HYPERLIPAEMIA on fasting, lipaemia retinalis (milky appearance of retinal blood vessels) and peripheral neuropathy.

Hyperglycaemia
An excess of sugar in the blood. (See DIABETES MELLITUS.)

Hyper-Immune Serum
The serum of an animal which has been hyper-immunised by repeated injections of a toxin or vaccine. It is rich in antibodies, and is used for curative treatment of, e.g., tetanus.

Hyperinsulinaemia, Hyperinsulinemia (US)
Increased circulating levels of INSULIN. It is seen in various metabolic problems such as DIABETES MELLITUS, EQUINE METABOLIC SYNDROME.

Hyperkalaemia
High concentration of potassium in the blood.

Hyperkeratosis
Hyperkeratosis is an excess of horn or KERATIN. It may be normal or pathological.

Cause In cattle, the disease has been caused by poisoning by minute quantities of chlorinated naphthalene compounds (and possibly other chemical substances also). These are found in many wood-preserving compounds in insecticides, lubricants and electrical insulation material. These substances bring about a secondary vitamin A deficiency. In America the disease has followed the feeding of pellets prepared by machinery lubricated with grease or oil containing naphthalene compounds – an indication of the minute quantities sufficient to cause trouble. Usually, however, the disease is a sequel to housing stock in recently creosoted buildings. Similar skin lesions can be observed in cage birds on diets deficient in vitamin A, but more commonly it affects the lining of gland ducts such as salivary and lacrimal glands. (For the disease in pigs, see also ZINC and CALCIUM SUPPLEMENTS.)

Signs A thickening of the skin, sometimes with loss of hair, on neck and shoulders. In calves, stunted growth, a discharge from the eye (often

VetBooks.ir

VetBooks.ir

with a corneal opacity), frothing at the mouth, weakness and emaciation occur, and death may precede any obvious skin changes. EPIPHORA and intra-oral swellings are observed in birds.

Treatment Vitamin A will assist recovery.

Hyperkinesis

Overactivity that may be caused by dietary or environmental factors. It can be accompanied by aggression, especially in the reaction to attempted restraint (e.g. putting a dog on a lead). The heart and respiratory rates may increase; sedation may be a temporary measure. Expert evaluation of the diet may be necessary and the animal may have to be referred to an animal behaviour specialist.

Hyperlipaemia

An excess of lipids in the blood, which can be fatal in ponies and donkeys. It was first reported in Europe, then in Australia. Mares are affected in late pregnancy or early lactation.

Signs Depression, weakness, loss of appetite, diarrhoea and terminal convulsions.

Autopsy findings: liver much enlarged, yellow and friable.

Hypermetria

A high-stepping gait. (See COENURIOSIS.)

Hyperostosis

Increased calcification and ossification, usually involving the soft tissues adjacent to bones.

Hyperoxaluria

An excess of oxalates in the urine. This accompanies L-glyceric aciduria in kidney disease of kittens five to nine months old.

Acute kidney failure develops together with atrophy of nerves supplying muscles.

Signs Extreme weakness, affecting standing and walking.

Cause A recessive gene.

Hyperparathyroidism

A condition of abnormally increased activity of the PARATHYROID GLANDS. Primary parathyroidism is due to diseases of the gland, particularly neoplasia (see NEOPLASM). Secondary parathyroidism is usually nutritional in origin and due to a deficiency of calcium or an excess of phosphorus in the diet. This latter form is common in cage birds fed a poorly balanced seed-based diet.

Signs Thirst, listlessness, weakness, loss of appetite.

Hyperparathyroidism, Nutritional Secondary

(See CANINE and FELINE JUVENILE OSTEODYSTROPHY.)

Hyperplasia

Hyperplasia is the term applied to an abnormally large development of some organ or tissue. (See HYPERTROPHY.)

Hyperplastic Gingivitis

The abnormal increase in the gum tissues. It is seen mainly in dogs and is common in BOXERS.

Hyperpotassaemia

Too high a level of potassium in the bloodstream. This may be brought about artificially, with fatal results, by the mistaken use of potassium iodide intravenously instead of sodium iodide.

Hyperpyrexia

Hyperpyrexia means a high degree of fever. (See FEVER; TEMPERATURE, BODY.)

Hypersensitivity

Once an animal has been 'primed' or sensitised by an antigen, further contact with this will boost the immune response – but may also provoke tissue-damaging reactions. (See IMMUNE RESPONSE; ALLERGY; PENICILLIN, SENSITIVITY TO; ANAPHYLAXIS; SERUM SICKNESS; 'SWEET ITCH'.)

Hypersexuality

Hypersexuality is usually found in males with excessive testosterone production; it may also be the result of a malfunction of the cerebral cortex. Administration of short-acting progesterones may help diagnosis but, long term, castration is often the answer.

Hypertension

High arterial blood pressure. In dogs, kidney disease is the most common cause of hypertension. In cats the most common cause is HYPERTHYROIDISM.

Signs Detachment of the retina, or bleeding from it, may be the first indication. The animal may suddenly go blind. Long-term effects may include enlargement of the heart, and kidney failure.

Hyperthermia

A body temperature greatly in excess of the normal, as occurs in fevers. It can arise because of high environmental temperatures (HEAT-STROKE), following strenuous exercise, and in cases of sensitivity to certain inhaled anaesthetics (see HYPERTHERMIA, MALIGNANT). When body temperatures reach an excessively high level, e.g.

41.5° C (107° F) tissues and organs can be damaged, while if it exceeds 42° C or 42.5° C (108° F or 109° F) for any length of time death invariably occurs. (See also FEVER.)

Hyperthermia, Malignant

When some dogs of the Great Dane breed, some pigs of the Piétrain breed, and some human beings (about 1 in every 10,000 people) are anaesthetised with halothane, their body temperature rises to a point at which, unless the anaesthesia is discontinued, the hyperthermia is likely to prove fatal.

Hyperthermia may occur in animals poisoned by chlorinated hydrocarbon insecticides. (See also HEAT-STROKE; TROPICS, LIVESTOCK PRODUCTION IN THE; FEVER.)

Malignant hyperthermia may also develop as a result of stress.

Hyperthyroidism

Overactivity of the THYROID GLAND. A common occurrence in elderly cats in which the main clinical signs are exaggerated responses in external stimuli, a greatly increased appetite, and marked loss of weight. As other geriatric dysfunctions (e.g. chronic RENAL FAILURE) frequently accompany the condition, the animal's condition should be assessed by a series of blood tests and treatment dispensed accordingly. METHIMAZOLE and THIAMAZOLE are licensed for medication of these animals but total thyroidectomy is sometimes preferred. Radioactive destruction of the gland is also performed but requires specialised facilities. IODINE restricted diets can be helpful.

Hypertonic

(See under ISOTONIC.)

Hypertrophic Cardiomyopathy

A thickening of the heart muscle (MYOCARDIUM). It can arise from defects within the muscle, a common scenario in cats including the PERSIAN CAT, RAGDOLL cat and SPHYNX CAT. In the second form of hypertrophy, the ventricles are dilated and enlarged, but wall thickness is not greatly increased. This occurs when the heart starts to fail and tries to compensate, and also in diseases of the heart muscle itself (dilated CARDIOMYOPATHY).

Hypertrophic Osteopathy, Marie's Disease

This was first described in man in 1890. It has been reported in the dog (see also ACROPACHIA) and in the horse. In Africa, the roundworm *Spirocerca lupi* has been reported as associated with the condition in the dog.

In the dog the disease takes the form of a non-oedematous swelling of all 4 legs. It is associated with tumours of the lung. Severing of the vagus nerve has been recommended in cases (the majority) where surgical removal of the lung lesions is not possible, and has led to a reduction of the bone enlargement in the limbs, and of the swelling, pain, and lameness. Euthanasia may, of course, be preferable.

Hypertrophic Pododermatitis

Inflammation of the skin of the foot and often the term is used to describe EQUINE CANKER, where usually the frog is first affected.

Hypertrophic Polyneuropathy

This is sometimes seen in cats at about one year old in animals having tremors, mild sensory loss, decreased postural reactions and reduced response to stimuli (hyporeflexia).

Hypertrophy
(adjective, Hypertrophic)

Hypertrophy means extra size or development of an organ or tissue in response to natural causes or to failure of an associated organ.

In certain valvular diseases of the heart when obstruction to the free flow of blood occurs, the muscle wall of the heart becomes increased in thickness and strength, and a compensation results. In the training of horses the trainer aims at getting the maximum efficiency from the skeletal muscles, which under the influence of judicious training and feeding become hypertrophied.

After one organ of a pair has been removed – as, for instance, the kidney or the ovary – the remaining organ becomes increased in size so as to be able to perform practically the same amount of work as was previously done by the pair. (See HYPERPLASIA.)

Hyperuricosuria

A condition in which there is excessive uric acid in the urine; it is seen in BULLDOGS, DALMATIANS, LARGE MUNSTERLANDER and RUSSIAN BLACK TERRIER. There is a DNA test for the condition.

Hypervitaminosis

Disease associated with an excess of a particular vitamin. For example, chronic hypervitaminosis A occurs in cats fed exclusively, or virtually so, on an all-liver diet. Cleft palates in rats and possibly in puppies and kittens may result when their dams are fed high vitamin A levels in the first third of pregnancy. (See under CAT FOODS.)

Hyphaemia

An infusion of blood (haemorrhage) into the anterior chamber of the eye.

Hypo-

Hypo- is a prefix indicating a deficiency.

VetBooks.ir

Hypoadrenocorticism
(See ADDISON'S DISEASE.)

Hypoalbuminaemia
A low level of albumin in the blood. It may be indicative of kidney or liver disease, or malnutrition.

Hypocalcaemia
An insufficiency of blood calcium. Seen in cattle and sheep, it occurs in all species including mares and bitches. The signs are a stiff gait, with the hind legs placed forward when standing still, trismus and dyspnoea.

For hypocalcaemic tetany in cage-birds see FITS. (See MILK FEVER; TRANSIT TETANY; LAMBING SICKNESS IN EWES; ECLAMPSIA; METABOLIC PROFILE TESTS.)

Hypochlorites
Effective disinfectants widely used in milking machines, dairy equipment and food premises; preparations are marketed under a number of trade names. They leave no persistent odour or taint. Their efficacy depends upon the amount of available chlorine, which is more active against viruses than most disinfectants. Hypochlorites are unable to penetrate grease and so they are often combined with detergents. Sodium hypochlorite is useful for disinfecting premises after an outbreak of a virus disease. It is a disinfectant of choice where TUBERCULOSIS is present. (See also TEAT DIPPING.)

Hypocretin
(See OREXIN.)

Hypocupraemia
A condition in which there is too little copper in the bloodstream. This occurs in SWAYBACK in lambs, and is also associated with serious ill-health in cattle. On the Shropshire–Cheshire border, for example, hypocupraemia is accompanied by scouring and stunted growth. Two-year-old heifers have been mistaken for eight-month-old calves. In Caithness, hypocupraemia is liable to occur on 75 per cent of the farms unless precautions are taken. Scouring is not a common sign there but calves of the beef breeds show a stilted gait and progressive unthriftiness. (See also COPPER.)

Hypocuprosis
A disease caused by a copper deficiency. (See HYPOCUPRAEMIA and COPPER.)

Hypodermic
(See INJECTIONS.)

Hypoglossal Nerve
The hypoglossal nerve is the 12th cranial nerve and supplies the muscles of the tongue, together with others nearby.

Hypoglycaemia
Hypoglycaemia is a deficiency of sugar in the blood. It causes acetonaemia in ruminants and pregnancy toxaemia in sheep. It may occur in states of starvation, but is of special importance in connection with the administration of insulin, which is injected to lower the blood sugar from an abnormal amount and which, if given in too large a dose, may produce too great a reduction with signs of nervousness, breathlessness and excitement. In human medicine hypoglycaemia may be a sequel to the use of sulfonamides, e.g. sulfadiazine. These signs are relieved by taking some food containing sugar and by an injection of adrenaline, which checks the action of insulin.

Hypokalaemia
A deficiency of potassium in the blood. (See 'DOWNER COW' SYNDROME.)

In cats, hypokalaemia may be associated with kidney disease and results in weakness, the neck bending downwards. It is seen in the BURMESE.

Hypomagnesaemia
Also known as 'grass staggers' or Hereford disease, it is caused by too little magnesium in the bloodstream.

Hypomagnesaemia is of particular importance in cattle. It occurs when a herd is turned on to lush spring grass after being stall-fed during the winter, and often follows a frosty or wet spell; an interval of a few days may elapse before signs appear. The problem is particularly common where potash (potassium) and nitrogen fertilisers have been used, but the causes are complex. Low sodium and fibre intakes also exacerbate the problem. The low blood magnesium often results from a reduced intake of magnesium, while the absorption of that mineral is inhibited by the presence of potash and the rapid movement of feed through the gut. Hypomagnesaemia can also occur in the autumn in dry cows or suckler cows at grass and not receiving supplementary feed.

Hypomagnesaemia has apparently been more common in the Ayrshire than in other British breeds of cattle. Cows which have had several calves are more prone to it than heifers.

It is more common in ewes in the first four weeks after lambing than before lambing. Magnesium absorption is usually about 20 per cent, but can be as low as 10 per cent in cows and sheep.

In calves, hypomagnesaemia can occur where the diet consists mainly of milk, which is not by

itself an adequate source of magnesium for a rapidly growing young animal. The condition is thus seen mainly in suckler calves and those being reared for veal. (See OMASUM.)

Signs Animals are often recumbent; if on their sides, they paddle with their legs when stimulated, the head extends backwards and they froth at the mouth and defecate. The heart rate, which is rapid, may be heard several paces from the animal. Unless treated early they often die. If not recumbent, shivering, a staggering gait, excitement, convulsions and paralysis may precede death. In less acute cases, the animals appear 'nervy' – responding violently to sensations of touch or sound – and there may be muscular tremors.

Treatment This must be prompt. A 25 per cent solution of magnesium sulphate is given subcutaneously. Intravenous injection may kill the animal; if it is used intravenously, magnesium should be given combined with calcium borogluconate. Great care is necessary, however, in giving the injection and even approaching the animal – which may otherwise die at the prick of the needle.

An enema of up to 5 tablespoonfuls of magnesium chloride in 250 ml of warm water is recommended by the Tennessee State University.

Magnesium can also be given in the drinking water, using a proprietary product.

Prevention The feeding of magnesium-rich supplements three weeks before early spring grazing and for up to six weeks after turnout or, in sheep, the use of a magnesium lick, from a month after service till a month after lambing. (For adult cattle producing 25 litres of milk absorbing 20 per cent of magnesium, a daily dose of 60 g (2 oz) per head of calcined magnesite, mixed with damp sugarbeet pulp, is recommended.) A cow producing 40 l (nearly 9 gal) will require 40 g (1.3 oz) daily. A mixture of magnesium acetate solution and molasses may be offered ad lib from ball feeders on pasture, as an alternative. Magnesium 'bullets' are also used but only release 2 g to 3 g (1/15 oz to 1/10 oz) daily. Top-dressing pasture with calcined magnesite is helpful. (See MAGNESIUM; MILK FEVER.) Magnesium can also be given in the drinking water; proprietary preparations are available.

Hypomyelinogenesis

An inadequate synthesis of myelin, which provides a coating around the axons of some nerves. This can result from a complete failure of myelin formation or incomplete or delayed myelination. It can be the result of inherited conditions, nutritional deficiencies or viral infections. It is seen in many species including calves, sheep and dogs, where it is particularly seen in the BERNESE MOUNTAIN DOGS.

Hypomyelinogenesis Congenita in Calves

A condition which is often the result of BOVINE VIRAL DIARRHOEA virus infection in the early stages of the dam's pregnancy. Such calves usually cannot rise, they have muscular tremors with periods of spasticity. At post-mortem examination there is no, or reduced, myelin present on the cerebellum and brain stem.

Hypomyelinogenesis Congenita in Sheep

A congenital disease of lambs, characterised by trembling or twitching, staggering, and sometimes shaking of the head.

Hyponatraemia

A deficiency of sodium in the blood.

Hypophosphataemia

A condition in which the level of blood phosphorus is too low. (See MILK FEVER; 'DOWNER COW' SYNDROME.)

Hypophysectomy

The removal of the pituitary gland.

Hypophysis

The pituitary gland.

Hypopigmentation

A lack of skin pigmentation.

Hypoplasia

Under-development. Hypoplasia of the genital organs is a cause of sterility.

Hypotension

Low arterial blood pressure. It is not common in animals except following shock, for example after an accident.

Hypotensive Drugs

Hypotensive drugs are those which reduce blood pressure.

Hypothalamus

A part of the brain below the thalamus which acts as a thermostat, maintaining body temperature. It also influences blood circulation, urinary secretion, and appetite. (See BRAIN.)

Hypothermia

(adjective, Hypothermic)

An abnormally low body temperature; it is a common cause of lamb mortality. It can be caused by exposure in the first few hours after birth or, after about 12 hours, because of starvation. Affected lambs should be warmed; starved lambs

must receive food or 20 per cent solution of glucose, injected intraperitoneally, before warming.

Piglets are also susceptible to hypothermia and will often die if creep areas are not adequately heated. (See OVERLYING; HOUSING OF ANIMALS.)

Hypothermia is a real hazard in small animals under general anaesthesia, especially rodents and small birds, as the body thermostats are less able to counteract a lowered body core temperature encountered in these circumstances.

Hypothermia, Accidental

The chilling of newborn animals, or of those under a general anaesthetic, is a life-threatening condition. Post-anaesthetic hypothermia is very common in cats. The smaller the animal, the larger the external surface area and the greater the likelihood of heat loss. Warmth is essential. (See also under SHEEP BREEDING AND MANAGEMENT; HOUSING OF ANIMALS; 'FADING' PUPPY SYNDROME.)

Hypothyroidism

A condition caused by underactivity of the thyroid gland. It is not uncommon in dogs and causes lethargy, weight gain and also alopecia. It is treated by isomers of THYROXINE. It is associated in cattle with a high incidence of aborted, stillborn or weakly calves. (See also GOITRE.)

Hypovolaemia

A diminished volume of blood. (See SHOCK.)

Hypoxanthine

A precursor of XANTHINE and is an intermediate product in URIC ACID synthesis formed from adenylic acid.

Hypoxia

A reduced level of oxygen-supply to the body tissues. It can occur in newborn animals deprived of oxygen during birth. The animal is dull and weak, often unable to suck.

Hysterectomy

A surgical operation for removal of the uterus. Usually the ovaries are removed at the same time. (See OVARIO-HYSTERECTOMY.)

Hysteria, Canine

A decline of this condition in the UK has been attributed to the abandonment of the use of agenised flour in the manufacture of dog biscuits. (The agene process involved the bleaching of flour with nitrogen chloride.)

It has been suggested that some cases may have been due to the use of flour, containing the spores of *Tilletia tritici*, in dog-biscuit manufacture.

Signs The dog would suddenly 'appear to go mad', racing round with a fixed stare, barking or howling.

(For distemper-like signs, see MENINGITIS.)

