A diagnostic agent derived from *M. paratuberculosis* used for JOHNE'S DISEASE. Cutaneous injection results in thickening of the skin in positive cases. While insufficiently sensitive for individual diagnosis, the test is useful for identifying infected herds.

Joint-Ill

Also called NAVEL-ILL or POLYARTHRITIS, this is a disease of foals, lambs, and calves, in which abscesses form at the umbilicus and in some of the joints of the limbs, due, in the majority of cases, to the entrance of organisms into the body by way of the unclosed navel; infection can also be through the tonsils. There are numerous organisms associated with the disease, the commonest of which are streptococci, staphylococci, *Pasteurella*, *E. coli*, the necrosis bacillus, and see under FOALS, DISEASES OF.

Signs Usually the young animal becomes dull, takes no interest in its dam, refuses to suckle; the breathing is hurried; the temperature rises from 0.6° C to 1.2° C (2° F to 4° F) above normal; the foal prefers to lie stretched out on its side, and may have attacks of either diarrhoea or constipation. If the navel is examined it is found to be wet and oozing bloodstained serous material, or it may be dry, swollen, painful to the touch, and hard, owing to abscess formation within. In cases that appear later in life there may be no umbilical signs. Within a day or so, one or more of the joints swells up. The joints most commonly attacked are the stifle, hip, knee, hock, shoulder and elbow, but it may be seen in any of the others. The swelling is tense, painful, hot, and oedematous. There is the danger of a fatal septicaemia.

A chronic form of infection resulting in internal umbilical abscesses is sometimes seen. The primary infection occurs at, or soon after, birth; but once the umbilicus has sealed over, external signs are not evident, and the umbilical remnant appears normal.

Calves are usually presented as unthrifty, depressed and slow in their movements. Their temperature invariably normal.

Prevention Attention must always be paid to the cleanliness of the foaling-box, the calving-box and the lambing-pen. Where climatic and other conditions are favourable, the pregnant females should be allowed to give birth to their young out of doors. Lambing-pens should without fail be changed to a fresh site every year.

Investigations undertaken by the Animal Health Trust suggest that thoroughbred foals in the UK suffer severe illness as a result of being deprived of a not inconsiderable volume of blood when the navel cord is severed prematurely by attendants. Severance of the cord, it seems, is always best left to the mare. The use of strong disinfectants applied to the stump of the navel cord is likewise deprecated.

An application of a sulphanilamide or other antibiotic dry dressing may be safer than iodine solution.

In those rare cases when it is necessary to cut and tie the umbilical cord, the strictest cleanliness must be maintained. Scissors should be sterilised, and sterile tape used.

Treatment Antibiotics and, if available, antiserum for the causative micro-organisms (not available in the UK) should be administered. Surgically, the umbilicus is opened up, evacuated and disinfected. Isolation and other hygiene measures are needed.

All pails, and other feeding utensils that are liable to get infected, should be thoroughly cleaned using boiling water or steamed before future use, and the pen or box that houses a case should be occasionally washed out with disinfectant. (See also FOALS, DISEASES OF.)

Joint Mouse

A small loose body within a joint. It is usually made up of cartilage or bone that has separated from one or other of the bones forming the joint.

Joints

Joints fall into two great divisions: movable joints and fixed joints. In a movable joint there are four main structures. First, there are the two bones whose junction forms the joint; second, there is a layer of smooth cartilage covering the ends of these bones where they meet, which is called 'articular' cartilage; thirdly, there is a sheath of fibrous tissue known as the 'joint capsule', which is thickened into bands or 'ligaments' which hold the bones together at various points; and finally, there is a closed bladder of membrane, known as the 'synovial membrane', which lines the capsule and

VetBooks.ir

VetBooks.ir

produces a synovial fluid to lubricate the movements of the joint. Further, the bones are kept in position at the joints by the various muscles passing over them. This type is known as a diarthrodial joint.

Some joints possess subsidiary structures such as discs of fibro-cartilage, which adapt the bones more perfectly to one another where they do not quite correspond, and allow of slightly freer movement, e.g. the stifle-joint. In others, movable pads of fat under the synovial membrane fill up larger cavities and afford additional protection to the joint, e.g. the hock-joint. In some, the edge of one bone is amplified by a margin of cartilage which makes dislocation less of a risk than otherwise, e.g. the hip and the shoulder-joints.

In the fixed joints a layer of cartilage or of fibrous tissue intervenes between the bones and binds them firmly together (synarthrodial joint). This type of joint is exemplified by the 'sutures' between the bones that make up the skull. Classified among these fixed joints are the amphiarthrodial joints of the spinal column, in which there is a thick disc of fibro-cartilage between the bones, so that, although the individual joint is capable of only limited movement, a series of these, like the joints between the bodies of the vertebrae, gives the column, as a whole, a very flexible character. In this connection it is noticeable that the movement in the region of the neck may be much more free than in some of the true movable joints, such as between the small bones of the hock or carpus.

Varieties Apart from the division into fixed and movable joints, those that are movable are further classified. Gliding joints are those in which the bones have flat surfaces capable only of a limited amount of movement, such as the bones of the carpus and tarsus. In hinge-joints like the elbow, fetlock and pastern, movement can take place around one axis only, and is called flexion and extension. In the ball-and-socket joints, such as the shoulder and hip-joints, free movement can occur in any direction. There are other subsidiary varieties, named according to the shape of the bones which enter into the joint.

Joints, Diseases of

Arthritis means inflammation which involves all the structures of the joint – viz. synovial membrane, capsular ligaments, cartilages, and the ends of the bones that take part in the formation of the joint. Arthritis is a general term which includes osteoarthritis and rheumatoid arthritis. Arthritis often begins as a SYNOVITIS (see below), but the degree of inflammation is severe enough to extend to the structures around the synovial membrane. Its causes, signs and treatment are similar to those given for synovitis, but it sometimes leads to ankylosis and fixation of the joint. (See CORTISONE.) The joints that are most often affected are the stifle, hock, knee and fetlocks, but the shoulder, hip, elbow and the lower joints of the digit are not infrequently the seat of disease as well. Among diseases that are associated with joints, and which are treated separately, are NAVICULAR DISEASE; 'SLIPPED SHOULDER'; SLIPPED STIFLE; HYGROMA; CAPPED ELBOW; CAPPED HOCK; KNUCKLING; JOINT-ILL; see also below and BURSITIS; ANKYLOSIS; FRACTURES; DISLOCATIONS; GLÄSSER'S DISEASE; HIP DYSPLASIA IN DOGS; SWINE ERYSIPELAS.

Rheumatoid arthritis This can be important in the dog, and may occur at any age from eight months to two years. Clinical signs may be vague at first; the animal appears depressed, with a poor appetite and often some degree of fever, but with no lameness. Eventually the latter sign appears, sometimes involving several joints, sometimes affecting only one limb and then shifting to another. There may be crepitus – a grating sound – when the limb is moved.

Diagnosis depends upon radiography and – as in human medicine – there are certain laboratory tests, the results of which provide additional criteria for deciding whether the condition really is rheumatoid arthritis or not.

Intractable arthritis of the hip-joint in dogs, as in human beings, may be overcome by major surgery involving removal of the top of the femur and replacement of the ball part of the ball-and-socket joint with a plastic prosthesis.

Synovitis is the name given to any inflammation of the membrane lining a joint cavity. It may be acute, subacute, or chronic.

Generally this is not a separate condition but occurs during the course of rheumatism, rickets, gout (in poultry), severe sprains and bruises, and in a variety of specific infections such as brucellosis, swine erysipelas, tuberculosis. Tubercular joint disease often produces a chronic synovitis in the neck bones of the horse, which leads to an arthritis later.

Conditions such as wind-galls, curb, bog spavin, etc., are really only synovitis that have become chronic or are complicated with other pathological conditions.

The synovial membrane becomes inflamed, thickened, and secretes an excessive amount of fluid into the joint. As a result the joint becomes hot, swollen and painful. The animal goes lame in greater or lesser degree according to the extent of the inflammation. When at rest, the joint is usually kept flexed with the toe of the affected leg just

VetBooks.ir

resting on the ground. If it is a simple condition, such as a mild sprain, these signs last for a few days and then gradually pass off. In more severe cases, such as in joint-ill, there may be pus formation, septicaemia and death. In the chronic type the swelling persists. The animal is able to use its limb as usual, but the accumulated fluid in the cavity does not disappear (e.g. BOG SPAVIN, WIND GALLS, etc.).

Open joint is a condition in which, by accident or other trauma, the inside of the joint is exposed to infection.

The seriousness of an open joint is not so much due to the initial injury as to the danger of infection. This may cause tissue destruction within the joint, and even lead to a fatal SEPTICAEMIA.

The most striking signs of open joint are, first, the excessive degree of pain that seems out of all proportion to the visible amount of damage that has been inflicted; secondly, the great amount of swelling that is usually seen; and thirdly, the discharge of a thin, straw-coloured or bloodstained sticky synovia which has a tendency to coagulate around the skin opening.

Veterinary advice should be sought at once. Prompt treatment with antibiotics, and surgery if required, is necessary to prevent or limit infection.

Dislocations (See main dictionary entry.)

Bursitis, an inflammation of a bursa, commonly occurs in the region of a joint. The prominences of the hock, elbow, knee, stifle, etc., are protected by bursae – lined on their insides by synovial membrane. These sometimes become inflamed and lead to the formation of fluctuating swellings which have a tendency to become chronic. Capped elbow, capped hock and hygroma of the knee are of this nature. (See also BURSAE; OSTEOARTHRITIS; MAST CELLS; OSTEOCHONDROSIS; RHEUMATISM.)

Joule

A derived SI unit of metabolisable energy. (See CALORIES and STARCH EQUIVALENT, which it replaced; also SI UNITS.)

Jugular Veins

Jugular veins carry the blood back to the chest from the head and anterior parts of the neck. The jugular vein is often used for taking blood samples and for intravenous injection. The jugular furrow is the groove between the trachea and the muscles of the neck, in the depths of which lies the jugular vein. The jugular vein on the right side is larger than that on the left in birds and is favoured for venepuncture in cage birds (except pigeons and raptors).

Jungle Fowl

(*Gallus gallus*) A native of the rain forests of South-East Asia, it is the species from which the domestic fowl originated. In its normal environment it prefers hot, humid, shady conditions with frequent rain showers. A broiler-producing company has replicated the climate found in the rain forest in its broiler houses. Mortality was very low and lameness almost non-existent, although the birds took a little longer to reach market weight.

Juvenile Cellulitis

Also known as 'puppy strangles', this condition affects pups between three weeks and four months of age. The cause is unknown but a hypersensitivity reaction may be involved. Clinical signs are CELLULITIS with severe swelling of the face and head, prepuce and anus, accompanied by lethargy, anorexia and, possibly, raised temperature. There may be enlarged LYMPH NODES (adenopathy). Steroid and antibiotic therapy is indicated. Permanent scarring may result.

Juvenile Epilepsy

It is seen in some dog breeds, e.g. LAGOTTO ROMAGNOLO. (See EPILEPSY.)

K

K88 Antigen
This is possessed by certain strains of *E. coli* which cause diarrhoea in piglets during their first few days of life. (See *E. Coli*; BACTERIAL ADHESIVENESS.

K99 Antigen
K99 Antigen is found in strains of *E. coli* which cause diarrhoea in calves.

Kala-Azar, Dumdum Fever
A human disease caused by LEISHMANIA.

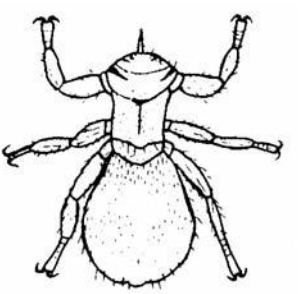
Kale
Kale contains a factor which gives rise to goitre if fed in large amounts, without other foods, over a long period. Haemoglobinuria sometimes follows the grazing of frosted kale by cattle, which may suffer anaemia without showing this sign. The illness can be serious, resembling POST-PARTURIENT HAEMOGLOBINURIA, and may result in sudden death. The frothy type of bloat may also occur in cattle eating excessive quantities of kale – especially, it seems, during wet weather and when no hay is fed. There is some evidence to suggest that the feeding of large quantities of kale may lead to low conception rates, and to mastitis. (See also BLOAT.)

NB Kale anaemia and haemoglobinuria are by no means always associated with frosted kale, but merely with an excessive (probably over 18 kg (40 lb) per cow per day) intake of kale. The signs of kale anaemia include lassitude and rapid breathing and pulse-rate.

Kanamycin
An antibiotic used in conjunction with cephalexin in an intramammary preparation to control mastitis in dairy cows; it is mainly effective against Gram-negative bacteria especially *E. coli*.

'Kangaroo Gait'
'Kangaroo gait' in ewes, both in New Zealand and in the UK, appears to be associated with disease of the radial nerves, which causes difficulty in advancing the front feet. When made to move rapidly, they do so with a bounding gait. The condition is seen in ewes during lactation; it normally resolves after weaning. It can also be seen in sheep and CAMELIDAE afflicted by 'Ryegrass Staggers'. (See RYE-GRASS.)

Kaolin, China Clay
Kaolin (China Clay) is a native aluminium silicate, which is used as a protective and astringent dry dusting powder. Kaolin is sometimes given internally as an adsorbent in intestinal disorders. Mixed into a paste with glycerine and some antiseptic, it is applied as a poultice to acute sprains of tendons, etc. (See POULTICES AND FOMENTATIONS.)