VetBooks.ir

IAD
(See INFLAMMATORY AIRWAY DISEASE.)

IAH
(See INSTITUTE OF ANIMAL HEALTH.)

Iatrogenic
This is an adjective describing a problem or illness resulting in an adverse outcome as a result of an intervention or advice of a physician or from a medicine prescribed by a physician. It is sometimes used to describe a reaction to any medicine, whether or not prescribed. (See also NOSOCOMIAL.)

Iatrogenic Disease
Any illness resulting from treatment, such as the side-effects of some drugs or unexpected reaction to surgery. In many cases it results from an abnormal natural metabolism reaction of the animal. This is one of the main reasons why owners are required to give informed consent prior to any surgical procedure. (See also GLOVES, SURGICAL, SIDE-EFFECTS; DRUG INTERACTIONS.)

Ibafloxacin
A fluoroquinolone antibiotic administered as a gel orally in the treatment of infectious dermatitis and infected wounds in dogs and cats.

IBD, IBS
(See INFLAMMATORY BOWEL DISEASE.)

IBK, IBKC
Infectious bovine keratitis (infectious ophthalmia of cattle) or infectious bovine keratoconjunctivitis. (See EYE, DISEASES AND INJURIES OF.)

IBR
Infectious bovine rhinotracheitis. (See RHINOTRACHEITIS, INFECTIOUS BOVINE.)

Ibuprofen
A non-steroidal anti-inflammatory drug, much used in human medicine. It has a narrow margin of safety in dogs, in which it can cause a sometimes fatal gastric ulceration. Ibuprofen is palatable and attractive to dogs, which can be poisoned by consuming their owner's medication.

ICC
(See INTERNATIONAL CAT CARE.)

Ice Cubes
Of use in cases of haemorrhage from the stomach, as an aid to control bleeding from wounds, and as an application in cases of meningitis and paraphimosis; also in cases of hyperthermia and sunstroke.

Icelandic Horses/Ponies
These are usually ponies (no more than 14.2 HANDS [1.42 m] high) but some may be taller, and they have many colours. They are unusual in that they have a fifth pace of movement called a TOLT, which is between a trot and a canter.

Icelandic Pneumonia
(See PULMONARY ADENOMATOSIS; also MAEDI/VISNA.)

Ichthyophonus
A fungus that usually infects marine fish but is pathogenic to salmon in both sea and fresh water. It is caused by feeding salmon infected dead fish which have not been processed properly.

Ichthyophthirius
(See WHITE SPOT OF FISH.)

Ichthyosis
Fish scale disease. A rare skin disease reported in many species including cattle, pigs and dogs. The skin is extensively thickened, scaly and SEBORRHOEIC. It may be seen at birth, indicating a genetic defect, but there are many other causes. In some cases in dogs, large irregular cracks may appear, especially over the elbow and hocks. These become filled with dirt, and infection can result. Combined ichthyosis and KERATOCONJUNCTIVITIS SICCA are seen in CAVALIER KING CHARLES SPANIELS and probably occur as a recessive condition.

Icterus
(See JAUNDICE.)

Identical Twins
The result of a fertilised egg dividing after fertilisation. The animals are thus HOMOZYGOUS.

Identification of Animals
An electronically coded microchip, the size of a grain of rice, encased in implant-grade glass, is often inserted in the loose skin of the neck of mammals (under local anaesthesia), in various sites in tortoises, and the pectoral muscles of birds.

The microchip is encoded with a unique number linked to the animal-owner's address, etc., kept on a central computer register. Electronic scanners ('readers') are used to read the data in the chips.

VetBooks.ir

A database of animals with an Identichip is kept, under the name Anibase, by Animalcare Ltd, of Common Road, Dunnington, York YO1 SRU (See also MICROCHIPS; HORSES, IDENTIFICATION OF.)

Identification of Birds and Reptiles

Identification of exotic birds is difficult as individuals of each species all look the same! The insertion of an electronic transponder is the preferred method. There is a legal and economic necessity for correct identification of individuals.

Identification of Cattle

This is controlled by law in the UK. The Bovine Animals (Records, Identification and Movement) Order 1995, as amended by the Cattle Identification (Amendment) Regulations 1999 and the Cattle (Identification of Older Animals) Regulations 2000, requires that all cattle be identified by an ear tag in each ear. Each animal must have a CATTLE PASSPORT that must accompany it wherever it goes and in which the following details must be entered: date of movement on to a particular holding, or date of birth on the holding; ear tag number; breed; sex; dam's identification number (replacement ear tag where applicable). When the animal is moved off a holding, its age or date of birth, the holding from which it is moved, and that to which it is moved are recorded. Ear tags must be applied to dairy cattle within 36 hours of birth and, in other cattle, within 30 days of birth.

Identification of Dogs

All dogs in the UK will be required to be microchipped, and from 6 April 2016, owners found without such identification by local authorities or the police could be fined. This should allow better owner identity, and was aimed to reduce stray dogs, improve welfare, identify wandering dogs and reduce thefts. (See also MICROCHIPS.)

Identification of Goats

(See IDENTIFICATION OF SHEEP, GOATS.)

Identification of Horses

Under the Horse Passports Order 2004, as amended, each horse must have a passport prepared as specified. The document must be in French and English. Details of the individual horse are given and a silhouette of the animal is filled in with the markings. Information of vaccinations and dates of administration must also be stated in the passport. There is also provision for the results of veterinary examinations to be included and signed by the veterinary surgeon in charge of an event in which the horse is entered, or when the animal is about to undertake a journey. (See also HORSES, IDENTIFICATION OF.)

Identification of Pigs

All pigs must be identifiable to the premises of origin, under regulations set out in the Pigs (Records, Identification and Movement) Order 1995. Breeding stock are usually ear-tagged before leaving the breeding farm. Pigs for slaughter are usually identified by a slap mark; those travelling across an EU frontier must be ear-tagged. Records must be kept of pigs born on a holding. Very strict measures have been taken to control disease transmission, because many viruses multiply rapidly in an infected pig and the quantity of virus shed can be much more than is the case with cattle, sheep or goats with the same infection. All movements of pigs must be recorded in a specified manner. Regulations set out the format for the declaration of pigs moved off a holding, moved from a farm for breeding, exhibition, artificial insemination or veterinary treatment, and returned to the farm after having left it for breeding purposes. The form of declaration is also specified for the movement off a farm of pigs that have been fed waste food (NB feeding of catering waste, including swill, is banned), and for those moved from a collection centre to a farm. Pigs must not be moved to an abattoir within 72 hours of their arrival on a holding; normally, pigs can only be moved after at least 20 days.

Identification of Sheep, Goats

Identification of sheep is controlled by the Sheep and Goats (Records, Identification and Movement (England)) Order 2009 with similar legislation in Scotland, Wales and Northern Ireland. All sheep and goats unless slaughtered before 12 months old (one tag then allowed), must be identified in two ways approved by the national government, one of which must be an ear tag. The permitted second means of identification can be a second ear tag, a tattoo spread between both ears, an approved design pastern tag or electronic bolus. These devices must be in place by nine months old or, if the sheep/goats are housed, by six months old. In sheep, but not goats, one of the identifiers must be of an electronic type. There are detailed rules about what must be done if an identifier is lost and what colour of tag must be used and in what circumstances. The ear tags are colour-coded, tags with electronic I/D, other I/D tags can be any other colour than red, yellow or black. Red is used for replacement tags, black when a bolus. The detail of the Order continues to be refined in the light of new developments. Animals must be marked before they are moved off the holding where they were born.

VetBooks.ir

Idiopathic
Idiopathic is a term applied to diseases where their cause is unknown.

Idiopathic Colitis
A condition in dogs often resulting in chronic DIARRHOEA, and often treated with SULFASALAZINE.

Idiopathic Cystitis
(See FELINE LOWER URINARY TRACT DISEASE.)

Idiopathic Feline Vestibular Syndrome (IFVS)
(See under FELINE VESTIBULAR SYNDROME, IDIOPATHIC.)

Idiopathic Haemorrhagic Diathesis
(See BOVINE NEONATAL PANCYTOPENIA.)

Idiopathic Hippocampal Necrosis in Cats
(See FELINE HIPPOCAMPAL NECROSIS.)

Idiopathic Skeletal Hyperostosis
An unusual condition seen in dogs and of unknown cause. It involves calcification and ossification of the skeletal tissues. It is also called Disseminated Idiopathic Skeletal Hyperostosis (DISH).

Idiosyncrasy
An atypical reaction to a drug or to a food; in a behavioural sense, a quirk.

IFAW
(See INTERNATIONAL FUND FOR ANIMAL WELFARE.)

IgA, IgE, IgG and IgM
IgA, IgE, IgG and IgM are antibody/immunoglobulins found in the blood serum and also in secretions from mucous membranes. (See IMMUNOGLOBULINS; SECRETORY IGA.)

IgR
(See INSECT GROWTH REGULATOR.)

Iguana
A large lizard (*Iguana iguana*) from Central America popular as a pet (or as a food item in Japan). It requires special husbandry facilities including a source of heat and humidity and a basking area irradiated with ultraviolet light. It can perform AUTOTOMY so the tail should not be grasped when handled – one hand should be placed over the pectoral girdle, the other hand should be placed over the pelvic girdle before encircling the torso with the fingers. (See REPTILES; HOUSING OF ANIMALS - REPTILES.)

Ile De France
A French breed of sheep.

Ileitis
Inflammation of the ileum.

'Ileitis' in Pigs The name commonly used to refer to PORCINE INTESTINAL ADENOMATOSIS (PIA) caused by *Lawsonia intracellularis*. (See also HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Ileocaecal
Ileocaecal refers to the junction between ileum and caecum, between the end of the small intestine and the commencement of the large. The so-called ileocaecal valve is formed by the caecum in such a manner that while food material may readily travel from ileum into caecum, it is difficult for it to pass in the opposite direction.

Ileocaecal Junction
The junction between the ileum, caecum and colon. In LAGOMORPHS this is a more complex area than in other mammals as food particles are distributed between the colon and caecum according to size.

Ileum
The ileum is the last arbitrary division of the small intestine.

Inflammation of the ileum – which becomes thickened and stiff, almost like a piece of rubber hose – is a cause of death in piglets two to four months old. In pigs, foals and hamsters inflammation is often caused by *Lawsonia intracellularis* and in pigs it has increased following the ban on antibiotic growth promoters. There is foetid diarrhoea, dehydration, some evidence of abdominal pain and, in severe cases, rectal prolapse. Antibiotics can be helpful, care must be observed in their use in hamsters. A vaccine can be effective in pigs. (See INTESTINES.)

It has been suggested that there is a hereditary predisposition to this condition, which often affects the whole litter. In many instances, the trouble is recognised only at the bacon factory, having caused no apparent illness in the pigs. Those that die, on the other hand, do so from perforating ulcers and peritonitis, after showing evidence of thirst, a bluish colour of the skin, and collapse. (See PORCINE INTESTINAL ADENOMATOSIS.) A 'rosy' inflammation of the ileum is seen in cases of FELINE INFECTIOUS ENTERITIS.

Inflammation of the ileum is the main cause of 'WET TAIL' IN HAMSTERS.

Ileus
The intestinal obstruction which can follow failure of PERISTALSIS. A common sequel to gastrointestinal disease in small herbivorous mammals.

Ilex
(See HOLLY.)

Iliac
Relating to the flank. (See ARTERIES.)

Ilium
Ilium is the anatomical name for the haunch-bone, the outer angle of which forms the 'point of the hip'. The ilium is the largest and most anteriorly situated bone of the pelvis. (See BONE.)

I/M, i/m or im
Short for intramuscular; usually refers to the route of an injection.

Imbalance
A term used to describe, for example, a faulty calcium to phosphorus ratio in the food of an animal, or an excess of one hormone in the bloodstream, or a deficiency of another – with resulting disease. (See RICKETS; INFERTILITY; METABOLIC PROFILE TESTS; CALCIUM SUPPLEMENTS; DOGS' DIET.)

Imepitoin
A treatment for primary canine EPILEPSY. By reducing the positive charge on a NEURON it lowers conductivity and it passes easily across the BLOOD-BRAIN BARRIER.

Imidacloprid
An insecticide applied to the skin at the back of the neck in cats and between the shoulder blades of dogs to control external parasites especially fleas. It can be used in rabbits.

Imidapril
It is an angiotensin converting enzyme inhibitor (ACE) used for moderate or severe heart failure in dogs caused by mitral regurgitation or dilated cardiomyopathy. It increases vasodilation.

Imidazoline Compounds
These are human over-the-counter preparations used as ophthalmic solutions and nasal sprays and often as DECONGESTANTS. They include nephazoline, oxymetazoline, tetrahydrozoline and xylometazoline. They are alpha-2 adrenergic agonists and act on the gastrointestinal tract, cardiovascular system and nervous systems often resulting in toxicity, especially in young dogs. Signs are about 30 minutes after use and include vomiting, slow heart rate, initial hypertension, DEPRESSION, HYPOTHERMIA, panting and weakness.

Imidocarb dipropionate
A drug used for the treatment and prevention of bovine babesiosis (Red-water fever, *Babesia divergens* infection). It is given, by subcutaneous injection in the neck, at the first clinical appearance of the disease; all animals in the same group should be treated as a precaution. Some animals may have an anaphylactic reaction that could be fatal. Imidocarb has also been used for treatment of canine babesiosis, although it is not registered in the UK for this purpose. In the dog it is given by slow intravenous injection or intramuscularly at a dose of 5 mg to 6 mg per kg bodyweight, repeated after two to three weeks.

Immobilon/Revivon
Immobilon and Revivon (VetaPharm) are two products that are always used in sequence. Immobilon is a neuroleptanalgesic, i.e. it produces sedation with analgesia, licensed for use in large animals; usually deer and horse but also often wild mammals. It consists of etorphine hydrochloride with acepromazine. Given by intravenous injection in the horse, it provides immobilisation and analgesia useful for restraint and minor surgical procedures. Immobilon does not, like morphine, cause excitement, vomiting or defecation. It does, however, act as a respiratory depressant, and slows heart action.

Immobilon is reversible in its effects by means of Revivon (diprenorphine hydrochloride). It is absolutely essential that the manufacturer's directions are followed.

Precautions Donkeys are more sensitive to Immobilon than are horses and it is not licensed for that species. Immobilon is rapidly fatal for man and must be handled with great care. A veterinary surgeon died within 15 minutes after accidental self-inoculation when a colt made a sudden violent movement. Unfortunately the antidote, Narcan (naloxone), was not available.

Recommended precautions include the wearing of gloves to avoid skin contamination (which has required hospital treatment), and protection of the eyes. Once the dose has been withdrawn from the container into the syringe, the needle should be discarded and a fresh one inserted into the injection site; the syringe containing Immobilon is then attached to the needle and the dose injected. An assistant capable of administering the antidote must always be on hand with the antidote ready. (See INJECTIONS.)

Immune-Mediated Disease
Immune-Mediated Disease include PEMPHIGUS; FELINE INFECTIOUS PERITONITIS; MYASTHENIA

GRAVIS. THROMBOCYTOPENIA and POLYARTHRITIS may also, in some instances, be immune-mediated diseases. (See AUTO-IMMUNE DISEASE.)

Immune Response

This is a term used in immunology, which is the study of the body's reaction to the presence of foreign substances.

Such substances (usually polysaccharide or protein) are present in bacteria, viruses and other parasites, but are dissimilar to any substances occurring naturally in the host's body. Foreign substances act as antigens and give rise to antibodies. This is the immune response.

When antigen enters the body, the immune response may take two forms: (1) humoral immunity, which involves the synthesis and release of antibody into the blood and other body fluids; and (2) cell-mediated immunity, involving the production of 'sensitised' lymphocytes which have the antibody on their cell surfaces. (See IMMUNOGLOBULINS; INTERFERON; INFECTION.)

Antibodies combine with (and for all practical purposes neutralise) the antigens. In this way an animal may overcome infection.

Lymphocytes play an important part in the immune response, attacking cells containing the antigens. This happens in graft rejection and organ transplants, in reaction to malignant tumours, and in infections where bacteria, viruses or other parasites are present inside host cells.

B lymphocytes are the precursors of the plasma cells which secrete antibodies. B cells have antibody-like receptors on their surfaces which aid in the recognition of specific antigens. (See under BLOOD; B CELLS; T CELLS; RETICULO-ENDOTHELIAL SYSTEM; ANTIBODY; IMMUNOGLOBULINS; SECRETORY IGA.)

Immunisation

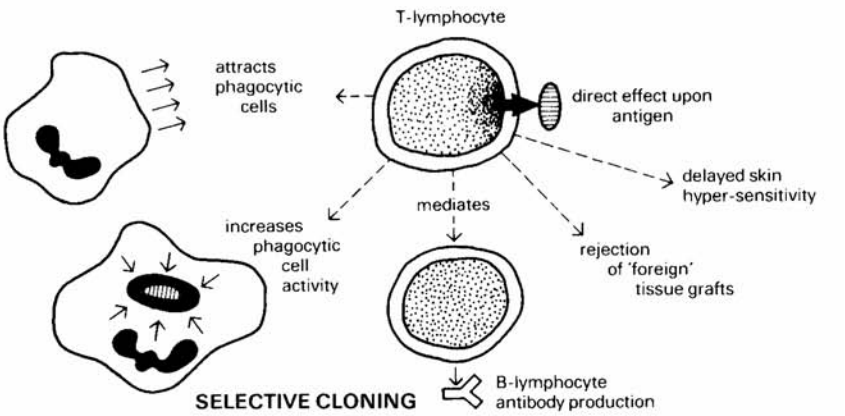
Immunisation is the process of artificially producing resistance to a given infection – generally by means of a vaccine, sometimes by means of an antiserum or antitoxin. (See IMMUNITY; VACCINES; ANTISERUM.)

Side-effects Immunisation is not always attained without side-effects. (See SERUM SICKNESS; ANAPHYLACTIC SHOCK.) In human medicine both serum shock and serum neuritis may very occasionally follow the use of equine antitetanus serum or of antitoxin.

Immunity

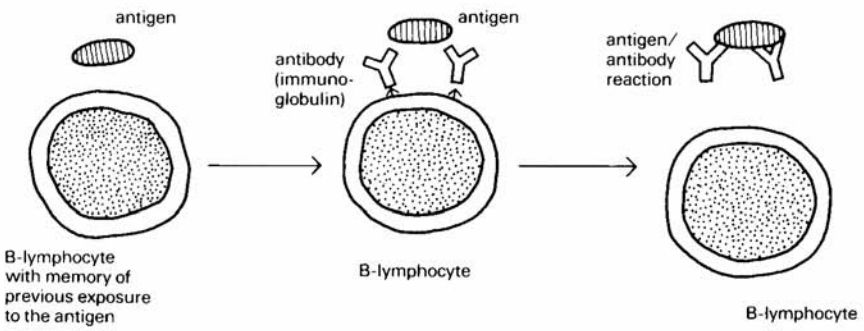
Immunity is the power to resist infection or the action of certain poisons. This immunity is (1) inherited; (2) acquired naturally; or (3) acquired artificially.