Karyotype
This is, roughly speaking, a plan showing an animal's chromosomes. In technical terms, a karyotype is a presentation of the metaphase chromosomes characteristic of an individual animal or species. (See CYTOGENETICS.)

'Kebbing'
An alternative name for ovine enzootic abortion. (See ABORTION, ENZOOTIC, OF EWES AND GOATS.)

Ked
Melophagus ovinus, the sheep ked, is wingless and lives on the wool and skin of the sheep. It is much larger than any of the lice, being 0.6 cm (¼ inch) long. It can easily be distinguished from the ticks by its tripartite body. It is a dark brown colour with a sharp biting proboscis. The nearly mature larvae are laid on the wool and they at once pupate. The pupa may remain in the wool or fall to the ground. The young hatch in 19 to 24 days, and the females start to deposit larvae in 12 to 23 days after emergence, and lay a larva every nine days. The fly can live for about 12 days away from the sheep, while the pupa can live for six weeks on the ground. The whole life-cycle may be completed on the sheep within one month.

The sheep ked can cause severe anaemia if present in large numbers, and also leads to a damaged fleece. Shearing aids control, which is achieved by means of a sheep dip.

The ked may attack people while shearing and inflict a very painful bite.

Melophagus. × 4.

VetBooks.ir

Keel Bone
The longitudinal ventral prominence of the sternum of a bird. It is the point of attachment of the pectoral muscles, which are important to the bird for flight.

Keeshond
A medium-sized breed of dog, weighing about 15 kg (35 lb), originally from Flanders, with a very thick coat, fox-like face and a tail that curls over the back. It is prone to HIP DYSPLASIA. EPILEPSY can be inherited as an autosomal recessive trait. The incidence of TETRALOGY OF FALLOT (a potentially fatal heart defect) in the breed is 1 in 10,000 births, the highest known in any animal.

Kelpie Dogs
An Australian breed of HUNTAWAY DOGS. They are used for herding or driving cattle, sheep or goats. They are medium-sized dogs and come in several colours, weighing about 14 kg to 21 kg (30 lb to 45 lb) and are at the shoulder about 50 cm (19.5 in) high for females and about 55 cm (21.5 in) male. There are two types – working and show.

Kemps
Coarse hairs, the presence of which reduces the value of a fleece.

Kennel Club
Founded in 1873, its stated aim is 'to promote the health and welfare of dogs'. It sets breed standards and organises Crufts dog show. Address: 1–5, Clarges Street, Piccadilly, London W1J 8AB; Telephone: 0844 463 3980; website: www.thekennelclub.org.uk

Kennel Cough
Kennel cough is a convenient term for those outbreaks of respiratory disease, distinct from canine distemper, which are troublesome in boarding kennels and dog pounds. Other names are infectious tracheobronchitis (see BRONCHITIS) and bordetellosis (see *Bordetella* SPP.).

Usually only the upper air passages are involved in kennel cough, the chief clinical sign being a fit of coughing which is aggravated by exercise or excitement. The cough is a harsh, dry one. It has to be differentiated from other causes of cough including congestive heart failure (see HEART DISEASES) and infestation with TRACHEAL WORMS.

Causes *Bordetella bronchiseptica* is the principal cause (hence the name bordetellosis). Other organisms involved are the canine parainfluenza virus (CPI), a canine herpesvirus, two adenoviruses, a reovirus, and a mycoplasma. Bacterial secondary invaders may complicate the syndrome.

Prevention Vaccination is advisable a fortnight before a dog is taken to a show or left in boarding kennels. An intranasal live *B. bronchiseptica* vaccine is available.

Treatment Antibiotics, antitussives and management of the animal to avoid exposure to changes in ambient temperature and excitement all assist.

Kennel Lameness
A colloquial term for lameness arising from a nutritional deficiency, such as may occur in a dog fed entirely on dog-biscuits. (See RICKETS.)

Kennel Sickness
A colloquial name used in the USA for outbreaks of salmonellosis, the signs of which may include pneumonia and convulsions. (See also under SALMONELLOSIS.)

Kent Sheep
Another name for ROMNEY MARSH SHEEP.

Keratin
Keratin is the substance of which horn and the surface layers of the skin are composed. It is a modified form of skin which has undergone compression and toughening. It is present in the hoof of the feet of animals, in claws, horns, and nails.

Keratinisation
The transformation of epidermal cells into keratin. (See CORNIFICATION.)

Keratitis
Inflammation of the cornea. (See EYE, DISEASES AND INJURIES OF.)

Keratocoele
Keratocoele is a hernia through the cornea. (See EYE, DISEASES AND INJURIES OF.)

Keratoconjunctivitis sicca, Dry Eye
A disease of the eye characterised by a reduction in the production of tears and manifested by a glutinous discharge and a reddening of the SCLERA. It is commonly seen in dogs, especially the WEST HIGHLAND WHITE TERRIER breed. Most cases respond well to the application of CYCLOSPORIN. (See EYE, DISEASES AND INJURIES OF.) The condition has been linked to the use of sulfasalazine for the treatment of idiopathic colitis in dogs. (See IDIOPATHIC; COLITIS.)

Keratoma
A local area of excessive horny growth from the EPIDERMIS. It can occur on cornified tissues such as the claws and horns of animals and is commonly

found affecting the inner aspect of the wall of the equine hoof. It is sometimes seen on the legs of backyard poultry affected with 'SCALY LEG'. (See CORNIFICATION; KERATINISATION.)

Kerosene Poisoning
(See PARAFFIN.)

Kerry Blue Terrier
A medium-sized dog, born with a black coat that gradually lightens to grey, and an upright tail. It is predisposed to CEREBELLAR ABIOTROPHY, a degeneration in the cerebellum, that manifests as ATAXIA. It can suffer from HAEMOPHILIA (Factor XI deficiency), VON WILLEBRAND'S DISEASE (DNA tests available for both).

Kerry Cattle
These dairy cattle originated in Ireland from Celtic cattle, as did DEXTER CATTLE, and are black in colour with possibly some white on the udder. They have thin white horns, but are usually dehorned. They are small, 350 kg to 450 kg.

Kerry-Dexter Cattle
(See DEXTER CATTLE.)

Kerry Hill Sheep
The breed originated in Wales and is mentioned from the early 19th century. They have a white face, with black markings around the mouth, eyes and ears. The rams and ewes are polled, the wool is white and the legs have black markings. Used mainly for meat. Formerly considered a rare breed, its numbers have increased.

Ketamine
Ketamine is a non-barbiturate, non-narcotic anaesthetic. It can be administered by intravenous, intra-muscular or subcutaneous injection and is used in various species including cats, dogs, non-human primates and horses. It is used (off-licence) in birds, rabbits, rodents, other small mammals and some reptiles. Ketamine is often used in conjunction with other agents, such as XYLAZINE, MEDETOMIDINE and DETOMIDINE, to improve muscle relaxation during surgical procedures. It has been used to calm aggressive cats by spraying into the open mouth. Ketamine is a Controlled Drug (POM-V CD (Schedule 4 Part 1); it must be kept under lock and key and a record kept of its purchase and use. In June 2014 it was reclassified as a Class B drug under Schedule 2 of the Misuse of Drugs Act 1971.

Ketanserin
A topical application that is useful in aiding the healing of WOUNDS and ULCERS. Its main action is as a potent SEROTONIN S-2 antagonist. It promotes rapid healing without producing exuberant granulation tissue (PROUD FLESH).

Ketoacidosis
A condition leading to diabetic coma. (See DIABETES MELLITUS.)

Ketoconazole
An antifungal compound used to treat systemic candidiasis and ringworm in dogs and cats and candidiasis in cage-birds. It is administered orally.

Ketone Bodies
Ketone bodies arise from acetyl coenzyme A. The three main ketone bodies are acetone, acetoacetate and beta hydroxybutyrate. While acetone is not part of the metabolic process in the healthy animal, the others are involved in the energy metabolism of ruminants. If the diet provides insufficient energy sources in the diabetic, excess ketone bodies arise, producing ketosis (ACETONAEMIA). Professor Sir Hans Krebs describes the process thus: 'The severe forms of ketosis of the diabetic coma or of the lactating cow are connected with the high rates of GLUCONEOGENESIS which occur under these conditions. Oxaloacetate, which is an intermediate in gluconeogenesis, is diverted from the tricarboxylic acid cycle to gluconeogenesis, owing to the high activity of the enzyme converting it to phosphopyruvate. The liver compensates the loss of energy from a reduced rate of the tricarboxylic acid cycle by an increased rate of oxidations outside the cycle. The main reaction of this type is the oxidation of fatty acids to ketone bodies. These arise grossly in excess of needs, as a by-product of reactions which satisfy the requirements for energy.'

Ketonuria is the term applied to the presence of ketone bodies in the urine. (See also ACETONAEMIA.)

Ketoacidosis . A condition leading to diabetic coma. (See DIABETES MELLITUS.)

Ketoprofen
A potent non-steroidal anti-inflammatory and antipyretic analgesic derived from phenylpropri-onic acid. It is used in the relief of painful skeletal disorders.

Ketorolac
A non-steroidal anti-inflammatory drug used topically in eye drops prior to phacoemulsifi-cation of cataracts. The (non-licensed) product is called Acular, available in a multi-dose dropper bottle. (See also FLURBIPROFEN, PHACO-EMULSIFICATION.)

Ketosis
(See ACETONAEMIA.)

Key-Gaskell Syndrome
(See FELINE DYSAUTONOMIA.)

Khaki Campbell Ducks
The breed was developed by a Mrs. Campbell of Uley, Gloucester in the 19th century. Also called Campbells, they are khaki, dark or blue. They weigh 1.8 kg (4 lb) and females are mature at six months; they can lay 300 eggs a year.

Khat
This plant (*Catha edulis*) contains two compounds – cathine and cathinone – which are both structurally related to amphetamine. It is called by the Swahili name 'Marrah' in Africa.

Chewing of khat leaves, popular in Arabia and East Africa, appears to be on the increase in the UK. Addicts esteem khat for the euphoria and extra energy which it provides, but over-use can lead to mental illness.

Veterinary surgeons in small-animal practice should look out for cases of khat poisoning in dogs and cats – as they already are for the effects of CANNABIS POISONING.

Kicking
(See 'VICES' AND VICIOUSNESS.)

Kidneys
Kidneys are paired organs situated high up against the roof of the abdomen, and in most animals lying one on either side of the spinal column. Their function is described below.

Horse The kidneys of the horse differ from each other in both shape and position. The right has the outline of a playing-card heart, and lies under the last two or three ribs and the transverse process of the first lumbar vertebra, while the left is roughly bean-shaped and lies under the last rib and the first two or three lumbar transverse processes. They are held in place by the surrounding organs and by fibrous tissue, called the renal fascia. Each of them moves slightly backwards and forwards during the respiratory movements of the animal.

Cattle The kidneys are lobulated, each possessing from 20 to 25 lobes separated by fissures filled with fat in the living animal. The right kidney lies below the last rib and the first two or three lumbar transverse processes, and is somewhat elliptical in outline. The left occupies a variable position. When the rumen is full, it pushes the left kidney over to the right side of the body into a position slightly below and behind the right organ, but when it is empty the left kidney lies underneath the vertebral column about the level of the third to the fifth lumbar vertebra. It may lie partly on the left side of the body in this position in some cases.

Sheep In the sheep the kidneys are bean-shaped and smooth. In position they resemble those of the cow, except that the right is usually a little farther back.

Pig In this animal the kidneys are shaped like elongated beans, and they are placed almost symmetrically on either side of the bodies of the first four lumbar vertebrae. They sometimes vary in position.

Dogs and cats In these animals the kidneys are also bean-shaped, but they are thicker than in other animals, and relatively larger. As in most animals, the right kidney is placed farther forward than the left, the latter varying in position according to the degree of fullness of the digestive organs. In the cat the left kidney is very loosely attached and can usually be felt as a rounded mass which is quite movable in the anterior part of the abdominal cavity.

Birds have paired kidneys, seen as elongated brown organs closely attached to the ileum on each side of the vertebrae.

Fish have a single kidney which is seen in salmonids as a long black structure in the dorsal part of the abdomen extending from the back of the head to the vent. The vena cava runs through the centre of the organ. The kidney also contains the haematopoietic tissue (see HAEMATOPOEISIS), especially at the cranial end. There is also a network of fixed macrophage cells to combat incoming infections.

Chelonia In these the kidneys lie on the floor of the coelomic cavity just anterior to the cloaca.

Lizards In these the kidneys are carried on the pelvic floor.

Rabbits The kidneys are more round than bean-shaped and much more freely mobile than in other species.

Snakes The kidneys are paired but the right is positioned cranial to the left one, allowing for the elongated nature of the coelomic cavity.

Structure In mammals, the organ is enveloped in a fibrous coat continuous with the rest of the peritoneal membrane, and attached to the kidney capsule. This capsule does not permit of much swelling or enlargement of the organ, and consequently any inflammation of the kidney

VetBooks.ir

causes severe pain. On the inner border there is an indentation called the hilus, which acts as a place of entrance and exit for vessels, nerves, etc. Entering each kidney at its hilus are a renal artery and renal nerves; leaving the kidney are renal vein or veins, lymphatics and the ureter. A section of the kidney shows there are two distinct areas seen in its substance. Lying outermost is the reddish-brown granular cortex, which contains small dark spots known as Malpighian corpuscles.

Within the cortex is the medulla, an area presenting a radiated appearance, whose periphery is of a deep red colour.