Inherent (natural) immunity There are some species of animals that are not affected by diseases or by some toxins that are dangerous to others. The snake-killing MONGOOSE of India possesses an immunity against cobra venom; the pigeon can withstand large doses of morphine without harm; fowls are resistant to TETANUS; the horse does not become affected with FOOT-AND-MOUTH DISEASE; rats are not attacked by TUBERCULOSIS; the ox is immune from GLANDERS; man is not affected by SWINE FEVER and many other diseases that are fatal to the lower animals, while, with the exception of the monkey, animals are not susceptible to syphilis. It is probable that species immunity cannot be broken down even by massive inoculation of the causal agent.



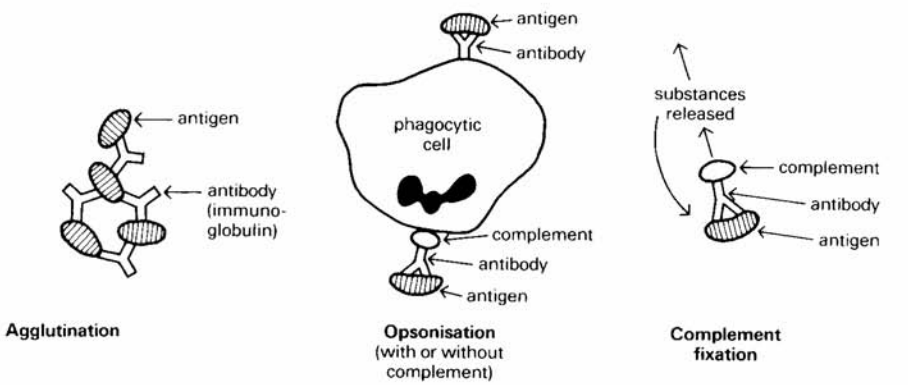
Actively acquired immunity results from an attack of some disease from which the animal has recovered. It is probable that most diseases confer a certain amount of immunity, but this varies greatly. It may be lifelong, or virtually so, as in POX, SHEEP POX, SWINE FEVER or SWINE ERYSIPELAS; in most instances, however, its duration is less, and in some only temporary. For example, cattle may be attacked by foot-and-mouth disease several times during their lives, and horses after recovery from one attack of tetanus may have a second natural attack. The immunity conferred by recovery is liable in many of the viral diseases (e.g. BLUETONGUE), and in some protozoal diseases to break down in the presence of massive infection subsequently. Recovery from a disease involves a process of natural immunisation against that disease, the toxins or other antigens present in the body being destroyed by antibodies elaborated by the body tissues.

Artificially acquired immunity is of two varieties, either active or passive.



(a) Active acquired immunity may be artificially produced by inoculating an animal with a vaccine (i.e. dead or attenuated bacteria or virus) or with a toxoid.

(b) Passive acquired immunity is that form of artificial immunity obtained by injecting into the body of one animal, blood or serum drawn from the body of another animal which has previously been rendered actively immune by injecting particular antigens or by previous exposure to the infection. The serum contains antibodies or 'antitoxins', which enable an in-contact animal to resist an infection, or enable an already infected animal to overcome the infection, so that an attack of illness – if it occurs at all – is milder than it would otherwise have been. (See ANTISERUM.) A young animal may acquire passive immunity through the colostrum of its dam which had been



VetBooks.ir

Specific immunity: humoral antibody production.

Specific immunity: cell-mediated immune response.

Specific immunity: immunoglobulin activity.

immunised with this purpose in mind. (For an example, see LAMB DYSENTERY.)

The immune system normally 'learns' to discriminate between self and non-self antigens early in development, leading to the normal state known as self-tolerance. A newborn mouse or rat injected with large numbers of cells from a genetically foreign individual will grow up tolerant of the foreign allo-antigens of the donor, so that, for example, it will accept a skin graft from the donor which would normally be rejected. It has been shown that this induced state of 'neonatal tolerance' is maintained by suppressor T-cells. Some dietary ingredients, including nucleotides,

β-glucans and mannans, can bolster the immune system.

There are many complexities involved in immunity, which is far from being the simple subject it may here appear. (See IMMUNE RESPONSE; ORIFICES, IMMUNITY AT.)

Passively acquired immunity A degree of immunity to locally occurring infections is transmitted to it by ingestion of the colostrum in its mother's milk or *in utero*, depending on the species. (See COLOSTRUM; IMMUNOGLOBULINS.)

Immunity at Orifices

(See ORIFICES, IMMUNITY AT.)

Immunodeficiency

This may involve a specific factor, such as antibody or lymphocytes; or a non-specific factor such as a complement component. In either case the deficiency results in some failure of the IMMUNE RESPONSE, so that viral, bacterial or fungal disease may ensue.

Deficiencies of immunity can be either primary or secondary.

Primary immunodeficiency is due to congenital dysfunction of the immune mechanism and has been studied more fully in humans than in animals, although a condition of foals called 'inherited combined immunodeficiency in foals of Arabian breeding' has been documented in America.

Theoretically, if the deficiency is mainly of B-lymphocytes, the animal is likely to have measurably low levels of immunoglobulins and a deficiency of lymphoid follicles in lymph nodes. Such an animal would be susceptible to pyogenic bacterial infection, but would be able to cope with most viral infections.

Conversely, if the deficiency is mainly of T-lymphocytes, the animal will have reduced 'delayed skin hypersensitivity' and will be more susceptible to viruses.

Foals affected by the inherited combined immunodeficiency frequently suffer from adenoviral pneumonia due to their inability to resist infection.

Secondary partial immunodeficiency is much more common, and is being increasingly recognised as an important cause of failure to recover completely from certain diseases.

Severe malnutrition, certain viral infections, exposure to radiation (e.g. X-rays), and corticosteroid therapy can all lead to a reduction in the immune response. (See also IMMUNOSUPPRESSION.)

Immunoenhancement

An increase in the immune response which may be due to IMMUNOSTIMULATION.

Immunofluorescent Microscopy

This is a useful laboratory method of diagnosis, described as specific and very sensitive. It enables a virus to be identified during the course of an unknown infection. It can demonstrate the presence of swine fever virus, for example, even before the appearance of signs. Results can be obtained within a matter of hours.

The principle involved is that antigens in tissues are identified by using their ability to respond to, and fix, the homologous antibody previously labelled with a fluorescent tracer which does not affect its properties.

The method has demonstrated swine fever virus using impressions from lymph nodes taken from pigs killed during the first 60 hours after experimental infection. The virus is revealed first in the cytoplasm as a diffuse granular fluorescence; later bright, fluorescent particles become visible within the nucleus.

The term 'fluorescent antibody test' is applied to this technique. (See also under RABIES.)

Immunoglobulins

These are the basis of immunity and contain high concentrations of isoleucine, leucine, threonine and valine. They are passed from their dams in the colostrum to provide passive immunity to the offspring. Immunoglobulins – found in blood, colostrum, and most secretions – are proteins produced by PLASMA CELLS in response to stimulation by antigens, and play an important part in the IMMUNE RESPONSE. Immunoglobulins inactivate or destroy antigens. In cattle, four main classes of immunoglobulin are recognised: IgA, IgE, IgG, and IgM.

IgA is mainly secreted locally in mammals. Its function is aimed at combating micro-organisms entering the body at a specific site, e.g. upper respiratory tract, lungs, intestines. In birds, whilst it is produced locally, it can also be distributed by the blood.

IgE is present in increased amounts in animals with allergies. It is attached to the mast cells and, on exposure to the antigen, anaphylactic and allergic mediators are released.

IgG is the main circulating immunoglobulin and the one responsible for transferring passive immunity from parent to offspring.

IgM is found in the serum and is the first antibody produced in an immune response. It is the only antibody produced by fish. Amphibia produce IgM.

All IgM domestic animals have IgA, IgG and IgM; a fifth immunoglobulin, IgD of uncertain function, is found in some other species, including man.

IgY is another fraction produced in amphibians, but its function has yet to be determined.

VetBooks.ir

VetBooks.ir

Immunological
Related to the study or science of the immune system, immunity and the immune activity. The term is also simply used to relate to the activity of the immune system.

Immunology
The science and immunity of the immune system.

Immunomodulation
This is an adjustment of the immune system to a required level such as in IMMUNOSUPPRESSION, immunopotentiation or enhancement or induction of an immunological tolerance.

Immunomodulator
An agent that modulates immunity by IMMUNOSUPPRESSION or IMMUNOENHANCEMENT. Inactivated parapox ovis virus is used to boost the horse's immune system to reduce the effects of infectious respiratory disease (see PARAPOX VIRUSES).

Immunoperoxidase Test
A method of staining tissue to show the presence of specific antigens.

Immunostimulation
Immunostimulants are used to try and prevent disease or enhance the natural body defences when infection has occurred. They are variable and include organisms or derivatives from them such as BCG, parapox ovis, and substances such as lactoferrin, and LEVAMISOLE. Some vaccines have an overall stimulatory effect on the immune system thereby providing greater resistance against other diseases.

Immunostimulator
An agent used to boost immunity. (See also IMMUNOENHANCEMENT; IMMUNOMODULATION.)

Immunosuppression
Suppression of the immune response, leading to greater susceptibility of an animal to pathogens, such as may occur in trypanosomiasis, influenza, distemper and brucellosis. (See under CORTISONE; ANERGY; LEVAMISOLE; SPLEEN.)

The occurrence of anergy following certain viral infections is worth emphasising; affected animals show a reduced cell-mediated response, especially following infections by viruses having a cytotoxic effect on lymphoid cells, e.g. Newcastle disease virus. A reduction in immune response also occurs in cattle so that, with long-standing TUBERCULOSIS, they may not react to the skin test.

Immunosuppressants include CORTICOSTEROIDS and cytotoxic drugs such as CYCLOPHOSPHAMIDE. Some infections such as INFLUENZA viruses and BOVINE VIRAL DIARRHOEA are also immunosuppressant.

Impaction
Impaction is a condition in which two or more organs, body parts or substances are firmly lodged together. For example, when after a fracture one fragment of bone is driven into the other, this is known as an impacted fracture; when a temporary tooth is so firmly lodged in its socket that the eruption of the permanent tooth below is prevented, this is known as dental impaction. A type of dental impaction occurs in ELEPHANTS where a tooth is not shed; it affects the animal and is a major cause of so-called 'rogue' elephants. Impaction of rumen or of colon means that food materials have become tightly packed into these organs, causing a blockage. GIZZARD impaction is quite common in FREE RANGE POULTRY due to excessive ingestion of coarse fibrous material. (See STOMACH, DISEASES OF; INTESTINES, DISEASES OF; and COLIC in horses.)

Impetigo
A staphylococcal infection of the epidermis seen in many species e.g. on the teats and udders of cows, facial skin in pugs and abdomen in puppies. It may be secondary to parasitism. It is characterised by the formation of painless pustules, shallow, thin-walled, and usually projecting upwards above the level of the surface of the skin. (See also ACNE.)

Implant
Any material, tissue or object inserted into the body on a more or less permanent basis. Implants may be prosthetic, such as replacement hip-joints; biodegradable, such as long-acting medicinal preparations; or for the purposes of identification, such as electronic microchips.

Implantation
1. The application beneath the skin of pellets containing medication released gradually to provide a long-lasting effect. Microchips coded with identity data are also implanted. (See HORMONES IN MEAT PRODUCTION; CAPONISATION; also IDENTIFICATION OF ANIMALS.)
2. In reproduction, it refers to the attachment of the mammalian ovum or ZYGOTE to the uterine lining.
3. The insertion of a new tissue organ into the body.

Importing/Exporting Animals
Many animal-owners – including sophisticated travellers completely familiar with passports, visas and vaccination certificates – overlook the fact that

VetBooks.ir

they cannot legally take their pet animals with them across any and every national frontier. Some governments exercise a total ban on the import of certain species of animal; others require prior vaccination and production of a certificate; others insist upon an animal going straight into quarantine on arrival. Australia and New Zealand, for example, will admit dogs only from each other's territories or from the UK.

Pet animals Dogs and cats may travel to and from certain countries and the UK, without the need for quarantine, provided that strict conditions for vaccination against rabies and health checks are observed. For details, see under PET TRAVEL SCHEME.

Sheep Animals imported to Britain from outside the EU require a period of month-long on-farm isolation following release from the reception/quarantine station. During the isolation period, testing for maedi/visna, *Brucella ovis*, and *Mycoplasma agalactiae* is carried out; with slaughter or re-export required for positive reactors.

(See also HORSES, IMPORT CONTROLS; BIRD IMPORT CONTROLS; RABIES; QUARANTINE.)

Farm animals Requirements depend on the country where being exported to or imported from. There are restrictions on the import of cattle and semen on account of BLUETONGUE and other diseases. The Export of Animals (Protection) Order 1981 laid down certain welfare requirements for the export of cattle, sheep, goats and pigs from Britain.

Impotence
Inability of the male to mate successfully. Causes include malformation of the genital organs, weakness, starvation, and constrictions resulting from injuries or operations. Impotence may be only a temporary phase in the life of the animal from which it recovers with rest and good food. (See also PENIS; INFERTILITY.)

Impregnated Seed
Seed for cage birds into which medication has been applied to the seed kernel after mechanical dehusking. The advantage over TOP DRESSED SEED is that all the medication is consumed.

Imprinting
This is a mental process in which an inborn tendency in the animal causes it to attach itself to a set group of objects or a single object within a few hours after birth. It is a very important process if the young lamb or calf is to be properly suckled and cared for. Imprinting should be avoided when orphan wild animals, especially birds, are being hand-reared as imprinted animals show no fear of humans.

Inactivated
Made inactive. The term may be used to describe bacteria or viruses whose virulence has been removed, without destroying the antigenic properties. This may be achieved by heat, ultra-violet light or chemicals. Many vaccines are manufactured using inactivated micro-organisms.

Inapunga
A regional name for HEARTWATER.

Inbreeding
Mating of closely related animals. It may be practised deliberately to preserve desirable characteristics, but tends to encourage undesirable and enfeebling ones.

Incidence
In relation to disease outbreaks, incidence describes the number of new cases in a particular area in a specific time period. (See also PREVALENCE.)

Incision
A surgical incision is a cut made by a surgeon with a sharp instrument such as a scalpel.

Incisor
The front teeth in the dental arcade. Used to seize feed and cut into small portions prior to mastication. There are no upper incisor teeth in domesticated ruminants. (See TEETH.)

Inclusion Bodies
Round, oval or irregular-shaped structures of a homogeneous or granular nature, found in cells during the course of viral infections, e.g. in nerve cells in RABIES; BOLLINGER BODIES in epithelial cells in FOWL POX.

Inclusion Body Disease of Boids
Caused by a retrovirus in boid snakes (constrictors) and pythons (more common) resulting in paralysis, loss of righting reflex, food regurgitation and pneumonia. There is no effective treatment.

Inclusion Body Hepatitis
An adenovirus disease of chickens, and also of intensively-reared pheasant poults. In broilers the disease may appear at about five to seven weeks of age, giving rise to an increased mortality but with some birds remaining healthy. Often there is sudden death and post mortem examination shows HYDROPERICARDIUM, pulmonary oedema and liver involvement. An inactivated vaccine is available.

Inclusion Body Rhinitis

A viral cause of rhinitis in pigs, which is often included in ATROPHIC RHINITIS. (See RHINITIS, ATROPHIC.)

Incompetence

Inability to function effectively. The term is applied e.g. to the valves of the heart when, as a result of disease in the valves or alterations in the size of the chambers of the heart, the valves are unable to close the orifices which they should protect. (See HEART DISEASES.)

Incontinence

Inability to control faecal and urinary function. Incontinence may follow injury to the spinal cord. (See PARALYSIS.) Faecal incontinence alone in the dog and cat may result from DIARRHOEA, STRESS or possibly weakness of the SPHINCTER ANI in old animals.

A rare cause is an ectopic URETER.

Occasionally, urinary incontinence is a sequel to spaying of the bitch, and is attributed either to a hormonal deficiency or to adhesion between the vaginal stump and the bladder or urethra.

In the cat, as in the dog, chronic nephritis in the elderly animal is a common cause. The animal is obliged to drink more, and to pass urine during the night-time. Stress may be a factor too; for example, the appearance of an aggressive entire tom cat in the neighbourhood, being left alone for long periods, or the addition of a baby or another cat to the household. (See also POLYDIPSIA; INTERSTITIAL CYSTITIS.)

Incoordination

Incoordination is a term meaning irregularity in movement. Various muscles or, in some instances, portions of a muscle contract or fail to contract without relation to each other or to the whole. Deliberate purposeful movements are no longer possible or are carried out imperfectly.

Incubation Period

1. The time that elapses between the laying and hatching of an egg in birds and reptiles.
2. The time that elapses between infection and appearance of signs of a disease.

The average incubation periods for the commoner infectious diseases are:

Anthrax	12 to 24 hours or more
Black-quarter	1 to 5 days
Braxy	12 to 48 hours
Ca9 distemper	3 days to 3 weeks
Dourine	15 to 40 days
East Coast fever	10 to 20 days
Erysipelas (swine)	2 to 3 days
Feline influenza	2 to 10 days
Foot-and-mouth disease	2 to 12 days
Heartwater	11 to 18 days
Influenza	3 to 10 days
Lymphangitis, epizootic	8 days to 9 months
Myxamatosis	2 to 8 days
Piroplasmosis, British bovine	14 days at earliest
Piroplasmosis, other forms	Up to 3 weeks
Pleuro-Pneumonia, contagious bovine	3 weeks to 3 months
Pleuro-Pneumonia, contagious equine	3 to 10 days
Rabies	10 days to 5* months
Rinderpest	4 to 5 days
African horse Sickness	6 to 8 days
Strangles	3 to 8 days
Surra	5 to 30 days
Swine fever	5 to 15 days
Tetanus, horse	4 days to 3 weeks
Tetanus, ox	5 to 8 days
Texas fever	6 weeks
Tuberculosis	2 weeks to 6 months

(*but see under RABIES)

Caution It is always wise to allow at least a week more than the longest incubation period given before allowing an animal that has been in contact with an infection and has not developed the disease to resume its place with other healthy animals. (See also INFECTION; ISOLATION; QUARANTINE.)

Index Case

It is the first case in an epidemiological investigation and is usually, but not always, the PRIMARY CASE, i.e. the first to be diagnosed. This is the first case of the infection in a disease outbreak and may indicate the source of an outbreak as well as the spread of infection, and also possibly the reservoir of infection between disease outbreaks. (See also CO-PRIMARY CASE, PRIMARY CASE, SECONDARY CASE.)

Indian Runner Duck

Originating from Indonesia (East Indies), these ducks have an erect posture. The duck weighs 1.4 kg to 2.3 kg (3 lb to 5 lb) and the small female has a height from crown to tail tip of 50 cm (20 in) and large males 66 cm (26 in). They produce 150 to 200 green-white eggs. They love foraging and swimming. The females quack and males have a hoarse whisper.

Indicator

A substance used in chemistry, etc., to show by a colour change that a reaction has taken place. Litmus is an example. (See also COMPLEMENT.)

VetBooks.ir

Indoxocarb, Indoxacarb

It is an oxadiazide insecticide which blocks insect nerve sodium channels. A treatment for FLEAS (*Ctenocephalides felis*) in dogs and cats and is effective against all development life stages and so also controls environmental infestation.

Induction of Parturition

(See PARTURITION, DRUG-INDUCED.)

Inductotherm

An electrical apparatus used in the treatment of sprained tendons, etc. (See DIATHERMY.)

Infarct

A localised area of necrosis resulting from the blockage of a blood vessel. (See EMBOLISM.)

Infection

The presence in the body of micro-organisms capable of causing disease; the passing on of disease from one animal to another. Exposure to infection may or may not be followed by disease, depending upon whether the potential host animal has or has not a useful degree of immunity against that particular infective agent, whether the animal is well nourished, not under stress, and has not any other major infection, disease, or defect which might lower its power to resist the new infection. (See IMMUNOSUPPRESSION; IMMUNODEFICIENCY.)

The virulence or otherwise of the infective agent, and the quantity of it, will also have a bearing upon whether disease will follow. For example, a heifer vaccinated against *Brucella abortus* will normally be able to resist exposure to this organism; but her immunity might break down if challenged by a massive dose of *B. abortus infection*.

With rabies, for example, there is a 'threshold' dose of virus, and below this the infected animal will not become rabid (especially in the absence of stress).

Susceptibility to infection is also influenced by genetics. For example, see K88 ANTIGEN and MAREK'S DISEASE.

Concurrent infections The average farm animal is host to several different organisms at one and the same time – including viruses, mycoplasmas, bacteria, fungi, protozoans and worms. Accordingly, when one speaks of a calf having pneumonia, it is unrealistic to imagine that, say, the parainfluenza 3 virus (causing the inflammation of the lungs) is the calf's sole resident parasite/foreign organism.

Some organisms may be present in relatively small numbers and may not be causing active disease. Some, owing to the host's powers of resistance (the immune response), may be on the decline. Others may have a sudden opportunity for multiplication and increased activity as the host's resistance becomes lowered by some additional infection or by stress arising from cold, insufficiency of good food, poor ventilation, or the rigours of transport, etc.

Again, infections should be thought of as not merely mixed but changing all the time, developing, and with complex interactions between a number of factors, including management ones. (See under RESPIRATORY DISEASE IN PIGS.)

In respiratory diseases there is often a synergism between viruses and certain bacteria. In CANINE DISTEMPER, for instance, *Bordetella bronchiseptica* is quick to invade in the wake of the canine distemper virus and produce BRONCHITIS.

In rabbits, *Pasteurella multocida* invades after the actions and damage of *Bordetella* species. FOOT-ROT OF SHEEP is often a mixed bacterial infection, with *Fusiformis necrophorus* causing sufficient damage to permit the entry of *Bacteroides nodosus*. LIVER-FLUKES and bacteria may both be involved in production of BLACK DISEASE.

Clinical and subclinical infections Exposure to infection may lead to overt or clinical disease in which signs are in evidence; or there may be a subclinical infection in which few if any signs – detectable without laboratory aids – are shown. A good example is subclinical mastitis. (See MASTITIS IN COWS.)

Infection may persist in an animal which has recovered from a disease and is no longer showing signs but is excreting the infective agent. Such an animal is known as a carrier. For example, a bull may be a carrier of BRUCELLOSIS; a dog of LEPTOSPIROSIS; a horse of EQUINE INFECTIOUS ANAEMIA; a cat of FELINE LEUKAEMIA.

Routes/modes of infection An animal may breathe in air containing droplets in which the infective agent is present, e.g. influenza virus or tubercle bacillus. This is called an aerosol infection.

The oral route provides a common mode of infection. Infective material may be licked, an infected carcase eaten, or an animal may eat feed contaminated with salmonella organisms or anthrax spores. (In some instances, an infective agent, such as salmonella, is already in the intestine but becomes pathogenic when its bacterial competitors are mostly destroyed by an antibiotic. See DIARRHOEA – Horses.)

Spirochaetes and hookworm larvae are examples of organisms which can enter the host through unbroken skin. Small, even insignificant, wounds can be followed by tetanus. Biting flies can transmit diseases (see under FLIES), and ticks are notorious vectors. Dog bites and cat scratches can lead to RABIES, the virus of which can penetrate intact mucous membranes.

Infection may be transmitted at mating, e.g. brucellosis by the carrier bull. Dourine in the

VetBooks.ir

horse, and venereal tumours in the dog, are 2 other examples of infections transmitted at coitus. Congenital infections also occur e.g. BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE; BLUETONGUE.

Inter-species infections Many micro-organisms have a wide range of possible hosts, e.g. the rabies virus, the influenza viruses, the anthrax bacillus. Infections from man to farm animals are ANTHROPONOSES. Farmers may also be interested in diseases which arise in one species following their use of buildings which previously housed another species. For example, turkeys have become infected in this way with swine erysipelas, which also affects game birds. (See also under HOUSING OF ANIMALS.) With cattle kept in association with pigs (as in North America), acute interstitial pneumonia may occur in cattle due to the pig worm *Ascaris suum*. (See also DOG, KENNELS.)

Infections transmissible from animals to man are listed under ZOONOSES. In Britain, those of importance to farmers and stockmen include BRUCELLOSIS, Q-FEVER, canicola fever, Weil's disease (leptospiral jaundice), *L. hardjo*, LOUPING-ILL, ANTHRAX, ERYSIPELAS, SWINE, TUBERCULOSIS and SALMONELLOSIS. CRYPTOSPORIDIOSIS and *E. coli* O157 have been transmitted to children visiting open farms; thorough hand hygiene is essential on sites where children have access to animals and are encouraged to touch them.

Blood cells which counter infection When bacteria gain entrance through a wound in the skin, for example, they are attacked by white blood cells (leukocytes). The first to attack are neutrophils, which have their origin in the bone marrow. They pass through the walls of the capillaries and engulf the bacteria. Monocytes perform a similar task when they have turned into macrophages, but in addition to engulfing bacteria they also dispose of disintegrating neutrophils. Lymphocytes (T-cells or B-cells) also reach the site of infection. (See LYMPHOCYTES; also INTERFERON, IRON-BINDING PROTEINS.)

Other aspects of infection are dealt with under separate headings such as ANTIBODY; COLOSTRUM; FOMITES; IMMUNE RESPONSE; IMMUNITY; ISOLATION; NOTIFIABLE DISEASES; NURSING OF SICK ANIMALS; DISINFECTION.

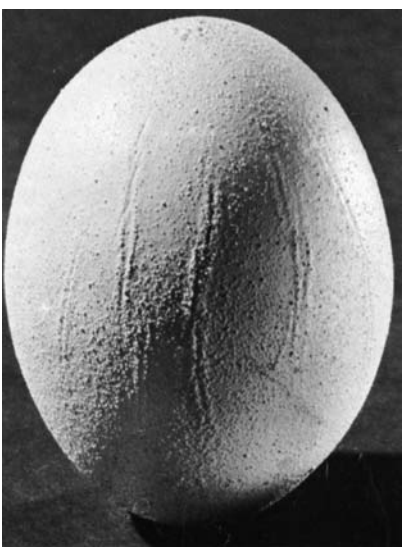
Infectious Bovine Keratitis

(See NEW FOREST DISEASE.)

Infectious Bovine Keratoconjunctivitis

(See EYE, DISEASES AND INJURIES OF.)

Infectious Bovine Rhinotracheitis



(See under RHINOTRACHEITIS, INFECTIOUS BOVINE.)

Infectious Bronchitis of Chickens

Cause A coronavirus. A disease long unrecognised initially in the UK because the original strains had a predilection for kidney tissue and few of the birds showed clinical respiratory signs. This strain is still present.

Signs Breathing difficulties which may be evident only when the birds are at rest. A reduced egg yield. Misshapen eggs may be laid; this may persist following recovery. Mortality is usually low and due to secondary infections such as mycoplasma or *E. coli*. One viral strain in the UK causes NEPHRITIS with very few respiratory signs.

Prevention Live vaccines are available to control the disease; compound vaccines offer protection against other avian viral diseases as well as infectious bronchitis.

Infectious bronchitis can result in a marked deterioration in egg quality with consequent heavy economic loss. The illustration shows some of the effects, which include roughening and scoring of the shell. Shells may also be distorted and thin, or soft-shelled eggs may be laid by infected birds.

Infectious Bursal Disease (IBD)

Infectious bursal disease (IBD) of chickens affects the BURSA OF FABRICIUS, an important part of the avian immune system, leaving the birds with lowered resistance to infection. It is also known as GUMBORO DISEASE from the town in Maryland, USA, where it was first identified. It is caused by a

VetBooks.ir

BIRNAVIRUS. Young birds between one and five weeks are affected, with a peak at 3½ weeks. Mortality from IBD may be high; because of subsequent infections, high rates of mortality will continue. The main signs of disease are listlessness and diarrhoea. Post-mortem examination shows haemorrhage or a caseous plug in the bursa. Prevention is by vaccination of breeding stock. Ducks may be symptomless carriers of IBD.

Infectious Canine Hepatitis
(See CANINE VIRAL HEPATITIS.)

Infectious Canine Tracheobronchitis
(See KENNEL COUGH.)

Infectious Clinical Waste
(See HANDLING VETERINARY WASTE.)

Infectious Coryza of Chickens
Infectious coryza of chickens is caused by *Haemophilus paragallinarum*. The disease is sudden in onset and spreads so rapidly that it seems as if all the birds have been infected simultaneously. Clinical signs include swelling of the head, wattles and sinuses, discharges from the eyes and nose, coughing, noisy breathing, lack of appetite and depression. Mortality is low but recovery takes time.

Infectious Haematopoietic Necrosis
A viral disease of salmonid fish, at present confined to North America and Japan.

Infectious Laryngotracheitis
(See under AVIAN INFECTIOUS LARYNGOTRACHEITIS.)

Infectious Nasal Granulomata in Cattle
In certain parts of India, cattle in restricted areas (sometimes in single herds only) may become affected with this condition. Large tumour-like masses develop in connection with the frontal sinus and the turbinated bones in the nasal passages.

The cause is a schistosome, *Schistosoma nasalis*, which is present in the veins of the nasal mucous membrane.

Treatment Injections of various antimonial preparations have been used in the past, but they have toxic side-effects. PRAZIQUANTEL is among other drugs that may be effective, but regular administration is required. Prevention by control of the intermediate snail hosts is preferable.

Infectious Necrotic Hepatitis
(See BLACK DISEASE.)

Infectious Pancreatic Necrosis
A viral condition of salmon and trout that is a NOTIFIABLE DISEASE throughout the EU and caused by a BIRNAVIRUS. The clinical disease lasts only about four days. Affected fish often swim on their sides or with slow spiral movements and sink to the bottom of the pond. They may be darker than normal in colour and have swollen abdomens. It is mainly, but not exclusively, a disease of young fish. Losses are around 20 per cent but the survivors do not thrive. There is no treatment.

Infectious Proventriculitis
Probably caused by a novel adenovirus (AdLV (R11/3). It is an important cause of production losses in broiler chickens, which show impaired growth and reduced ability to digest feed. The PROVENTRICULUS can enlarge and even rupture.

Infectious Pustular Vulvovaginitis
A reproductive disorder of cattle caused by infectious bovine rhinotracheitis (see under RHINOTRACHEITIS, INFECTIOUS BOVINE).

Infectious Salmon Anaemia
A NOTIFIABLE DISEASE of viral origin. Infected salmon are pale and lack energy. They may try to gulp air to make up for a lack of oxygen in the blood. There is no treatment. Affected pools or cages of fish are slaughtered and any eggs, etc. destroyed under the provision of the Animal By-products Order 2003 for high-risk material.

Infectious Sinusitis
Seen in chickens and related species such as grouse, pheasants, etc. It results in swollen eyelids, sticky eye discharges and nasal discharges. It is caused by *Mycoplasma gallisepticum*. In poultry and especially grouse it is called 'BULGY EYE'.

Infectious Tracheobronchitis
(See KENNEL COUGH.)

Infectious Ulcerative Stomatitis, Mouth Rot
Seen in reptiles, it is caused by Gram-negative bacteria, the most common of which is *Aeromonas hydrophila*. It is seen as stringy, frothy saliva, petechiation (see PETECHIAE) and oedema of the palate and gums. Further signs include ulceration and pus formation which, if untreated, may spread to the trachea, oesophagus; OSTEOMYELITIS of the MANDIBLE may develop. Affected areas should be debrided, and an antiseptic applied; antibiotic treatment may be necessary.

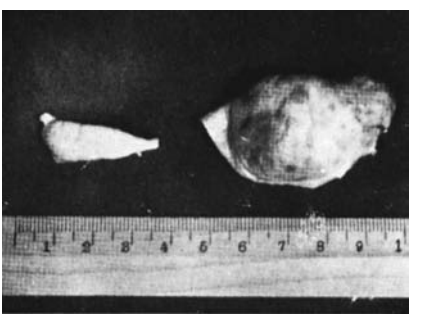
Infective Drug Resistance
Resistant strains of bacteria may arise as a result of chromosomal mutation. More commonly, drug

resistance is carried by PLASMIDS. (See ANTIBIOTIC RESISTANCE.)

Infective Granulomata

A contagious venereal (sexually transmitted disease) of dogs. (See VENEREAL TUMOURS.)

Infertility



Inability of the female or male to reproduce. Insidious but great losses are directly due to failure to breed on the part of otherwise promising animals. The immediate loss to the individual owner of livestock is not so apparent as with certain specific diseases, but it is infinitely greater than the loss accruing from any other single specific or non-specific disease. This loss is made up by the keep of the barren animals, the absence of offspring, reduction of the milk supply, and interference with breeding programmes. (See also CALVING INDEX.)

Causes The most common and important causes of infertility can be grouped for convenience under the following headings.

1. Feeding and Condition Under-feeding is a common cause of infertility in heifers. The diet must include adequate protein of good quality and sufficient vitamins, especially vitamin A, plus essential trace elements including copper and iodine.

Excessive fat in cows, heifers or bulls may lead to infertility problems or to inability on the part of the male to accomplish coitus. (See also FATTY LIVER/KIDNEY SYNDROME OF CHICKENS AND TURKEYS.)

In cows, temporary infertility may apparently be closely associated with the feeding at about the time of service. Cows losing weight are likely to be affected, especially if fed on poor-quality hay or silage. With ad lib feeding systems, heifers and more timid cows may not be receiving enough roughage. Kale is sometimes responsible.

Hypoplasia of the left ovary of a cow of the Swedish Highland breed. Compare its size with that of the normal right ovary from the same animal. (The ruler is graduated in centimetres.)

In ewes, infertility and fetal death can be serious in many hill areas as a result of severe winters and an inadequate supply of suitable feed. (See DIET AND DIETETICS; FLUSHING OF EWES; STILLBORN PIGS; REPRODUCTION; VITAMINS; KALE; SELENIUM.)

2. Environment and Management A sudden change of environment, close confinement in dark quarters (formerly the lot of many a bull), and lack of exercise may all predispose to, or cause, infertility. Abnormal segregation of the sexes and the use of vasectomised males (for purposes of detecting oestrus) are other factors. A low level of nutrition may cause a quiescent or dormant state on the part of the ovaries. At the same time there are seasonal cycles of sexual activity, and a 'failure to breed' during the winter months may be natural enough, even if the farmer regards it as infertility. This 'winter infertility', as it is often called, may be influenced by temperature, length of daylight, lack of pasture oestrogens, underfeeding, etc. At this season, heifers often have inactive ovaries, while in cows irregular and 'silent' heats give low conception rates.

Infertility may result from the oestrogenic effects of red clover in the UK, as well as from subterranean clovers in Australia.

In outdoor pig herds, 'summer infertility' is common, partly due to seasonal loss of fertility in the boars.

The most frequent reason for poor fertility is poor management or stockmanship. In cows, poor oestrus detection or timing, or bad technique if artificial insemination is used, are common. Similar problems occur in pigs. In cattle and, particularly, pigs, when natural service is used, all matings must be seen and at least 2 undertaken within the heat period. In sheep, fertility problems often follow when too few rams are used, or those which are too young or unproven.

3. Diseases of the Genital Organs in the Female While there is a very long list of such diseases, their overall importance in causing infertility is much less than that of management problems such as poor oestrus detection.

Inflammation or other disease of the ovaries: ovaritis; the non-maturation of Graafian follicles, from any cause, and the presence in the ovary of cysts (which often form from a corpus luteum), are causes of infertility; another is blocked Fallopian tubes.

Persistent corpora lutea: as a true clinical condition, these are not very common. Where they do exist, the animals may have a uterine infection. The persistence of the corpus luteum prevents the ripening of the Graafian follicle, so the animal does not display oestrus and is not mated. (See

VetBooks.ir

under OVARIES, DISEASES OF; HORMONES; HORMONE THERAPY.)

Inflammation of the uterine mucous membrane: a large number of cases of infertility can be ascribed to infection of the uterus (metritis) or the oviduct by organisms. (For a list of the infections which cause infertility, see under ABORTION. For infections causing infertility in the mare, see under EQUINE GENITAL INFECTIONS IN THE MARE.)

When the condition is mild, following a previous calving, it may disappear spontaneously, but in many instances it persists and becomes chronic. Associated with inflammation of the mucous membrane of the uterus or oviduct is often a persistent corpus luteum in the ovary. Carelessness during parturition, the use of unclean instruments or appliances, decomposition of retained membranes, and other similar factors, also bring about infection of the uterus. Brucellosis though not necessarily itself a cause of sterility, by lowering the vital resistance of the uterus, favours infection by a multitude of other organisms which normally may be non-pathogenic. The details of uterine infection, including SALPINGITIS (inflammation of the oviduct), in the causation of sterility, are highly technical, but, generally speaking, it may be said that the presence of organisms in the uterus, or the presence of the products of their activity, either kills the spermatozoa, or renders the locality unsuitable for anchorage of the fertilised ovum (or ova), with the result that it perishes.

Abnormalities of the cervix may prevent conception – mechanically when the lumen is occluded or plugged by mucus of a thick tenacious nature; and pathologically when there is acute inflammation of the mucous membrane of the cervix, or even of the whole uterus. Scirrhous cervix – where much fibrous tissue is laid down in the cervix – when very advanced may cause sterility, but by itself is not usually of great importance. It is much more serious as a hindrance to parturition (see, for example, 'RINGWOMB' of the ewe).

Cysts and fibrous bands in the cervical os are seldom sufficiently extensive to occlude the passage through the cervical canal. Occlusion may, however, occur as the result of swelling and congestion of the mucous membrane, due to infection and inflammation. In such cases the sperms are unable to penetrate into the uterus, and fertilisation does not occur. This may also be the result of acidity (and thickened mucus) following a mild infection, and sometimes syringing the vagina a short time before service with a weak alkaline solution (e.g. 5 per cent potassium bicarbonate) proves successful. (See 'WHITES'; EPIVAG.)