The kidney tissue contains many thousands of filtration units called nephrons. Each of these comprises the glomerulus (almost a spherical arrangement of capillaries on an arteriole); Bowman's capsule, the blind end of a proximal tubule which expands so as almost to surround the glomerulus; the convoluted tubule itself (with its loop of Henle); and the distal convoluted tubule which leads on to an arched collecting tubule. The latter continues with a straight tubule in the cortex of the kidney, and on into the medulla, where papillary ducts are formed to take the urine to the pelvis of the kidney.

The Malpighian corpuscle, comprising the glomerulus and inner and outer layers of Bowman's capsule, is where most of the filtration of fluid from the blood occurs; but only a small percentage of this fluid is finally excreted as urine.

In birds, the glomeruli are of two different kinds; one type is similar to mammalian glomeruli; the other is more akin to the type found in reptiles.

Function The kidney's two main functions are: first, the excretion of waste (and excess) materials from the bloodstream; and, second, the maintenance of the correct proportions of water in the blood, the correct levels of its chemical constituents, and the correct pH. (See HOMEOSTASIS.)

Blood pressure in the arteries determines pressure in each glomerulus and has an important bearing on the quantity of fluid filtered from the blood.

For its controlling effect on the kidney, see ANTIDIURETIC HORMONE.

The proximal tubules reabsorb a high percentage of the water, sodium chloride and bicarbonate. The distal tubules reabsorb sodium, or exchange sodium ions for hydrogen, potassium or ammonium ions; determining thereby the pH of the urine.

The kidney also secretes the hormone erythropoietin (see under ERYTHROPOIESIS) and produces RENIN. Additionally, the kidney converts vitamin D_1 into its active form.

Kidneys, Diseases of

Diseases of the kidney are referred to according to the part of the kidney affected. Hence there may be Glomerulitis (inflammation of the glomerulus), Membranous glomerulonephropathy, Membranous Glomerulonephritis or even Membranoproliferative Glomerulonephritis. When the glomerulus is affected there can be a nephritic syndrome with raised cholesterol levels in the blood, proteinuria and the development of oedema. (See also CHOLESTEROL, NEPHRITIS, NEPHROSIS, NEPHROTIC SYNDROME, OEDEMA, PROTEINURIA.) These are particularly common in the dog, and must account for a high proportion of deaths in dogs and cats.

Exact diagnosis is based almost entirely upon macroscopic, microscopic and chemical examination of the urine in the laboratory. Blood urea nitrogen (BUN) and serum creatinine concentrations are used to evaluate renal function in several species.

Nephrosis/nephrotic syndrome This may be a stage in nephritis and involves damage to the tubules of the kidneys, resulting in defective filtering, so that albumin is excreted in the urine to the detriment of albumin levels in the blood. This leads to OEDEMA.

Nephrosis may be caused by poisoning with the salts of heavy metals, and with various toxins; or it may follow certain other diseases. In lambs, clostridial infections have been suggested as a cause of the disease, while nematodirus infestation may be responsible in older animals. (See also MEMBRANOUS NEPHROPATHY.)

Acute nephritis is a rapid inflammation of the kidney tissues as a whole, or of the glomeruli (glomerulonephritis) and the secreting tubules only (tubulonephritis). The latter is much the more common among all animals. Since the diagnosis and signs of each are clinically the same, and as their differentiation is only possible by microscopic examination after death it will suffice to describe the commoner type only.

Dogs Acute and subacute nephritis is often associated with LEPTOSPIROSIS, especially with *Leptospira canicola* infection; it may follow the nephrotic syndrome, and may co-exist with DISTEMPER or canine viral hepatitis. It is often called 'lamppost sickness' and can be vaccinated against.

Signs may include depression, loss of appetite, thirst, vomiting. The back may be arched, and there may be stiffness. There is fever, and sometimes ulcers are present in the mouth.

Lambs Acute kidney failure (NEPHROSIS) has been diagnosed by clinical examination and autopsy in the UK. It invariably occurs in lambs at

VetBooks.ir

pasture in spring and early summer. Two age groups are susceptible: one to four weeks, when the cause is unknown (but suggested to be a bacterial toxin); and two to four months, when it is often due to *Nematodirus* infection.

Mortality in clinically affected lambs was almost 100 per cent, with no response to various treatments.

First-aid The animal needs rest, warmth, and light food. Reliable proprietary foods can be obtained for kidney disease cases. Barley water instead of plain water is often advisable. (See under NURSING OF SICK ANIMALS.)

Treatment includes the use of antibiotics. If there is much vomiting, normal saline may be necessary.

Chronic nephritis may follow the acute form, or it may arise insidiously. One episode of nephritis is always likely to render the dog more susceptible to subsequent attacks, and chronic nephritis is common in middle-aged and old dogs. In some cases of this disease 'RUBBER JAW' may be present. Sometimes, despite treatment, kidney failure occurs.

Kidney failure may also follow either chronic interstitial nephritis (involving some degree of fibrosis), which often results from leptospiral nephritis; or from glomerular disease (glomerulonephritis). Clinically, the two conditions are virtually indistinguishable.

Cattle Kidney disease may also be associated with LEPTOSPIROSIS, and may be a sequel to various other infections. *Corynebacterium renale* attacks the kidneys, and abscesses of these organs are not uncommonly found in cattle. (See also pyelitis and pyelonephritis below.) Some poisons may damage the kidneys.

Signs in cattle include stiffness, an arched back, often the passing of small amounts of bloodstained urine, a poor appetite. Rumination may cease.

However, in non-acute cases signs may not be noticed, and the existence of nephritis discovered only after death. A survey carried out at a Dublin abattoir showed that of 4,166 cattle, 4.2 per cent had kidneys rejected under EU export regulations. The rejection rate was 7.7, 1.7, 2.2 and 28 per cent for cows, bullocks, heifers and bulls, respectively; the most common reason being focal interstitial nephritis (60 per cent). Other lesions included cysts (26 per cent), pyelonephritis, pigmentation, amyloidosis and glomerulonephritis.

Horses Nephritis may be a complication of influenza and other infections; follow contusions (arising from blows, falls) in the lumbar region; or follow feeding with mouldy or otherwise contaminated fodder. (See also pyelonephritis below.)

In the horse, signs of kidney disease may be somewhat vague, but in severe cases there is usually evidence of pain, stiffness in the gait, a poor appetite, often fever, and urine is passed as described above for cattle. Oedema may involve abdomen, chest and legs.

Cats Kidney disease is, generally speaking, likely to result in a poor appetite, loss of weight, dullness, thirst. Intermittent vomiting may occur. The cat may become pot-bellied, due to ASCITES.

A cat with chronic nephritis may live to old age, seemingly still able to enjoy life. There is likely to come a time, however, when the kidneys fail, and uraemia occurs.

Some forms of kidney failure cause a cat to lose protein in its urine, the need is for a high-protein diet; but with chronic nephritis, a low-protein diet is usually indicated. A number of specially formulated proprietary diets are available. (See PRESCRIPTION DIETS.)