Tumours – either malignant or benign.

Specific disease, such as tuberculosis in cattle, or in mares. Contagious equine uretritis. (See VULVOVAGINITIS.)

4. Hereditary Abnormalities in the Female (See FREEMARTIN.)

(a) HYPOPLASIA of the ovaries may occur as an inherited condition in the female. It may involve one or both ovaries, causing either infertility or complete sterility. The uterus, also, may be hypoplastic. (See also under GENETICS, HEREDITY AND BREEDING.)
(b) Endocrine failure: heredity may be involved.
(c) HERMAPHRODITISM.
(d) 'WHITE HEIFER DISEASE'.

5. Disease of the Genital Organs in the Male Orchitis, or inflammation of the testicle, and epididymitis, inflammation of the epididymis, due to injury from kicks, or to infection from external wounds, or from specific infection, such as *brucellosis* or *trichomoniasis* in the bull. (See TESTICLE, DISEASES OF; VENEREAL DISEASES.)

Tumours of the testicles may destroy the tubules or prevent spermatogenesis, and on the penis, or in connection with the prepuce, may act as purely mechanical agents, which prevent coitus by the male.

Adhesions between penis and prepuce, the result of acute or chronic balanitis, though rare, may cause mechanical inability to protrude the penis and fertilise the female. (See also under PENIS.)

Inflammation in the secondary sexual glands – i.e. in prostate, seminal vesicles, or other glands – may occlude the *vasa deferentia* or ejaculatory ducts, and cause inability to pass semen, while in other cases the semen may be so altered as to cause death of the sperms in the female passages.

Where the prepuce is affected, such as in cases of balanitis (see PENIS AND PREPUCE, ABNORMALITIES AND LESIONS), and injuries accompanied by laceration or severe bruising, temporary sterility may result, but when recovery occurs fertility returns. (See also under PENIS.)

6. Hereditary and Congenital Abnormalities in the Male Cryptorchidism, in which one or both testicles do not descend into the scrotum, is a well-known cause of infertility in the male. When one of them descends properly, and is fully developed, conception may follow service, and a sire suffering from this disability has upon some occasions been regularly used in a flock or herd; but when the rig animal has both organs retained, although sexual desire may be emphatic, service is usually unsuccessful. The condition makes a a male animal unfit for use as a breeding sire, since there is evidence that it is a hereditary unsoundness. (See HORMONE THERAPY.)

VetBooks.ir

Hypoplasia or under-development of the male sex organs, particularly of the testis, is an important cause of sterility. It may involve both testicles or only one.

Endocrine failure may arise as a result of an inherited predisposition. In bulls this may occur in later life, rendering them sterile after they have produced a number of progeny which, in their turn, may perpetuate this form of infertility.

Hermaphrodism, or hermaphroditism, in which an animal possesses both male and female organs, but is without a full complement of either, is usually, but not always, associated with sterility. (See also GENETICS, HEREDITY AND BREEDING; INTERSEX.)

7. Physical or Psychical Inability or Disturbance Under this heading are grouped a number of conditions which are difficult to classify elsewhere. Some occur in the male, some in the female, and some are common to both sexes.

Incompatibility between the blood of sire and dam may be responsible for some cases of abortion in cattle, etc. (See FOALS, DISEASES OF - HAEMOLYTIC DISEASE.)

Old age: when an animal reaches a certain age, reproduction becomes impossible. The periods of oestrus cease. Breeding ceases earlier in the female than in the male.

Discrepancies in size between male and female may result in failure to breed. The penis may be too short or too large; the vagina may be too long or too small; the female may not have the strength to carry a heavy male; or the male may not be tall enough to reach the female.

Injuries to the back, hips, hind legs or feet of the male, and sometimes to the same regions of the female, may be severe enough to prevent successful coitus. Progressive spinal arthritis is a common condition in bulls. (See also BREEDING OF LIVESTOCK; REPRODUCTION; EMBRYOLOGY; UTERUS, DISEASES OF; HORMONE THERAPY; GENETICS, HEREDITY AND BREEDING; VENEREAL DISEASES; ANOESTRUS; ABORTION; MUMMIFICATION OF FETUS.)

Infertility may also be a problem in cage birds, especially those monomorphic species (e.g. parrots) in which it is difficult to tell the sexes apart. Surgical sexing by an experienced veterinarian may be requested by bird breeders in preference to DNA sexing as the veterinarian is in a position to assess visually the health of the (internal) genital organs.

Inflammation

Inflammation may be briefly defined as the reaction of the tissues to any injury short of one sufficiently severe to cause death. There are five cardinal signs of inflammation – heat, pain, redness, swelling and loss of function of the affected part. The suffix –itis is added to the name of the organ to indicate that it is inflamed: e.g. tonsillitis, pharyngitis, orchitis, dermatitis, etc. (See ABSCESS; WOUNDS; ALLERGY.)

For the inflammations of special organs, see under PNEUMONIA; PLEURISY; PERITONITIS; MAMMARY GLAND.

For anti-inflammatory drugs, see CORTICOSTEROIDS; CORTICOTROPHIN; CORTISONE; NSAIDs; IBUPROFEN; FLURBIPROFEN; ANTIHISTAMINES; CALAMINE.

Inflammatory Airway Disease (IAD), Inflammatory Infectious Airway Disease

An infection of horses under six years old and common in thoroughbred training stables. Often it is seasonal and seen in warm humid weather. The animal may have a cough but the main problem is that performance is affected. The problem is MULTIFACTORIAL and *Streptococcus zooepidemicus* may be involved.

Inflammatory Bowel Disease, Inflammatory Bowel Syndrome

A syndrome seen in dogs, similar to that in humans, involving a group of chronic gastro-intestinal disorders. The exact aetiology is unknown but is probably multifactorial, involving interactions between the environment, the immune system, genetics and the intestinal microflora. Several breeds seem highly susceptible, including BORDER COLLIES, BOXERS, GERMAN SHEPHERD DOGS, ROTTWEILERS and WEIMARANERS.

Influenza

Scientifically, this term is now applied only to diseases caused by a myxovirus.

It has long been known that there is a relationship between human influenza and swine influenza. The human influenza virus (type A) was isolated from the pig lungworm. Larvae of these lungworms are harboured by earthworms – the only known intermediate hosts – which live for as long as 10 years.

Between epidemics, the virus is not found in the tissues of the pigs. However, earthworms taken from infected pig farms seem to carry inapparent viruses, and these can develop, in pigs eating the worms, into normal viruses capable of being isolated from the respiratory system. The question, therefore, arises whether the pigs are, in fact, the virus reservoirs, rather than being secondarily infected by the human virus. (See also SWINE INFLUENZA.)

Influenza viruses of mammals and birds play an important part in the emergence of new viruses which cause outbreaks of illness in man in several continents.

The recovery from pigs in Taiwan in 1970 of influenza virus indistinguishable from that causing

VetBooks.ir

type A Hong Kong influenza epidemics in man in 1968 provided the first direct evidence of the inter-species transfer of influenza viruses. Pigs experimentally inoculated with that virus transmitted it to pen-mates. Moreover, the Taiwan virus taken from pigs readily infected human volunteers, who developed antibodies effective against virus from both pigs and people.

For influenza in the horse, see under EQUINE INFLUENZA.

Pneumonia in calves may be caused by a virus of influenza-type.

In the dog, parainfluenza virus SV5 has been isolated in the USA and the UK from dogs with upper respiratory disease. (See KENNEL COUGH.)

Avian strains of type A influenza virus cause a number of diseases in hens, ducks, turkeys, etc. Highly pathogenic avian influenza virus has caused serious outbreaks among turkeys.

Avian influenza is a NOTIFIABLE DISEASE throughout the EU. Waterfowl are the main reservoir host for both avian and mammalian strains but they are not themselves much affected by the disease. The slaughter of all chickens in Hong Kong in 1997 was justified as the strain of virus present transmitted fairly easily to the human population. (See AVIAN INFLUENZA.)

'Influenza', Cat

(See FELINE INFLUENZA.)

Infra-Red Lamps

Infra-red lamps are used as a source of heat in the creeps of piggeries and in poultry brooders; also for sickly lambs and calves and following surgery in cool conditions. Either 'bright' or 'dull' emitters are available, the latter being preferred for chick-rearing. They are also used for heating accommodation of exotic species – care must be taken that the animals do not contact the hot lamps. They have many advantages, but a power-cut can cause severe losses. (See also under TOES, TWISTED.)

Ingluvies

Another name for CROP or craw.

Ingluvitis

(See CROP, DISEASES OF.)

Inguinal Canal

The inguinal canal is the passage from the abdominal cavity to the subcutaneous area, down which pass the spermatic cords and their associated structures in the male, and in the female, the round ligament of the uterus. It is a slit-like opening, about 12.5 cm (5 in) long in the horse, and is directed downwards, inwards and forwards. It is bounded behind by a strong band called the inguinal or Poupart's ligament. The canal is important, because if it is dilated from any cause, some part of the small intestines may pass through it, resulting in inguinal hernia. (See HERNIAS.) It serves as the opening through which retained testicles are removed in the 'rig' or cryptorchid horse. Retained testicles in dogs and cats are often intra-abdominal.

Inguinal Hernia

The hernia present in the inguinal or groin region where the abdominal folds meet the thigh. The hernia is variable in size and may contain fat, and/or intestine and/or OMENTUM. Occasionally it can also include a gravid uterus, which either passes down the inguinal canal or through a weakness in the abdominal wall. In some cases the hernia is irreducible and occasionally it strangulates, with swelling and pain. Inguinal hernias are seen most commonly in the dog, especially the bitch, but they are also relatively common in pigs and cattle. In dogs it is common in some breeds including BASENJIS, BASSET HOUNDS, CAIRN TERRIERS, PEKINGESE and WEST HIGHLAND WHITE TERRIERS. (See also HERNIA – INGUINAL HERNIA.)

Inguinal Region

The inguinal region is the region of the inguinal canal, i.e. that part of the posterior and uppermost division of the abdominal wall which lies below the brim of the pelvis. The scrotum, penis, and their vessels, etc., are situated in the inguinal region in the male horse, and in the female the mammary glands with the vessels that supply them. In some animals such as the dog and boar, the scrotum is farther back, i.e. in the perineal region, while in the bull and ram the penis is farther forwards.

Inhalation

Taking air or substances into the lungs.

Inhalation Pneumonia

The inhalation or aspiration into the lungs of solids or liquids which the damage the lungs and cause pneumonia. It is often very difficult to treat successfully. (See PNEUMONIA - NON-INFECTIVE PNEUMONIA.)

Inherited Defects, Inherited Diseases

Inherited defects/diseases are referred to under GENETICS, HEREDITY AND BREEDING. (See also DEFORMITIES and HORSES.) Inherited conditions are not synonymous with CONGENITAL CONDITIONS. In companion animals, genetic diseases and their welfare impact can be studied on the website www.ufaw.org.uk/geneticwelfare problems.php.

VetBooks.ir

Injections

Parenteral administration of medicines may be hypodermic or subcutaneous (sc), intra-articular (into a joint), intradermal, intramuscular (im), intravenous (iv – into a vein) intraperitoneal (into the abdominal cavity), epidural, or subconjunctival (beneath the eyelid). Precautions must be taken against the introduction of bacteria, dirt, etc. The selected site should be cleaned with surgical spirit or an antiseptic and hair should be clipped away (what is used will depend on the type of injection). Needles and syringes should be sterilised before use, unless of the disposal type intended for once-only use and already sterilised and in a sealed wrapper.

Where the material to be injected is already fluid, this is generally guaranteed sterile by the manufacturers, and is presented in sealed vials. In cases where the drug has to be dissolved in water first, sterile water must be used. Manufacturers usually supply ampoules of sterile water with drugs that have to be dissolved; their instructions for use must be followed carefully. Neglect of these precautions is likely to be followed by the formation of an abscess at the point of injection or even by septicaemia. Injury to personnel may also arise from careless handling.

For subcutaneous injections in farm animals, a fold of the skin is picked up between the thumb and forefinger of the left hand in right-handed people, and the needle is inserted into the middle of this fold. The nozzle of the syringe, pre-loaded with the injection fluid, is slipped into the head of the needle and the piston is slowly but firmly pressed home so as to expel the contents into the loose tissues under the skin. Care should be taken that all air-bubbles are excluded from the barrel of the syringe, as it is unwise to introduce them into the animal.

A number of proprietary multi-injection devices are manufactured for herd inoculations.

Precautions Restless animals should always be secured so that they will not make a sudden movement when the needle is introduced, as this could break the stem of the needle. Abscesses in hams are common in pigs, and often result from anti-anaemia intramuscular injections made without due precautions as to cleanliness and to broken-off needles.

The sciatic nerve may be damaged as the result of an intramuscular injection into a pig's ham, with paralysis of the limb possibly following. This site should be avoided, and it has been recommended that the injection be given into the muscles of the neck, just behind the ear, and not into fatty tissue.

Care must be taken not to make what should be a subcutaneous injection into the chest. It has been demonstrated that it is possible to reach the pleural cavity with a cattle syringe, especially in thin lambs; many other 'vaccine failures' may have been due to inadvertent injections into the chest. Alternative sites, such as the side of the neck, would appear to offer a much reduced chance of complications.

With intravenous injections of certain preparations, severe tissue damage may follow if some of the drug enters the vein wall or surrounding tissue; the manufacturers' instructions must be followed.

Inoculations should not be carried out in a dusty shed.

(See ANTHRAX; also AMPOULE; DETERGENT RESIDUE; ENEMA.)

Large-bore needles Use of these is not without risk, especially when liver biopsies are carried out by means of suction through a needle, inserted intraperitoneally and attached to a syringe.

Accidental self-inoculation may occur owing to the sudden violent movement of a large animal. People have been infected with BRUCELLOSIS in this way; and veterinary surgeons have died from IMMOBILON. **Accidental self-injection with oil-based vaccines requires prompt hospital attention.** Holding syringes or needles in the mouth is a common practice and can lead to injection of the mouth or tongue.

Injuries

(See ACCIDENTS; WOUNDS; FRACTURES; BLEEDING; SHOCK.)

Injuries from Animals

In Australian and Canadian studies, large animal veterinarians are at most risk and were more likely to have to take off time from work. In Canada, 98 per cent of veterinarians suffered an injury in the previous five years, with 6 per cent having 25 or more injuries and 17 per cent losing one or more days off work, and 40 per cent having visited a doctor as a result of an injury. 98 per cent of equine and 68 per cent of farm veterinarians suffered a crush, kick or trampling injury. 93 per cent of companion animal practitioners received a bite or scratch injury, compared with 50 per cent of equine and 22 per cent of farm animal veterinarians. In Australian veterinarians, 75 per cent of injuries were animal-related and 30 per cent involved cattle, with kicks commonest, followed by obstetrical procedures and being pushed against or stood on.

Injuries from Shoeing

These are not always the fault of the farrier. There are some horses with such bad feet that it may be quite impossible to shoe them without running

the risk of injuring the sensitive structures. The nails, toe-clips, or even the shoe, may inflict damage.

1. The Nails either may produce lameness by actually penetrating the sensitive laminae – a condition called 'pricking'; or, by being driven too close to the laminae, by pressing upon the sensitive structures – a condition known as 'binding'.

Pricking may be only slight when the farrier knows that the nail has stabbed the quick and immediately withdraws it. All nail injuries should receive prompt attention, for they are usually amenable to treatment in the early stages; but if neglected they rapidly suppurate, causing the horse great pain and often permanent damage.

Binding is not so serious. Generally it suffices to remove the shoe, to allow the horse to remain barefooted for a day or so, and then to replace the shoe, taking special care that the nails are driven carefully. The lameness in this case very often only appears two or three days after the horse has been shod, and is attributed to some other cause.

2. The Clip may produce lameness by being driven too coarsely, and either burning the sensitive structures when being fitted, or pressing upon them unduly when hammered into position afterwards. When side-clips are used, i.e. one on each side of the foot, if they are forced home too far the foot is jammed in between two rigid structures which will not allow it to expand and contract with each movement of the foot, and lameness results. The shoe should be removed, the horse given a rest for a day or two, the clips altered, and the shoe reapplied, when it will usually go sound. If burning is suspected, the same procedure may be adopted. If the shoe loosens until it is held only by one nail, or if the shoe is partially torn off, the horse may tread on the clip which penetrates the sole of the foot and inflict a very severe wound. This is treated as for pricking, the area being pared out and treated appropriately with antiseptics and antibiotics.

3. The Shoe may cause injury if it has an uneven surface and presses upon a part too much. This is particularly liable to happen when the horn of the foot is weak and thin. Horses with flat feet, or those with dropped sole, may develop bruises of the sole if the web of the shoe presses upon the outer circumference of the sole, where it joins the white line. In such cases the shoe should be removed and the unevenness corrected, or the bearing surface of the foot should be eased. Some horses may require to be shod with a bar shoe, so that the frog may take some of the weight off the affected part, and others need a run at grass.

Burning of the sensitive parts of the foot may occur by holding a hot shoe in position on the foot for too long a time, so that it may 'bed itself in'. This is a most reprehensible practice and should not be tolerated. The injury usually results in a separation of the horn from the sensitive tissues below, and some weeks pass before the horse can resume work. (See CORNS; BRUISED SOLE.)

Innominate Bone

This is the bone of the pelvis and the structures associated with it. The pelvis is composed of six separate bones, three on either side: ilium, pubis and ischium.

Inoculation

1. Introduction into an animal or culture medium of micro-organisms.
2. To induce immunity by introducing a vaccine or serum. (See INJECTIONS; VACCINATION; INFECTION; IMMUNITY.)

Inositol

It is a carbohydrate with a six-fold alcohol attachment. In the phosphate form it can combine with metals and make them unavailable (see PHYTIN). This effect is counteracted by including phytase in the diet.

Insect Growth Regulator

A pharmaceutical product which interferes with the life cycle of an insect. Such products include dicyclanil and cyromazine, which are used as pour-on preparations to prevent fly strike in sheep.

Insecticides

A wide range of effective insecticides is available for both external application and systemic use. Some, such as the organophosphorus compounds, may be toxic if not used properly. They have been implicated in causing illness in humans. General notes are given below; more detail will be found in the cross-references listed.

Large animals Insecticides for the protection of large animals are discussed under FLIES and FLIES - FLY CONTROL FOR HORSES AND LIVESTOCK. They may be administered as sprays, by immersion (dipping), as 'pour-ons' or, in some cases, by mouth. IVERMECTIN is an example.

Small animals Insecticides are available in numerous formulations for application as wet shampoos, aerosol sprays, dry dusting powders, 'spot-on' formulations and 'flea collars'. Active ingredients include permethrin, dichlorvos, fenthion and carbaril. There are many others. Dichlorvos and diazinon (both organophosphorus compounds) are used in 'flea collars'.

VetBooks.ir

Manufacturers' instructions should be strictly followed, and **only preparations stated to be safe for cats and rabbits** should be used on those animals.