Diuretics are used in treating the nephrotic syndrome.

Other animals Causes, clinical signs and treatment (antibiotics, sometimes diuretics) are in general similar. Vomiting may occur in the pig. (See also AVIAN NEPHRITIS.)

Polycystic kidneys A congenital renal problem in which the kidney is enlarged and contains multiple fluid filled cysts. The condition, which has been recorded in pigs, is sporadic and does not usually cause illness.

Purulent nephritis, or 'suppurative nephritis', is a condition in which one or both kidneys show abscess formation. All species may be affected. It is caused by pus-producing (pyogenic) organisms, which may gain access to the kidneys either by the bloodstream – when the term 'pyaemic nephritis' is used – or by the ureters from the bladder – when the condition is pyelonephritis. Pyelitis, meaning pus in the pelvis of the kidney, is used to indicate abscess formation in the pelvis only, and generally precedes the more severe form of pyelonephritis. It may be associated with stone formation (renal calculus).

Pyelonephritis (inflammation of the renal pelvis and the deeper kidney tissues) is generally preceded by an attack of inflammation of the bladder, vagina, or uterus. It is commonest in cows and mares after parturition when the genital tract has become septic, but it is seen in all females under similar circumstances. It is not so common in male animals. Generally only one kidney is affected, and

the animal exhibits pain when turned sharply to the affected side, and tenderness when that side is handled.

In pyelitis the signs are practically the same as those of pyelonephritis, except when due to renal calculus. In such cases it causes an obscure form of colic, and small amounts of blood-stained urine are passed at frequent intervals.

Stone in the kidney A calculus or stone may sometimes form in the pelvis of the kidney as the result of the gradual deposition of salts from the urine around some particle of matter that acts as a nucleus. This is quite common in pet rabbits. (See UROLITHIASIS; CALCULI.)

Parasites of the kidney include *Dioctophyma* in the dog and, occasionally, *Eustrongylus gigas* in horses, dogs and cattle; the larvae of *Strongylus vulgaris* in colts, *Stephanurus dentatus* in pigs, and the cystic stages of certain tapeworms in the ruminants. (See also DIOCTOPHYMOSIS; LEPTOSPIROSIS.)

Tumours of the kidney include carcinoma (mainly in dogs and cattle) and the usually benign nephroblastoma in pigs, puppies and calves. In cats LYMPHOSARCOMA of the kidney is common.

Hydronephrosis In this condition the kidney may enlarge, owing to an obstruction. (See HYDRONEPHROSIS.)

Injuries of the kidney are not common, owing to the great protection that the lumbar muscles provide. They may be lacerated or bruised as the result of traffic accidents in the dog. Slips or falls in the hunting field may cause similar injuries in horses. The kidney capsule may be shattered and death from internal haemorrhage occurs, or in less severe cases the haemorrhage takes place below the capsule and the blood is passed in the urine. If only one kidney is affected, and provided the bleeding is not great, the other enlarges and acts for both.

Polycystic kidney disease is common in Persian cats, some of which are born with cysts in their kidneys. The cysts gradually enlarge and eventually cause kidney failure. It is advisable to have animals intended for breeding scanned by ultrasound before placing them at stud.

Kidney Worm, *Stephanurus dentatus*

Kidney worm (*Stephanurus dentatus*) is a parasite of pigs. Affected animals fail to thrive. Occasionally migration of the larvae in the spinal canal causes some degree of paralysis. The intermediate host is the earthworm. Thiabendazole, fenbendazole and ivermectin have proved effective in controlling this parasite. (For the kidney worm of dogs, see DIOCTOPHYMOSIS.)

Kilopascal (KpA)

The unit used to quantify vacuum pressure in milking machines.

Kimberley Horse Disease, Walkabout Disease

Kimberley horse disease (walkabout disease) occurs in the Kimberley district of Western Australia, and has a seasonal incidence – January to April (i.e. 'wet season'). Horses of all ages are susceptible.

Cause Whitewood (*Atalaya hemiglauca*) taken voluntarily or fed when food is scarce.

Signs Anorexia, dullness, wasting, irritability, biting other horses and gnawing at posts. Yawning is a marked and almost constant sign. Then muscular spasms lead to a phase of mad galloping in which the horse has no sense of direction and is uncontrollable. Gallops become more frequent but less violent, and gradually merge into the walking stage – slow, staggering gait, with low, stiff carriage of the head. The horse may walk about for hours, with a mouthful of unchewed grass protruding from its lips. (See also BIRDSVILLE DISEASE.)

King Charles Spaniel Dogs

A small toy breed, popular in the UK and USA. It is smaller (and rarer) than the CAVALIER KING CHARLES SPANIEL and has a head more domed, flatter, and with larger eyes than the CAVALIER. They have soft coats, longish droopy ears. They are black and white, tricoloured (black, tan, white), Blenheim (chestnut-red and white) and ruby (chestnut red with white patch on chest). Weight, 3.5 kg to 6.5 kg (8 lb to 14 lb). The breed has quite high levels of PATELLAR LUXATION and occasionally STROKES occur. Tear staining (CHROMODACTYORRHOEA) is common. It is suspected that CHIARI-LIKE MALFORMATION and SYRINGOMYELIA may be inherited in the breed. The breed is on the Kennel Club's 'vulnerable list'.

'Kinky-Back'

The colloquial name for a condition in broiler chickens involving distortion of the 6th thoracic vertebra. It is the cause of lameness and sometimes paraplegia. It appears to be of hereditary origin, perhaps influenced by growth-rate.

Kinky Tail

This can be a congenital problem and is particularly seen in BURMESE CATS.

VetBooks.ir

Kirschner-Ehmer Splint
Used in treating fractures in the dog and cat. It has transverse pins which are driven into parts of a long bone on either side of the fracture, and which are then held in position by an external clamp.

'Kitchen Deaths'
Kitchen deaths in small caged birds can result from overheated utensils, particularly frying pans, which have non-stick coatings of polytetrafluoroethylene (PTFE or TEFLON), or from acrolein or other vapours associated with cooking oils, or from carbon monoxide poisoning from improperly ventilated heaters. PTFE fumes cause acute pneumonitis with haemorrhages and death in small caged birds. (See CARBON MONOXIDE; 'FRYING PAN' DEATHS; TEFLON.)

In a study of nine incidents of bird deaths involving one to 18 birds investigated by Penrith Veterinary Investigation Centre, three cases were due to PTFE poisoning, three to cooking oil vapours, one to carbon monoxide and in two cases there were no obvious causes found.

Kittens
The young of domestic cats, ferrets (and rabbits).

Causes of death in kittens A Glasgow veterinary-school study of the cause of death in 274 kittens showed that 55 per cent died from infectious diseases, 33 per cent from unknown causes and 5 per cent from congenital defects. Feline parvovirus caused 25 per cent of all deaths.

Klebsiella
A genus of Gram-negative bacteria. It has been suggested that *K. pneumoniae* may be an important cause of infertility in the thoroughbred mare, but see EQUINE GENITAL INFECTIONS IN THE MARE.

Cattle The infection is occasionally the cause of mastitis and osteomyelitis; also pulmonary lesions.

Dog The infection may cause illness clinically indistinguishable from distemper, and may therefore account for some of the suspected 'breakdowns' following the use of distemper vaccines.

Sows The infection may result in acute mastitis. Both piglets and sow may die.

Small animals Respiratory infections in rabbits and chinchillas may be due to *Klebsiella*.

Klein's Disease
(See FOWL TYPHOID.)

Knackers
A knacker's yard is a place for the disposal of animals unfit for human consumption, and ill or recently dead (fallen stock) animals. Many of the tissues can be recycled, for a variety of purposes. They are subject to strict regulations.

Knee
Knee is the name, wrongly applied, to the carpus of the horse, ox, sheep and pig. This joint really corresponds to the human wrist and should not be called 'knee', but custom has ordained otherwise. The true 'knee' or femorotibial joint of humans is the 'stifle' in animals. (See JOINTS.)

Knemidocoptiasis
(See CNEMIDOCOPTIASIS; 'SCALY BEAK'; SCALY FOOT; TASSEL FOOT.)

Knocked-Up Shoe
Knocked-up shoe is one in which the inner branch is hammered laterally so as to increase its height but decrease its width. There is one nail-hole at the inside toe, and four or five along the outside branch. The shoe generally has a clip at the toe and the outside quarter, and may have a small CALKIN on the outside heel.

It is used for horses given to brushing, cutting, or interfering with their hind feet.

Knocked-Up Toe
A term used in racing greyhound circles to describe a type of lameness associated with the digits. It sometimes yields to rest but may require surgical treatment (even amputation of the third phalanx).

Knuckling
Knuckling of fetlock simply means that the fetlock joints are kept slightly flexed forwards above the hoof, instead of remaining extended. It may result from a number of causes: genetics, positioning of the fetus in the uterus, etc.

Knuckling of the fetlocks in calves of the Jersey, Ayrshire and Friesian breeds is an inherited defect which can sometimes be corrected by a minor surgical operation.

Occasionally foals are born with their FETLOCKS knuckled, but, like many other deformities of a similar nature, the condition gradually disappears as the muscles of the young animal obtain their proper control of the joints which they actuate. In older horses, the two chief conditions that are responsible for knuckling are: (l) thickening and contraction of the tendons or ligaments behind the CANNON BONE; and (2) chronic foot lameness, such as is produced by ringbones, navicular disease, chronic corns, etc. The horse assumes the position of partial flexion of the fetlock, apparently in order to ease the pain he

VetBooks.ir

feels; as the result of the relaxation of the tendons, shortening occurs, and it finally becomes impossible to straighten out the joint. (NB. For descriptive purposes the word 'flexion' here means a bending backwards of the lower section of the limb from the fetlock joint – the cannon remaining stationary. Otherwise confusion between 'flexion' and 'extension' of the fetlock might occur.)

Koala

(*Phascolarctos cinereus*) The koala bear is an arboreal, marsupial creature, a native of Australia. It is prone to chlamydophilial infections which can cause blindness and infertility.

Koi Herpes Virus

A disease restricted to any type of carp, but which was first discovered in koi. Fish become lethargic and unable to swim against the flow of water. There is mucus loss on the skin and gills and it appears as if the skin were stripped off.

Kola Nuts

They are included in a herbal preparation for dogs and cats. They contain 2.5 per cent caffeine and a trace of theobromine.

Komondor Dogs

Large powerful whitish dogs originating from Hungary with long corded hair and used to guard sheep, goats and cattle. The females weigh about 40 kg to 50 kg (85 lb to 110 lb) and stand on average 70 cm (27.5 in) at the shoulder, and the males weigh 50 kg to 60 kg (110 lb to 130 lb) and are on average 80 cm (31.5 in) high at the shoulder.

Kooikerhondje Dogs

A dog breed which is of a small spaniel-type from Holland; they were originally working dogs for duck shooting. They have a slender build and should weigh less than 9 kg to 11 kg (20 lb to 22 lb); they have slightly wavy hair of medium length with a shiny bi-coloured coat of white and orange-red. The breed is susceptible to VON WILLEBRAND'S DISEASE (DNA test available).

Kreb's Cycle

Also called the TRICARBOXYLIC ACID CYCLE and CITRIC ACID CYCLE. It is the conversion of glucose into energy within the body from carbohydrates (sugars), lipids (fatty acids), proteins (amino acids). They are oxidised into water, carbon dioxide and reduced coenzymes.

Krill

Shrimp-like ocean-living crustaceans found in large numbers which can be harvested for animal feed. They can harbour the first stage of *Anisakis* nematodes which, when ingested by salmon spoil the table value of the fish. Krill are the main diet of the sperm whale.

Kudu, Greater, *Tragelaphus strepsiceros*

An antelope with long spiral horns. One of these creatures died in the London Zoo in 1992 from a scrapie-like SPONGIFORM ENCEPHALOPATHY.

Kune Kune Pigs, Kunekune Pigs

A type of pig of a docile nature usually found in children's farms or kept as pets. They are hairy (long, short, straight or curly) and come in various colours; many have WATTLES under their chins (called piri piri). They are claimed to be the smallest breed of domesticated pig and stand 60 cm (24 in) tall at the shoulder, although some other pig breeds and types can be smaller. Some so-called KuneKunes are much larger and contain genetic material from other types of pigs. True KuneKune pigs originated in New Zealand and almost died out in the 1980s; numbers reduced to 50.

Kunjin Virus

Not a true virus, it is now regarded as a subtype of West Nile Virus mainly present in the Far East and Australia. (See WEST NILE VIRUS.)

Kunzea Oil

An oil obtained from the Australian bush *Kunzea ambigua*. It has been incorporated at 20 per cent into an ointment used to treat cases of pastern dermatitis in horses.

Kuppfer's Cells

Phagocytic cells lining the walls of sinusoids in the liver. (See PHAGOCYTOSIS.)

Kuru

A SPONGIFORM ENCEPHALOPATHY of humans, described in Papua New Guinea. It was transmitted by ritual cannibalism. Men ate the victims' muscles and heart while women and children ate the brain and other organs. 154 clinical cases occurred as a result of eating a single infected body. Although affected women did not produce affected infants, and the practice was outlawed in the 1950s, occasional cases still occur in the tribe that used to practise this ceremonial. 'Kuru' translates as 'trembling with fear'.

K Value

This is used as a measure of the insulating value of building materials such as glass fibre, wood.

Kyasanur Forest Fever

Kyasanur forest fever is a disease of man and monkeys, occurring in Mysore, and resembling Omsk fever. The causal virus is transmitted by the tick

Haemaphysalis spinigera, and believed to have been brought by birds from the former Soviet Union.