Over-exposure of animals to insecticides, either through too frequent use or use of excessive quantities, can lead to poisoning. (See CHLORINATED HYDROCARBONS; ORGANOPHOSPHORUS POISONING; PERMETHRIN.)

Accidental poisoning DDT fell into disrepute in the UK, the USA, Australia and New Zealand, but is still used for ground spraying in parts of Africa. The use of unsuitable insecticides can lead to fatal poisoning in cattle, etc. (See TEPP.) Poisoning may occur following absorption of an unsuitable insecticide spray through the skin. This, or inhalation of spray droplets, may lead to dangerously contaminated milk. The following insecticides are not recommended for dairy and cowshed use on account of this risk: DDT, aldrin, dieldrin, chlordane, lindane, methoxychlor, toxaphene and heptachlor. (See CHLORINATED HYDROCARBONS.)

Some insecticides may be safe for one species of animal but fatal to another. For example, on a farm in New York State, an insecticide spray containing thiophosphate had no effect on 50 chickens, but killed more than 7,000 ducklings.

Dieldrin, used as a seed dressing, has caused fatal poisoning in wood-pigeons and other wild birds. Lambs have been killed by ALDRIN. (See BHC; DDT; DIELDRIN; DERRIS; TEPP; PARATHION; PYRETHROIDS; FLIES - FLY CONTROL MEASURES; CARBAMATES; CHLORINATED HYDROCARBONS; GAME BIRDS, MORTALITY.)

Insecticide resistance Extensive use of an insecticide can encourage resistance among the target species. Only a few years after its introduction in the 1940s, house flies showed resistance to DDT, and by 1970 some 250 species of fly affecting man, his animals or crops, had developed resistance to one or more of the organochlorines, e.g. dieldrin; organophosphates; or carbamates.

Most cases of resistance apparently depend on a single gene, and are developed mostly following large-scale use of insecticides in control programmes. (See also under FLIES - FLY CONTROL MEASURES.)

Insectivorous
Insect-eating. The term is applied to animals that feed on insects or their products, usually their eggs or larvae.

Insects
These are arthropod invertebrates of the class Insectora; they have an exoskeleton, bodies divided into head, thorax and abdomen, three pairs of legs and two pairs of wings (which may be vestigial or absent). They are a very large class of invertebrates and many are of veterinary importance. For a general description of these, see FLIES. Ticks or spiders, which have eight legs in the adult stage are often colloquially called insects, but they are arachnids. Insects provide a rich source of PROTEIN and it has been suggested that edible species should be farmed to produce food, animal feed and replace FISH-MEAL. (See ARACHNIDA; FLIES; MITES, PARASITIC; TICKS.)

Insemination
The introduction of semen into the vagina or cervix. (See ARTIFICIAL INSEMINATION.)

Inspissated
The term describes fluid being thickened or dried by evaporation or fluid removal. It is often used to describe pus in cases of TUBERCULOSIS, CASEOUS LYMPHADENITIS, etc.

Institute of Animal Health
This is the main BBSRC institute in England studying animal diseases of mainly viral origin. Address: Pirbright Laboratory, Ash Road, Pirbright, Woking, Surrey GU24 0NF. Telephone: 01483 232441.

Insulation of Buildings, Floors
(See under HOUSING OF ANIMALS.)

Insulin
Insulin is a hormone secreted by part of the pancreas, where it is produced by the islets of Langerhans. In the healthy animal it stimulates the uptake of glucose by cells in the liver and muscle, storing it as glycogen. Clinically it is used in the treatment of diabetes in dogs and cats. (See DIABETES MELLITUS, GLUCAGON.)

Insulinoma
A tumour affecting cells of the islets of Langerhans in the pancreas, which may lead to collapse, convulsions, coma and death in the dog as a result of HYPOGLYCAEMIA.

Insulin Resistance
A reduction in an animal's ability to respond to INSULIN so that there is a reduction in uptake of GLUCOSE into cells. It is seen in some cases of DIABETES MELLITUS in dogs and cats and CUSHING'S SYNDROME in horses. Often it occurs in obese animals (See OBESITY).

Insurance
In the UK there is now a wide choice of comprehensive insurance policies available to

VetBooks.ir

animal-owners. Farmers can insure against the risks of foot-and-mouth disease or brucellosis, for example. There is insurance for horses, and dog- and cat-owners can avail themselves of policies covering veterinary fees, third-party liability, theft or death of an animal from illness or accident. Veterinary surgeons can advise clients about insurance. Policies can be issued through veterinary surgeons. With the possibility of having to pay for a major operation or prolonged treatment, such policies can minimise the owner's financial outlay, and are a safeguard against unexpected and sometimes large expenses.

Intensive Livestock Production

This involves, generally speaking, keeping farm animals indoors to a greater extent than traditionally, and also housing them within a smaller space inside a building. Such systems can also, however, occur outside. All intensive systems require skilled management and veterinary input to prevent the problems intrinsic among large densities of livestock. Although the public often consider such systems wrong, in order to succeed they often require higher management and welfare standards than more traditional systems.

The advantages claimed for intensive livestock production are the economies of scale through reducing costs of labour and equipment per animal housed; lower feed costs through bulk buying and mixing feed on farm; the ability to afford skilled management and labour; also a saving in acres of valuable land.

The disadvantages are the effect on stock of large stocking densities, disease, cannibalism (among poultry) and all the problems of stress, and intensive feeding methods.

The following describes potential hazards and health problems, and should not be regarded as condemnation of all current farming methods.

Poultry De-beaking, to prevent FEATHER PICKING and CANNIBALISM, if badly done can cause injury and reduce resistance to infection. In consequence minimal amounts are currently removed, to make the beak blunt (See BEAK TRIMMING). Deprivation of access to dust in which to bathe can render birds prone to severe infestation with lice and mites, which may be resistant to the commonly used parasiticides; infestation can be a problem in battery houses. Mutilation of a beak also prevents preening. Lack of exercise is conducive to fatty degeneration of the liver in battery birds and also possible development of arthritis. Among birds crowded together on deep litter, coccidiosis and worm infestations are apt to be serious. Faulty ventilation often gives rise to a harmful concentration of ammonia in houses where there is litter, and also predisposes to infectious bronchitis and other respiratory infections. The greater the concentration of birds, the greater the stress, it seems; and the more chance of an increasing proportion both of susceptible birds and of 'carriers' of various infections.

Beef cattle In calf-rearing units, salmonella infections cause a high proportion of the deaths of bought-in calves. PARASITIC BRONCHITIS is also an important cause of losses, which may amount to 7 per cent.

In units taking in 12-week-old calves, respiratory disease, principally viral infections, is an important concern. Other conditions encountered include FOUL-IN-THE-FOOT, INFECTIOUS BOVINE KERATOCONJUNCTIVITIS, and BLOAT.

If trough space is too limited, inflammation of the eyes may be caused by cattle flicking their ears into their neighbours' eyes – simulating the effects of infectious bovine keratoconjunctivitis.

Among veal and other indoor reared calves, CALF PNEUMONIA, BRONCHITIS and a peracute coliform SEPTICAEMIA are major causes of losses. Anaemia, parasites, and a form of anaphylactic shock are also among the hazards of rearing.

Pigs These animals are particularly prone to the effects of STRESS, and of confinement in poorly-ventilated buildings which favours respiratory infections such as enzootic pneumonia.

The use of farrow-to-finish pens which accommodate pigs from birth to slaughter day has been advocated. These obviate four or five moves to strange surroundings with its accompanying stress.

Sheep Respiratory troubles, including various forms of pneumonia, are a danger in buildings where ventilation is poor. There are some very successful flock houses, with one end virtually open, where disease problems have been minimal – foot-rot being controlled by regular use of a foot-bath. In such buildings, the ewes lamb indoors, to the great advantage of the shepherd. Straw is used for bedding. YORKSHIRE BOARDING assists ventilation.

Lameness Intensive systems of farming tend to ignore the social behaviour of animals to the detriment of their health.

Cattle transferred from straw yards to concrete floors may become acutely lame with septic or aseptic laminitis, and bruising and ulceration of the sole.

(See also HOUSING OF ANIMALS.)

Intention

Wounds are said to heal by intention; primary intention when the edges of a wound are positioned

closely together (as when the wound is sutured); secondary intention is when they heal by more natural means, by the build-up of fibrous tissue, followed by a layer of epithelial tissue. (See also WOUNDS and WOUNDS, HOW THEY HEAL.)

Intercellular
Between cells.

Intercostal
Between the ribs.

Intercurrent
Intercurrent is a term applied to a disease which occurs during the course of another disease already present, and modifies its course or increases its severity.

Interdigital
Between two toes or digits.

Interdigital Cyst, Interdigital Abscess
Interdigital cyst (interdigital abscess) is a condition commonly affecting the feet of dogs, in which abscesses about the size of a pea or larger appear in the spaces between the digits of the paws. It most often affects SPANIELS, AIREDALES, SCOTTISH TERRIERS, SEALYHAMS and DANDIE DINMONTS.

Causes are generally held to be damage or infection of the hair follicles between the toes, or to grit penetrating the skin there. In some instances the lesion may be a true cyst.

Signs The dog licks its foot, and upon examination a swelling (which is painful) is noticed, usually on the dorsal surface of the foot or in the interdigital space. Within a couple of days or so, the swelling may discharge a little bloodstained pus or granulated matter. If the lesions have formed repeatedly, they may suddenly cease, and the dog remains free from them for perhaps months at a time. Unfortunately, recurrences are likely at varying intervals.

Treatment The cyst should be lanced and explored to remove pus, granulation tissue, and foreign material, after which the cavity may initially be packed with sterile, possibly antibiotic-impregnated gauze, and the foot bandaged to maintain cleanliness. Dressings should be changed daily until there is no more discharge and the wound has healed.

In some cases the entire lesion can be excised, along with part, or all, of the interdigital web. Encouraging results have been obtained by the professional use of CRYOSURGERY.

Interdigital Necrobacillosis
(See FOUL-IN-THE-FOOT.)

Interdigital Web
The fold of skin between the digits of dogs and cats.

Interferon
A glycoprotein which inhibits the multiplication of viruses within living cells.

Many types of cells can produce interferon as a means of defence against further viral infection.

Recombinant DNA techniques have made possible the production of interferons for therapeutic use.

Interferon may be used as an adjunct to post-exposure PROPHYLAXIS of human and animal diseases. Interferon-omega is available for small animals including dogs. While there is no direct effect on the virus, it can be useful in cases of canine parvovirus infection. RECOMBINANT FELINE INTERFERON has been used against feline RETROVIRUSES and CANINE PARVOVIRUSES.

Interleukin-15
A member of the cytokine group that is released from muscle by a reciprocal muscle-to-fat signalling pathway. It is involved in adipocyte (fat cell) metabolism.

Internal Haemorrhage
Internal haemorrhage may result from rupture of some large blood vessel; or it may be the result of an injury to some organ that is richly supplied with blood, such as the liver or spleen. In either case the bleeding occurs into one of the body cavities and the blood is lost to the tissues of the animal. (See also HAEMANGIOSARCOMA, CARDIAC; diseases with names beginning with the word HAEMORRHAGIC; WARFARIN.)

Signs of severe internal haemorrhage include extreme pallor of mouth and mucous membrane lining the eyelids, coldness of the skin, rapid breathing, or a series of gasps, collapse, and a pulse becoming weak, slow, and then imperceptible. (See SHOCK.)

Treatment of severe internal haemorrhage can seldom be undertaken in time to save life. When the internal bleeding is less profuse, success may be achieved with ADRENALIN, BLOOD TRANSFUSION or DEXTRAN, VITAMIN K.

International Cat Care (ICC)
Previously known as the FELINE ADVISORY BUREAU. Address: High Street, Tisbury, Wiltshire SP3 6LD. Website: www.icatcare.org.

VetBooks.ir

International Fund for Animal Welfare (IFAW)

Founded in 1969 in Canada, it is currently one of the largest charities in the world for animal welfare and conservation, with offices in 16 countries. London Office: 87-90, Albert Embankment, London, SE1 7UD. Telephone: 0207 587 6700, Fax: 0207 587 6720.

International Society of Feline Medicine (ISFM)

A society for veterinarians with a specific interest in cats. Founded by FAB (the Feline Advisory Bureau), the ISFM publishes a monthly peer-reviewed journal, providing articles and practical information. (See also FELINE ADVISORY BUREAU.) The ISFM also offers continuing professional development for veterinarians through distance educational courses and an annual congress.

Intersex

An individual with characteristics intermediate between those of a male and a female. In cattle, examples include the FREEMARTIN, XY gonadal dysgenesis (in which there are no gonads) and testicular feminisation. A case of the latter has been described in a single-born cow showing signs of virilism and found to have abdominal testes, some undeveloped Mullerian duct derivatives, a normal vagina, and a 60XY genotype in all tissues examined.

In canine examples of intersex, the *os penis* is absent, the penis cannot be extruded from the prepuce, and no testicles are present in the scrotum. On laparotomy a uterus and ovaries may be present.

(See also under TRISOMY.)

Interstitial

Interstitial is a term applied to cells of different tissue set amongst the active tissue cells of an organ. It is generally of a supporting character and formed of fibrous tissue. The term is also applied to diseases which specially affect this tissue, as interstitial nephritis. (See under KIDNEYS, DISEASES OF - CHRONIC NEPHRITIS.)

Interstitial Cystitis

Inflammation of the urinary bladder, described in man and considered to share many similarities with idiopathic cystitis described in cats. There is a strong association with stressful events, such as cat-to-cat interactions. The clinical signs are as for CYSTITIS and the condition is often self-limiting. Treatment usually involves reducing environmental stress, analgesia; and NUTRACEUTICAL AGENTS may have a beneficial effect on the bladder mucosa. (See also FELINE LOWER URINARY TRACT DISEASE.)

Intersucking

(See SUCKING.)

Intertrigo

Also known as SKIN FOLD DERMATITIS; inflammation results from friction between opposing surfaces rubbing together. It is particularly common in obese cats and dogs. Breeding to produce characteristics scoring highly in shows has resulted in some breeds having pronounced folding of the skin, the Shar Pei being an extreme example, predisposing to intertrigo.

Intervertebral Disc Protrusion

Each intervertebral disc, which has a soft, pulpy centre and a fibrous or gristly outer ring, acts as a shock-absorber between the vertebrae, and supports the spinal cord between them. Disc injury usually involves partial or complete rupture, with compression of the spinal cord to a lesser or greater extent. The injury is most common in BEAGLES, DACHSHUNDS, LHASA APSOS, PEKINGESE, SCOTTISH TERRIERS, SEALYHAM TERRIERS, SHIH TZUS, SKYE TERRIERS and spaniels. It also occurs in cats. Signs consist of varying amounts of pain and weakness or paralysis of the hindquarters, and may appear shortly after the dog has been observed to jump, slip, or fall; or they may appear in cases where no violent movement has been seen. Improvement may take place within a fortnight, but where paralysis persists, the outlook becomes progressively less hopeful.

A 'fenestration' operation is occasionally performed to reduce pain by relieving pressure on the spinal cord, but it is not of much use for paralysis. Other measures are as for the treatment of paralysis generally. (See under SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Intestinal Adenomatosis

(See under PORCINE INTESTINAL ADENOMATOSIS.)

Intestine, Obstruction

This may result from an impacted mass of food material (see IMPACTION). In the dog, for example, a hard mass containing spicules of bone may render defecation impossible, and an enema will be necessary if a dose of medicinal liquid paraffin does not achieve the desired result. In the cat a mass of fur (fur-ball) may similarly cause obstruction. FOREIGN BODY of many kinds, including string, are another cause. In rabbits, ingested matted fur can cause intestinal obstruction.

Wood chewing A bad habit of some horses, whether stabled or at grass, which can lead to obstruction of the small intestine.

Signs Colic, passage of stomach contents down both nostrils.

Treatment ENTEROTOMY under a general anaesthetic; and removal of the obstruction.

Duodenal obstruction in cattle is not common but can occur. In most cases the obstruction is due to decreased motility of the duodenum, caused by inflammation of the duodenal wall and PERITONITIS, resulting from duodenal ulcers or penetrating foreign bodies respectively.

Other causes A strangulated HERNIA is a serious cause of obstruction, compression of blood vessels and nerves making matters worse. INTUSSUSCEPTION, in which a part of the intestine becomes turned in on itself (like the finger of a rubber glove may do), is fraught with similar dangers. VOLVULUS, or the twisting of a loop of intestine, is another cause. All these conditions may be followed by GANGRENE and PERITONITIS. Prompt surgical treatment is necessary to save life.

A growth affecting either the lumen of the intestine so blocking it, or the exterior and so constricting it, is another possibility. (See TUMOURS; CANCER.)

Signs Intestinal obstruction can be expected to cause depression, loss of appetite, dehydration, fever, some degree of toxaemia, vomiting and pain.

TYMPANY (distension of the intestine with gas) may occur in some cases of intestinal obstruction. In brood mares, tympany of the large intestine may predispose to rupture of the caecum (or other part) from pressure exerted by the fetal hind feet at the onset of parturition. (See also COLIC for diseases in horses.)

Intestines

Horse 1. Small intestine. This measures about 20 m (70 ft), and is divided into a fixed portion – duodenum and a more or less free portion – jejunum and ileum. Its diameter varies from 4 cm to 8 cm (1½ in to 3 in) when moderately distended, and its capacity is about 55 litres (12 gallons).

2. Large intestine. This extends from the end of the ileum to the anus, and measures about 8 m (25 ft) in length. Its diameter varies in different parts from about 8 cm (3 in) in the small colon to nearly 50 cm (20 in) across the widest part of the caecum. It is divided into caecum, large colon, small colon and rectum. The caecum is a large blind sac lying on the right side of the abdomen and extending downwards and forwards to within a hand's-breadth from the sternum. It is shaped somewhat like a reversed comma, having both its entrance and its exit near the base, and has a capacity of about 36 litres (8 gallons). Foodstuff enters it by the ileocaecal valve, and leaves by the caeco-colic valve, which opens into the large colon.

Cows The intestines lie entirely to the right of the middle line of the abdomen.

(1) Small intestine. Measures 40 m (130 ft) in length and lies in the lower part of the right side of the abdomen, filling in the spaces left between more fixed organs.
(2) Large intestine. Much smaller than in the horse, and not so complicated. The caecum lies in the upper posterior part of the abdomen, with its blind sac posteriorly in or near the pelvic inlet. The caecum is about 75 cm (2½ ft) long and is followed by the colon (there is no small colon in the ox), which has a length of about 11 m (35 ft). The colon is arranged like the coils of a watch-spring, with each coil double, consisting of one part running towards the centre (centripetal), and a corresponding part running from the centre (centrifugal).

Sheep/Goats The intestines of the sheep and goat are similar to those of the cow.

Pigs 1. Small intestine. This varies from 15 m to 20 m (50 ft to 65 ft) in length, and mainly lies on the left side and floor of the abdomen, with some coils pushed across on to the right side of the body.

2. Large intestine. About 4.5 m (15 ft) long and considerably wider than the small bowel.

Dogs The intestines are short in this animal, only reaching a length of about 4.5 m or 5 m (15 ft or 16 ft), of which the small intestine measures 3.75 m to 4.25 m (12 ft to 14 ft). The small intestine occupies the right side of the abdomen and part of the floor. From here the colon has a short course upwards towards the head, turns across to the left side of the body, and then runs backwards to end in the rectum.

Rabbits The rabbit is a hind-gut fermenter, like the horse. The caecum is the largest organ of the alimentary system and the site of protein and vitamin production – much like the rumen of the cow. The cardia (entrance) of the stomach is formed in such a way that regurgitation is impossible and so food has to pass through the stomachs and intestines twice to be fully digested. This requires the presence of particles or fibre of various sizes and so the dentition must be healthy to slice the food adequately. The fibre particles carry the food to the caecum, entry being controlled by the FUSUS COLI in the transverse

colon. This instigates passage of the food craniad (forwards) to the caecum for fermentation. Twice a day the fusus coli allows contents from the caecum to be passed to the anus for CAECOTROPHY to take place.

Structure In all animals the intestines, both small and large, are constructed of four main coats. They all consist of an inner mucous membrane lining, a submucous connective tissue coat, a middle muscular coat and an outer peritoneal one.

Mucous membrane coat: this is the soft, moist, velvety lining which is found in all parts of the intestine. (See BRUSH BORDER; PEYER'S PATCHES; VILLUS.)

Muscular coat: there are two definite layers of muscle fibres in the wall of the bowel. The innermost of these has its fibres all running in a circular manner round the submucous coat, and the outer layer has fibres running lengthwise. In the large intestine some of these longitudinal fibres are collected into distinct bands called 'taenia', which, being somewhat shorter than the other fibres, cause a certain amount of puckering of the bowels. The muscular arrangement of the intestines is very important, as it is responsible for all the movement of the bowels. In health it is continually contracting and expanding, shortening and lengthening, and moving the food either onwards or backwards. During the process the food is squeezed and churned and most thoroughly mixed with the digestive juices. The movement is called 'peristalsis' when it tends to move the food towards the anus, and 'antiperistalsis' when it is in the opposite direction.

Peritoneal coat: this forms the outermost covering of the bowel. It is continuous for the whole length of the canal from the pylorus to the anus, except for certain comparatively small regions where, for example, the duodenum and the caecum are bound directly to the roof of the abdomen or to other organs by fibrous tissue. It is a tough membrane with a layer of smooth glistening cells on its outer surface which rub against similar cells on the surfaces of adjacent organs and reduce friction to a minimum. (See PERITONEUM.)

Attachments The intestines are hung or held in position by folds of peritoneum which bind them, directly or indirectly, to some part of the abdominal wall. The fold in which the free part of the small intestine hangs is called the 'mesentery of the small intestine', and it is through this that the blood and lymph vessels and the nerves enter and leave the bowel. It is composed of two layers, in the middle of which pass the vessels.

Functions (See DIGESTION, ABSORPTION AND ASSIMILATION.)

Intestines, Diseases of

Intestinal inflammation, or ENTERITIS, is a common disease in all animals, and may take an acute or chronic form. In either case the chief clinical sign is diarrhoea, although in rabbits it may be constipation. Severe diarrhoea leads to DEHYDRATION; while in the chronic form of enteritis, the animal ceases to thrive and the abdomen becomes permanently 'tucked up'. The causes and treatment of enteritis are given under DIARRHOEA.

PERFORATION of part of the intestine may follow ulceration, itself a complication of some cases of enteritis. Perforation injuries received in battle used to be common in cavalry horses; they may follow stabbing injuries such as goring by bulls, farm and road accidents, or the swallowing of sharp-pointed objects. (See FOREIGN BODY.) Perforation of the wall of the intestine is obviously a very serious condition and an immediate threat to the animal's life, since bacteria which accompany partly digested food escaping from the intestine will cause PERITONITIS.

Necrosis and infarction may be detected by assessing the serum levels of CREATINE KINASE kinase. (See also VOLVULUS; INTUSSUSCEPTION; COLIC.)

Intracellular

Inside a cell.

Intracellular Fluid

Also called cytosol or and is the fluid present within cells. It mainly consists of water but contains a complex of substances. (See also EXTRACELLULAR FLUID.)

Intracelomic

American spelling of intracoelomic.

Intracoelomic

Intracoelomic refers to the COELOM of birds and reptiles.

Intracranial

Intracranial is the term applied to structures, diseases, or operations associated with the contents of the cranium.

Intradermal

Into the thickness of the skin as in intradermal injections.

Intramammary

Within, or into, the mammary gland (udder).

Intramedullary

Within the marrow cavity of long bones. Thus, intramedullary pins – used in the treatment of fractures.

Intramuscular
Within a muscle, e.g. intramuscular injection.

Intraocular
Inside the eyeball.

Intraosseous
Literally meaning "within the bone", this term usually refers to a specific type of fluid therapy, where the fluid is administered into the marrow cavity of selected long bones. It is particularly useful in animals with small bones such as rodents, rabbits, birds and reptiles, and also in puppies and kittens. Care must be taken that the bone is not damaged prior to, or due to, the technique and that PNEUMATISED BONES of birds are not used.

Intraperitoneal Injections
Intraperitoneal injections are those made direct into the abdominal cavity. The technique was used to inject glucose solution into lambs with hypothermia due to starvation.

Intraruminal
Into the rumen. Medicines and boluses can be administered by mouth or fluids injected through the abdominal wall usually in the sublumbar fossa. Fluid can be drained off for investigations.

Intrasynovial
Into the JOINT; often used in the context of obtaining samples or for treatment.

Intrathecal
Into a sheath; intraspinal.

Intratracheal
Into the 'windpipe'. The term is used to describe and includes the introduction of an endotracheal tube in anaesthesia, and it can be used for injections. (See also ENDOTRACHEAL ANAESTHESIA.)

Intravenous Injection
An injection direct into a vein, a technique employed in anaesthesia and where large quantities of fluid have to be injected. (See also INJECTIONS.)

Intussusception
Intussusception (invagination) is a form of obstruction of the bowels in which a part of the intestine turns in on itself like the finger of a rubber glove or inside itself like the sleeve of a coat pulled off too quickly. It usually follows increased gut motility and often results from diarrhoea. It occurs mostly in horses, hamsters, puppies and kittens, causes obstruction of the intestine and great pain.

If the condition is not relieved it leads to stopping of the blood supply in that part of the bowel which is enclosed, and death. Signs include loss of appetite, uneasiness due to abdominal pain, straining and blood in the faeces. In the dog a sausage-like swelling may be palpated in the abdomen, or, as occurs commonly in hamsters, there may be protrusion from the anus of a turgid, cylindrical mass having four thicknesses of bowel wall. Treatment involves manipulation under anaesthesia (after LAPAROTOMY in most cases), and sometimes the surgical removal of the innermost portion of the bowel and an end-to-end ANASTOMOSIS. In hamsters the prognosis is particularly poor.

Caecal intussusception has been recorded in ponies in which the CAECUM invaginated into the colon. It is not common.

Intussusceptum
The part of an INTUSSUSCEPTION which is inside the INTUSSUSCIPIENS.

Intussuscipiens
The outside part of an INTUSSUSCEPTION which encloses the INTUSSUSCEPTUM.

Inulin
A POLYSACCHARIDE found in the rhizomes in roots of many types of plants, especially those that do not store starches, and a substance vitamin-like in its activity. When fed to puppies there was an increase in the *Lactobacillus* spp. population thereby possibly counteracting infections such as *E. coli* and/or *Salmonella* spp. It is a useful source of sugar for birds with diabetes mellitus. It is found in Jerusalem artichoke.

Invertebrates
Animals without backbones. Some of these are kept as 'pets' (tarantula spiders, scorpions, millipedes, praying mantis, etc.). Where they are kept as captive animals they used to fall under the Protection of Animals Act 1911 and action has been taken in cases of neglect. However, this is not the case with the Animal Welfare Act 2006. In New Zealand, two classes of invertebrate (molluscs and crustaceans) are covered by the Animal Welfare Act 1999. In the UK, the common octopus (*Octopus vulgaris*) is protected under the Animals (Scientific Procedures) Act 1986.

In Vitro
Outside the living body, usually in a test tube or in an artificial environment.

In Vivo
In the living body.

Involution
A change back to its normal condition which an organ undergoes after fulfilling its normal

function, e.g. involution of the uterus following pregnancy.

Iodides

Iodides are salts of iodine. Sodium iodide is used in the treatment of ACTINOBACILLOSIS in cattle, and formerly it was used with other drugs in the treatment of oedema and of RINGWORM. Taken in excess, iodides cause a condition known as 'iodism' or iodine poisoning. The signs of this are diarrhoea, loss of appetite, emaciation, total refusal of water, a dry, scurfy condition of the skin with a loss of hair and, in some cases, catarrh of the nasal mucous membranes.

Iodine

Iodine is a non-metallic element which occurs naturally in seaweed, brine, etc. It is prepared in the form of dark violet-brown scales, which are soluble in alcohol and ether. Potassium iodide is soluble in water and was used as LUGOL'S SOLUTION. Excess can cause loss of production in laying hens. Combined with the amino acid TYROSINE, it forms the thyroid hormone.

Uses Pure iodine in the form of scales is never used. TINCTURE of iodine that is a common household remedy contains 2.5 per cent of iodine. Solubilised formulations of iodine known as IODOPHORS, e.g. Iosan CCT, are used for teat-dipping in dairy hygiene for the prevention of mastitis. (See also MASTITIS IN COWS – Teat-dipping.) Iodophors are also used in treating minor skin wounds and abrasions.

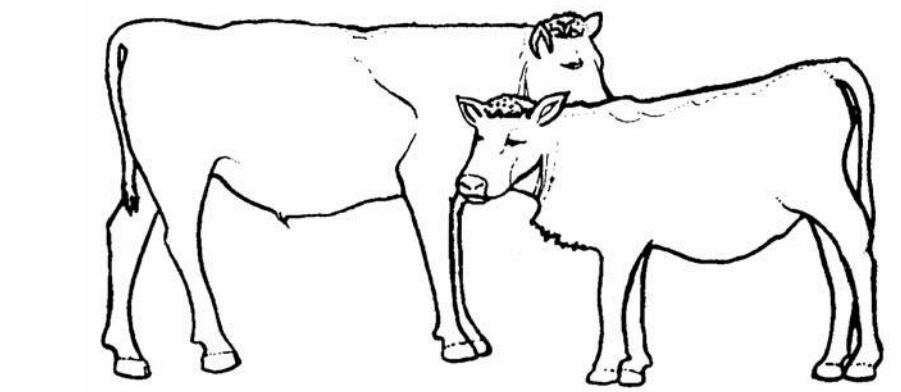
Internally, iodine is a violent irritant poison. (See also under RADIOACTIVE IODINE, POVIDONE IODINE.)

Iodine Deficiency on the Farm

Iodine is required by the body for the formation of thyroxine, the hormone produced by the thyroid gland, and the common sign of iodine deficiency is goitre. Acute iodine deficiency occurs in 14 states of the USA. In Britain, typical iodine deficiency is not common in farm stock, although in some areas the question of iodine intake below the optimum for health and fertility is of economic importance. The remedy is to provide salt licks or mineral mixtures containing traces of iodine. This is particularly important when large quantities of kale, cabbage or turnips are fed. (See TRACE ELEMENTS.)

Iodophor

(See under IODINE.)



Ionic Medication, Iontophoresis

A form of treatment involving the use of an electric current to cause ions of soluble substances to pass through the skin and subcutaneous tissues. Electrolytes which have been used include sodium chloride and magnesium sulphate, and copper sulphate, methylene blue, quinine sulphate and adrenaline have also been used. These are made into solutions in which pads of felt or lint are soaked and the pads are applied to the area to be treated. One electrode is laid over the pad, and another applied to some suitable part of the body and the current is applied. This causes a disintegration of the electrolyte into its constituent ions which are driven through the skin.

Uses Ionisation has been used to stimulate the healing of ulcers, in the treatment of demodectic mange, to soften scars, to exert local antiseptic or germicidal actions, to allay pain, and to induce local construction of vessels in treating inflammatory changes.

Ionised Air

A supportive therapy in humans with respiratory disease. In a turkey hatchery ionisers greatly reduced the bacterial counts. It was used in poultry houses in the Soviet Union to reduce disease.

Iodine deficiency – comparison of body size between the normal and deficient animal.

VetBooks.ir

Ionised Calcium
The amount of ionised calcium (Ca+) is preferred as a measure in blood biochemistry as giving a more accurate assessment of calcium metabolism than does total calcium.

Ionising Radiation Regulations 1999
These were introduced originally with the 1985 Regulations in the UK and cover the inspection of X-ray equipment in veterinary practices, from a safety point of view. The regulations also cover training of personnel involved, recording and monitoring of possible dosage of staff, and rules on maintenance and monitoring of x-ray equipment.

Ionophores
These include the antibiotics MONENSIN SODIUM, narasin, SALINOMYCIN and LASALOCID. They are so-called because they have the capability to combine with particular ions and to transport these ions through biological membranes. They are used as growth promoters and to control protozoal infections such as COCCIDIOSIS.

Ionophore poisoning (See MONENSIN SODIUM.)

Ipecac, Ipecacuanhua
Ipecac (or Ipecacuanhua) is the ground-up root or the dried rhizome of either *Cephaelis ipecacuanha* or *C. acuminate*. It is used as syrup or powder to promote vomiting (EMETIC) or as an EXPECTORANT.

Ipsilateral
Occurring on the same side.

Iridin
An isoflavone, a type of glucoside that can be isolated from several types of iris including *Iris versicolor* (the larger BLUE IRIS). The compound can be toxic to animals and man. Signs can include gastrointestinal irritation, blistering, salivation, recumbency and death.

Iridium
As its 192 radioactive isotope, iridium is used in anti-cancer therapy. The isotope has been sealed into a wire transducer and fixed with sutures into neoplastic tissue for treating horses with squamous cell carcinoma and MELANOMA.

Iris
(plural, Irides)
Iris is part of the CHOROID and the muscular and fibrous pigmented curtain which is in the anterior chamber and hangs behind the cornea of the eye and serves to regulate the amount of light that is allowed to reach the inner parts of the eye. It has a central hole or perforation (PUPIL). It possesses radiating and circular muscle fibres which, when they contract under the influence of light, enlarge and decrease the size of the pupil respectively. (See EYE - FRONT OF THE EYE.)

Iridectomy An operation by which a part or the whole of the iris is removed.

Iris
A plant Genus of the *Iridaceae* Family.

Irish Draught Horses
An old breed from Ireland which is lighter than the English draught breeds. They are valued as sires to breed event horses out of THOROUGHBREDS mares. Hunters can also be bred, by using thoroughbred stallions on Irish Draught mares. The progeny are clean limbed with good bone formation. They normally have a very good temperament and are usually bay or chestnut in colour.

Irish Red and White Setter
A largish dog, looking like other setters, with a long coat coloured red and white. It is prone to CANINE LEUKOCYTE ADHESION DEFICIENCY, PROGRESSIVE RETINAL ATROPHY, VON WILLEBRAND'S DISEASE (DNA tests available).

Irish Setter
This largish dog with pendulous ears and a silky chestnut coat was originally bred as a gun dog. Inherited defects include QUADRIPLEGIA, AMBLYOPIA and PROGRESSIVE RETINAL ATROPHY. Other conditions that may possibly be inherited are HAEMOPHILIA, spondylolithesis ('WOBBLER' SYNDROME), CATARACT and MEGAOESOPHAGUS. DNA tests are available for CANINE LEUKOCYTE ADHESION DEFICIENCY.

Irish Terrier
A smallish (10 kg to 15 kg; 20 lb to 30 lb) terrier-type dog with a harsh wheaten or red coat. It is susceptible to CONGENITAL MYOTONIA and CYSTINURIA.

Irish Water Spaniel
A spaniel-type dog, usually larger (20 kg to 30 kg, 45 lb to 65 lb) than the ENGLISH SPRINGER SPANIEL and compact, with large droopy ears and a dark chestnut 'curly' coat. It can be used as a gundog.

Irish Wolfhound
A very large, tall dog with long head, deep chest and flat coat; usually grey or beige in colour. Ununited ANCONEAL PROCESS (incompletely developed elbow-joint), congenital polysystemic

VetBooks.ir

(intra-hepatic) SHUNT and CALCINOSIS CIRCUMSCRIPTA may be inherited by unknown mechanisms. OSTEOCHONDROSIS appears to be a possible dominant trait, while PROGRESSIVE RETINAL ATROPHY is a recessive trait. The breed is prone to rhinitis. Conditions of the MYOCARDIUM lead to CONGESTIVE HEART FAILURE (See MYOCARDIUM).

Iritis
Inflammation of the iris. (See EYE; IRIS.)

Iron
Iron is a nutritional TRACE ELEMENT – essential for life. Over half the body's iron is contained in the haemoglobin of the red blood cells and myoglobin of muscles. Iron is additionally present as beta-globulin transferrin in the blood plasma and in enzymes.

Iron deficiency results in anaemia, often seen in fast-growing piglets reared indoors; there is paleness, dyspnoea and diarrhoea. It is also found in calves and lambs fed milk or milk substitute without iron supplementation and little or no roughage.

Iron also has a role in bodily resistance to infection. IRON-BINDING PROTEINS can be shown to inhibit the growth of bacteria *in vitro*. The ability of some micro-organisms to bind iron to themselves, depriving the host animal, is a feature of pathogenicity, and ability of the host to limit availability to the pathogen is associated with resistance to infection.

Bacteria (e.g. salmonellas and tubercle bacilli) and some fungi produce iron-binding substances.

Iron-Binding Proteins
These include conalbumin, a constituent of egg-white; transferrin, in blood plasma; lactoferrin, in milk, tears, saliva, bile, seminal secretions, cervical mucus, and in the granules of neutrophils. All these proteins inhibit the growth of bacteria, including salmonella.

Iron-Dextran
A compound of iron used in injectable form to prevent iron-deficiency anaemia in piglets.

Iron Poisoning
This may occur from overdosage, or from the eating by a pet animal of an iron preparation left within reach. (See also under FLOOR-FEEDING OF PIGS, for the danger of concrete made with sand rich in iron.)

Horses have died very soon after receiving an intramuscular injection of an organic iron preparation.

Piglets have been poisoned by iron-dextran preparations given to prevent anaemia and ASYMMETRIC HINDQUARTER SYNDROME may develop following organic iron injections.

In the dog, ferrous sulphate or ferrous gluconate in doses as low as 0.3 g or 0.75 g (4.6 or 11.6 grains) respectively of ferrous iron per kg body-weight, have caused severe illness with diarrhoea, vomiting and ulceration of stomach and intestine.

Iron Storage Disease
A disease of cage birds, especially Mynah birds, starlings, birds of paradise and toucans, in which excessive amounts of iron are deposited in the liver. Treatment involves the use of chelating agents and the supply of diets low in iron and vitamin C. (See HAEMOSIDEROSIS.)

Irradiated Meat
(See MEAT IRRADIATION.)

Irradiation
Exposure to X-rays, radioactive material, ultra-violet, or infra-red rays. Irradiation with measured doses of X-rays is used therapeutically in treating tumours; and to attenuate lungworm larvae for use as an oral vaccine against husk. Irradiation with ultra-violet light is used to sterilise, e.g. milk to extend its usable life. (See PARASITIC BRONCHITIS; also RADIATION SICKNESS; IONISING RADIATION REGULATIONS 1999.)

Irrigation
Irrigation is the washing-out of wounds or cavities of the body by means of large amounts of warm water or saline, often containing some antiseptic in solution.

Ischaemia
Restriction of blood supply to an area.

Ischaemic Contracture
(See under MUSCLES, DISEASES OF.)

Ischium
Ischium is the bone which forms the most posterior part of the pelvis, and forms the point of the buttock.

Ischuria
Ischuria means insufficiency in the amount of urine passed, due either to suppression of excretion in the kidneys or to retention in the bladder.

ISFM
(See INTERNATIONAL SOCIETY OF FELINE MEDICINE.)

Islets of Langerhans
(See PANCREAS.)

VetBooks.ir

Isoenzyme
One of a number of forms of the same enzyme which have similar activities but may vary in rate of action and other characteristics and which can often be differentiated by ELECTROPHORESIS.

Isoflavones
Organic compounds often naturally-occurring in plants such as the IRIS and also in SOY PROTEIN. They can act as PHYTOESTROGENS in mammals.

Isoflurane
A colourless liquid with an ether-like smell, non-explosive and non-inflammable in clinical concentrations, used as an inhalation anaesthetic for most species. Induction of anaesthesia and recovery are more rapid than with halothane, which it has more or less replaced. It is useful in high-risk cardiac cases. It is one of the few anaesthetics which can be legally used in food-producing animals.

Isolation
Isolation is an important procedure in the control of the spread of infectious disease. On a farm it is advisable, where practicable, to keep newly bought stock separate from previously existing stock for two or three weeks (the actual period length depends on the disease; it can be much longer for tuberculosis), so that if infectious/contagious disease occurs it may be possible to prevent its spread to the existing stock. (See INCUBATION PERIOD; INFECTION; QUARANTINE; NOTIFIABLE DISEASES.)

Isoleucine
An amino acid whose activity may be influenced by excess leucine in the diet. Levels must always be balanced with those of leucine and valine. It can be a limiting amino acid in broiler diets based on soya-bean and wheat or maize.

Isomer
These are compounds which have an identical chemical formula with the same number of atoms, but they are structurally or spatially different.

Isometamidine Chloride
It is used as a treatment of TRYPANOSOMIASIS such as NAGANA in cattle, but it is not suitable for CAMELS. (See NAGANA.)

Isoquinolinium
Isoquinolinium chloride lotion has been used in the treatment of ringworm in cattle.

Isospora
A genus of protozoal parasites which cause coccidiosis.

Isotonic
Isotonic is a term applied to solutions which have the same power of diffusion as one another. An isotonic solution used in medicine is one which can be mixed with body fluids without causing any disturbance. An isotonic saline solution for injection into the blood, so that it may possess the same osmotic pressure as the blood serum, contains 0.9 per cent sodium chloride (NORMAL SALINE). This is also known as normal or physiological salt solution. An isotonic solution of glucose for injection into the blood is one of 5 per cent strength in water. Solutions, which are weaker or stronger than the fluids of the body with which they are intended to be mixed, are known as hypotonic and hypertonic respectively.

Isoxsuprine
A peripheral vasodilating agent with activity confined to the lower limb and it has no effect on blood pressure, heart rate or rhythm. It can be used as an oral paste in horses to alleviate the ISCHAEMIA of NAVICULAR DISEASE in horses and for WING TIP OEDEMA in birds of prey.

Italian Greyhound
A toy breed of the greyhound type. They are small, 33 cm to 38 cm (13 in to 15 in) and weigh 3.5 kg to 8.2 kg (8 lb to 18 lb), of good temperament and make suitable pets. They are fast, with a high-stepping action, and of various colours. They are prone to CANINE AUTOIMMUNE HAEMOLYTIC ANAEMIA, CATARACT, EPILEPSY, PATELLAR LUXATION, LEGG-CALVÉ-PERTHES DISEASE, PROGRESSIVE RETINAL ATROPHY and VON WILLEBRAND'S DISEASE.

Italian Spinone Dogs
A breed strong which was used as a gundog. Dogs are about two ft to two ft three in (60 cm to 70 cm) and weigh 75 lb to 85 lb (34 kg to 39 kg). The coat is slightly coarse and white, orange roan and brown roan. It is susceptible to CEREBELLAR ATAXIA (DNA test available), HIP DYSPLASIA, and GASTRIC TORSION.

Itchiness
(See PRURITUS.)

'Itchy Leg'
A common term for chorioptic mange. It is seen in many species, including cattle and sheep.

-itis
A suffix added to the name of an organ to signify inflammation of that organ.

VetBooks.ir

Itraconazole

An antifungal substance administered orally in small animals and birds. It is gaining popularity as a treatment for RINGWORM. Its use should be closely monitored especially in cats suffering cardiac disease, and it should not be given to pregnant queens. (See GRISEOFULVIN; LUFENURON.)

IV

Short for intravenous; usually refers to that route of injection.

Ivermectin

Ivermectin, an AVERMECTIN, is a potent anthelmintic, effective at very low dosage, which can be given orally, by subcutaneous injection or as a pour-on (transdermally). Ivermectin also gives control of lungworms in addition to external parasites such as warbles, lice, and sarcoptic mange mites on pigs; it is an effective treatment for sheep scab, given as two injections, one week apart. It is effective against mature and immature roundworms of cattle, including *Ostertagia* larvae; against ticks, mange mites, warbles, etc. Horses can be dosed orally with a paste formulation of ivermectin for the control of roundworms and horse bots. Injectable ivermectin is used transdermally as a pour-on off-licence in cage birds for treating scaly face. (See CNEMIDOCOPTIASIS; WORMS, FARM TREATMENT AGAINST; HORSE BOTS.)

Formulations of ivermectin are available in the UK for sheep, pigs, cattle and horses; but not for dogs or cats.

A pour-on formulation is available for the control of internal and external parasites of cattle. The product contains isopropyl alcohol which is highly inflammable. Protective clothing (including gloves) must be worn when liquid ivermectin products are applied.

Ivermectin poisoning in dogs This is caused by a MUTATION of the multidrug resistance gene (MDR-1), with poisoning usually occurring as a result of ignoring manufacturers' recommendations. Some breeds (e.g. collies and their crossbreeds) appear very susceptible. Clinical signs include dilated pupils, ataxia, depression and coma. Recovery after intensive care has been reported but may take several weeks.

Ixodes

Ixodes is the generic name of one of the varieties of ticks that infest animals. (See TICKS.)

J

Jaagsiekte
A disease of adult sheep, first recognised in South Africa. (See PULMONARY ADENOMATOSIS.)

Jack
A male donkey.

Jack Beans
Jack Beans may cause poisoning if fed raw. (See LEGUME POISONING.)

Jack Russell Terrier
A small, lively dog, having a white coat with brown or black patches. Originally a crossbreed, it now breeds true. Jack Russell Terriers were formerly recognised as a type, but have now been accepted by the Kennel Club as a breed. There are three varieties of this terrier breed. The original hunting terrier is the Jack Russell bred by the Reverend John Russell in the East Midlands in the 19th century. This is a long-legged working terrier similar to a fox terrier. The second is a popular, extremely active smaller variety with slightly bowed front legs and is a popular pet in non-hunting circles. Another version is called the Parson Russell terrier. The breed is always white (to distinguish from the quarry in the days when it was bred exclusively for fox hunting) with various black and tan markings. It is generally a healthy breed but it is prone to LENS LUXATION, PATELLAR LUXATION and it may inherit ATAXIA and LEGG-CALVÉ-PERTHES DISEASE.

Jacob Sheep
A breed of sheep which is piebald (black and white). They are small: ewes weigh 35 kg to 40 kg (75 lb to 90 lb), polycerate (multi-horned, with two, four or six horns). They are used for meat, wool and hides. Although still considered rare, it is a very popular breed on smallholdings.

Jacobson's Organ
Also known as the vomeronasal organ, this is associated with the detection of flavours such as those of food, but is thought also to be able to detect pheromones. The organ has 2 small tubes which extend from the floor of the nasal cavity to the level of the 2nd/4th cheek tooth. It is active in most mammals, but even more highly developed in certain reptiles, especially snakes.

James Hutton Institute
A combination of the Macaulay Land Use Research Institute and Scottish Crop Research Institute, it is a research institute dealing with crop, soils, land use and environment. Addresses: The James Hutton Research Institute, Craigiebuckler, Aberdeen AB15 8QH; The James Hutton Institute, Invergowrie, Dundee DD2 5DA. Telephone: 0844 928 5428.

Janet
A female mule.

Japanese Akita Dogs, Akita inu Dogs
A breed also called Akita inu, originating from Japan. It is a large strong dog with a thick coat, prick ears and a tail curling over its back. It can suffer from UVEO-DERMATOLOGICAL SYNDROME.

Japanese B Encephalitis
This disease is present in Nepal and other regions of Asia. The virus can be carried by imported monkeys of various strains and from various parts of the world. It is a ZOONOSIS and a cause of human death. A vaccine has been used against human infection.

Cause A flavivirus. The disease is transmitted by mosquitoes from avian species which act as reservoirs of infection but are themselves asymptomatic.

Signs In horses, the sight is affected first. Later they become drowsy. Many die, and the recovery of others is seldom complete. Pigs are also susceptible; abortion and stillbirths result from infection.

Japanese Bobtail
A breed of cat of 'foreign' conformation with a rudimentary tail, linked to a recessive gene. The hind-legs are longer than the fore-legs but are kept angled so that the back is level. There are similarities with the Manx, but there does not appear to be the same frequency of defects as occurs in that breed.

Japanese Chin Dogs
A small 'toy' dog, weighing 2 kg to 7 kg (4 lb to 15 lb) and 20 cm to 27.5 cm (8 in to 11 in) high with a long silky coat. The colour is black and white, lemon and white, red and white, and black and white with tan points. The head is DOLICHOCEPHALIC. The tail is feathered and curls up over the back.

Japanese River Fever
(See SCRUB TYPHUS.)

VetBooks.ir

Japanese Tosa
A breed of dog raised in Japan for fighting. Importation into the UK is banned under the Dangerous Dogs Act 1991.

Jaundice
Jaundice is a yellowish discoloration of the visible mucous membranes of the body (eye, nose, mouth and genital organs). The discoloration is caused by bilirubin, an orange-yellow pigment produced following the breakdown of erythrocytes in the blood (haemolytic jaundice), due to liver disease (non-haemolytic jaundice), or due to obstruction of the bile flow from the liver and gall-bladder.

The clinical sign of jaundice (icterus) may also follow the destruction of red blood cells by parasites, such as may occur in cases of biliary fever and surra in the horse; red-water in cattle; malignant jaundice (canine babesiosis); it is seen also in leptospiral jaundice (see LEPTOSPIROSIS) and canine viral hepatitis.

In cats, jaundice is seen in many diseases, including the dry form of FELINE INFECTIOUS PERITONITIS, TOXOPLASMOSIS.

Jaundice may indicate an incompatibility between the blood of sire and dam causing haemolytic jaundice of the newborn foal or piglet.

When bile cannot enter the small intestine by the bile-duct from the liver in the usual way, it is absorbed by the lymphatics and the blood vessels, carried into the general circulation, and some of its constituents are deposited in the tissues. (See GALLSTONES, also under CIRRHOSIS; LIVER, DISEASES OF; EQUINE BILIARY FEVER; GALL-BLADDER.)

It may be seen during poisoning with copper, mercury, phosphorus, chloroform or lead, and after some snakebites. Aflatoxins may cause jaundice.

(See also BILIARY FEVER; FOALS, DISEASES OF; JAUNDICE; LEPTOSPIROSIS.)

Jaundice, Leptospiral
(See under LEPTOSPIROSIS for the appropriate animal.)

Java Bean Poisoning
The Java beans, *Phaseolus lunatus*, were once imported in large amounts. The beans are of varying origin, and differ in colour, thus: Java beans are as a rule reddish-brown, but they may be almost black; Rangoon or Burmah beans are smaller, plumper, and lighter in colour (so-called 'red-Rangoons' are pinkish with small purple splashes).

The active poisonous agent in the beans is a substance called phaseolunatin, which is a member of a group of cyanogenetic glucosides.

Signs These are exactly the same as those given under HYDROCYANIC ACID.

Jaw
The upper jawbones are two in number and are firmly united to the other bones of the face. The lower jaw – mandible or coronoid process – is composed of a single bone in horse, pig, dog and cat, but in the ruminants the fusion between right and left sides does not occur until old age. Each of the jaws presents a number of deep sockets or 'alveoli' which contain the teeth. (See DISLOCATIONS; FRACTURES - THE FACE BONES; TEETH; also MUSCLES, DISEASES OF; ACTINOMYCOSIS (LUMPY JAW).

Jaw, Diseases of
For overshot and undershot jaws, see under TEETH, DISEASES OF.

'Lion jaw' (CRANIOMANDIBULAR OSTEOPATHY): a disease seen mostly in WEST HIGHLAND TERRIERS. Eating becomes difficult; mouth-opening, painful. Diagnosis is by radiography of the craniomandibular joints. The condition is self-limiting.

(See 'BOTTLE-JAW'.)

Jejunal Haemorrhagic Syndrome (JHS)
Other synonyms include Haemorrhagic Bowel Syndrome (HBS), Haemorrhagic Gut Syndrome (HGS) or 'bloody gut'. An uncommon condition of adult cattle, mainly seen in dairy cows. Signs are acute in onset and involve rapid general malaise without pyrexia and usually without MELAENA signs of pain. Diagnosis is difficult but distended small intestinal loops may be palpated and there is a suggestion of intestinal obstruction. Most die and show jejunal haemorrhage at post mortem. The cause is debatable but may be *Clostridium perfringens* type A, but fungi have been found such as *Aspergillus fumigatus* and *Mucor* types. (See MUCORMYCOSIS.)

Jejunum
Jejunum is the central portion of the small INTESTINE.

'Jekyll and Hyde' Syndrome
(See COCKER RAGE SYNDROME.)

Jenny
A female ass.

Jequirity Poisoning
This is caused by the red and black seeds of the climbing plant *Abrus precatorius*, which grows in Australia, Asia and South America. It gives rise to cyanosis and pinpoint-sized haemorrhages from the skin, as well as diarrhoea.

Jersey Cattle
A Channel Island breed of cattle originating from Jersey which produces milk with a high fat and

solids content. It has a very female dished face and is relatively small. It has black pigmentation in the mouth and skin. It is a very economic converter of feed into milk. Cattle can suffer MILK ALLERGY and ALLERGIC NASAL GRANULOMA.

Jersian Cattle

Also known as an F–J hybrid, this is a beef cross obtained from a Jersey bull on a Friesian cow. (In New Zealand, the reverse cross is used.)

Jetting

Jetting is a technique developed in Australia, involving the application of insecticide under pressure by means of a jetting gun – a handpiece with 4 needle jets for combing through the wool. The pressure used is 10 to 14 kg/cm² (60 to 80 lb per sq in), which can be achieved by an ordinary medium/high-volume agricultural sprayer.

Jetting has not displaced dipping to any extent in the UK, where spraying has been found inefficient in the control of sheep scab.

JHS

See JEJUNAL HAEMORRHAGIC SYNDROME in Cattle.

Jigger Flea

(See under FLEAS – *Tunga penetrans*.)

Jill

A female donkey, ferret or hare.

Johne's Disease, Paratuberculosis

Johne's Disease (Paratuberculosis) is a chronic infection, involving the small and large intestines. It affects cattle particularly, but sometimes sheep, goats, camelids and deer, and is characterised by the appearance of a persistent diarrhoea, gradual emaciation and great weakness. A post-mortem examination usually reveals a characteristic 'corrugated cardboard' appearance of the large intestine. In other species the main sign is weight loss, sometimes diarrhoea (but usually not), leading eventually to CACHEXIA. The intestinal thickening characteristic of the disease in the bovine is rarely seen and often the changes are a slight enlargement of the mesenteric LYMPH NODES. Lymph tissue disease is confirmed by a positive ZIEHL-NEELSEN STAIN. There are PCR, ELISA and CFT tests for Johne's disease but often they do not detect infection until the disease is well established. Infection can occur in the rabbit and in the pig, when post-mortem findings may at first suggest tuberculosis. There is a possible association with some cases of Crohn's Disease in man.

Cause *Mycobacterium avium subspecies paratuberculosis (MAP), formerly M. johnei* and then *M. paratuberculosis*.

Experimentally, sheep can be infected with as few as 1000 *MAP* bacilli. These then multiply in the intestinal mucosa for the first two or three months after infection. Some animals are able to overcome the infection completely; others become carriers, with the bacilli remaining in the intestinal mucosa and lymph nodes. Some of the carriers eventually become clinically ill with Johne's disease.

Signs The disease is very slow in onset. Cattle that have become infected may not show signs for as long as two years after the last case occurred on that farm.

Pointers to the disease are an unexplained drop in milk yield (often months before other signs appear) and diarrhoea in an individual adult animal.

Loss of condition, general unthriftiness, a harsh, staring coat are then seen, with diarrhoea. The temperature fluctuates a degree or two above normal. Appetite is variable. In the last stages emaciation becomes very marked, and the animal becomes progressively weaker.

In sheep, goats and camelids diarrhoea is not a major sign.

Treatment When well established, Johne's disease is invariably fatal, and no treatment is effective or worthwhile.

Prevention Attention should be paid to the prevention of infection in other animals, especially calves. Pastures that are suspected of being heavily infected should be left without stock for four or five months. All infected litter should be stored in a dung-pit which is not accessible to other animals, and should be used for cultivated land. Loose-boxes, sheds, etc., that have housed a case should be carefully disinfected and diseased animals should be fed after healthy ones. Ponds and water-courses should be fenced to prevent fouling by faeces, water for drinking being pumped out.

Calfhood vaccination may prevent clinical disease but interferes with subsequent tuberculin tests. The vaccine is registered for goats but can be used under the 'CASCADE' for calves.

Kids are vaccinated at the age of two to four weeks.

Diagnosis The disease can usually be diagnosed on clinical evidence, with some confirmation afforded by microscopic examination of the faeces. Typical clumps of acid-fast bacilli may be found, and the complement fixation test is positive in

about 90 per cent of cattle with advanced disease. The fluorescent antibody test is equally useful.

Diagnosis of the carrier state is not possible with any certainty. There is no single test which can conclusively detect the presence or absence of MAP, although laboratory tests can identify the presence of *Mycobacteria* spp. The COMPLEMENT FIXATION TEST is positive in only a small proportion of carriers and can give false positive results.

The difficulty in identifying 'carriers' makes Johne's disease difficult to control and eradicate. However there are schemes being undertaken to reduce or remove the infection.

Johnin