Kyphosis

Kyphosis is a curvature of the spine when the concavity of the curve is directed downwards. It is sometimes seen in TETANUS, RABIES, etc., and is a sign of abdominal pain in the dog. It can also occur, as a chronic condition, following disease or damage of the intervertebral discs in many species, especially in aged pets.

VetBooks.ir

L

Labia
(plural, Labiae)
The lips, in animals it can refer to the entrance to the mouth or vulva.

Labial
Relating to the lips.

Labile
Unstable, e.g. thermo-labile – unstable in the presence of heat.

Labium
(plural, Labia)
Labium is the Latin word for lip or lip-shaped organ. The labia of the vulva (*labia vulvae*) are the outer edges of the organ.

Laboratory Animals
Animals bred and maintained specifically for scientific purposes; it is illegal to use non-purpose-bred animals for scientific research. Their welfare and the conditions in which they are kept are strictly controlled by the Animals (Scientific Procedures) Act 1986 (as amended 1998); by far the largest number of such animals are mice and rats.

Laboratory Tests
Laboratory tests are widely used as an aid to diagnosis but should always be interpreted in the light of the clinical signs presented by the animal. Many tests involve examination of samples of the blood or its cells (haematology), or plasma or serum (blood chemistry). Other tests are based on urine, pus, peritoneal or pleural fluid. Occasionally, samples of tissues are taken for examination (biopsy), often by aspiration through a needle (FINE NEEDLE ASPIRATION BIOPSY — FNAB). Tests may be used to determine the various biochemical constituents of the sample, to examine the cells present or to detect the presence of bacteria, viruses, fungi, mycoplasma or parasites. Blood samples (usually serum) may be used to detect the presence of antibodies to various infective agents.

In cattle, milk is increasingly used both to determine biological levels and to determine the herd exposure levels to infections such as BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE (BVD) and ENZOOTIC BOVINE LEUKOSIS (EBL). Milk samples may also be used to determine the levels of bacteria present in the herd. (See CYTOLOGY).

Labour
(See PARTURITION.)

Labradoodle Dogs
A common first cross between a LABRADOR RETRIEVER and a POODLE. (See MONGEE.) In the UK there is a relatively high prevalence of multifocal retinal dysplasia (see MRD) and a significant prevalence of CATARACTS similar to LABRADOR RETRIEVERS.

Labrador Retriever
A popular medium-sized breed of dog with black, yellow or chocolate coat. HIP DYSPLASIA is quite common and multifactorial in origin. CATARACT and ENTROPION are inherited as dominant traits, while MYOPATHY and PROGRESSIVE RETINAL ATROPHY are recessive. HAEMOPHILIA A (Factor VIII deficiency) is a sex-linked recessive. The mechanisms of inheritance of RETINAL DYSPLASIA, OSTEOCHONDROSIS and LARYNGEAL PARALYSIS or HEMIPLEGIA, MYOTONIA CONGENITA, PATELLAR LUXATION may also be found and the inheritance mechanisms are unknown. CYSTINURIA, NARCOLEPSY, EXERCISE-INDUCED COLLAPSE: all have DNA tests. (See 'FLOPPY' LABRADORS.)

Laburnum Poisoning
All parts of the plant, whose botanical name is *Cytisus* – root, wood, bark, leaves, flowers, and particularly the seeds in their pods – are poisonous, and all the domestic animals and birds are susceptible. Deaths are recorded commonly in goats and camelids.

Signs The toxic agent is an alkaloid called cystine and is most concentrated in the seed pods, which produces firstly excitement, then unconsciousness with incoordination of movement, and finally convulsions and death.

In the horse, when small amounts have been taken, there is little to be seen beyond a staggering gait, yawning, and a general abnormality in the behaviour of the animal. With larger doses there may be sweating, excitement, collapse, convulsions, coma and death.

In cattle and sheep, which are more resistant than the horse, the rumen becomes bloated, the limbs become paralysed, the pupils are dilated, the animal becomes sleepy, and later, salivation, coma and convulsive movements follow each other. Fatal cases in these animals are not common; the signs may last for several days and then gradually pass off.

In the dog and pig, which vomit easily, the irritant and acrid nature of the plant causes free vomiting, and usually the animal is enabled to get rid of what has been eaten before the signs become acute. However, this is not always so and fatalities

have been recorded. Dogs are usually exposed to the poison by chewing a stick from a laburnum while playing with it. One dog, after 24 hours' mild diarrhoea following repeated chewing of a low-lying branch, suddenly collapsed and died. In another case, a stick, which had been cut from a laburnum tree three months previously, was thrown for a dog to retrieve, and caused fatal poisoning after being chewed.

First-aid Very strong black tea or coffee that has been boiled instead of infused may be given as a drench.

Labyrinth
(See EAR.)

Lacerated
Having suffered a laceration.

Laceration
An untidy wound produced by tearing of the tissues, as opposed to a neatly incised or puncture wound.

Lacombe Pig
A lop-eared pig from Alberta, Canada. It is a white medium-sized pig with a docile temperament. It became a popular breed in Canada used by pork producers from 1957. It is currently on the endangered rare breeds list in Canada. It is bred from Danish Landrace 51 per cent, Chester White 25 per cent, Berkshire 24 per cent. (The Chester White comes from Pennsylvania and originates from 18th century imports.)

Lacrimal, Lachrymal
Lacrimal (Lachrymal) relates to tears, to the gland which secretes these, and to the ducts of the gland.

Lacrimal Apparatus
This is the system concerned with the production of lacrimal fluid (TEARS) and their drainage. It consists of the lacrimal gland, which produces the secretion, and the ducts which allow its passage to the eye's surface and then a series of channels (the lacrimal canaliculi, lacrimal sac and nasolacrimal duct) which allow the removal of tears into the nose. The nerve supply is provided by the lacrimal nucleus of the facial nerve (7th cranial nerve).

Lacrimal Caruncle
An area of modified skin lying in the medial canthus (corner) of the eye, usually pigmented and often supporting one or two tiny hairs.

Lacrimal Fluid
(See TEARS.)

Lacrimal Gland
Produces TEARS.

Lacrimation, Lachrymation
This term is often used to describe an excess of tears, as a result of a blocked duct or conjunctivitis, etc.

Lactate
1. The production and secretion of milk.
2. A salt or anion of LACTIC ACID.

Lactation
Lactation depends directly upon the fact that if the milk is not regularly removed, the secretion will cease. It reaches its maximum duration in the cow and goat which are milked by human agency for the production of milk for consumption. By this artificial method the duration of lactation and the quantities of milk have been enormously increased.

The duration of a lactation in the cow is taken to be 305 days, commencing from calving and ending when the cow ceases to be milked at least twice a day. This is in line with other European records. The period for butterfat sampling continues to be from the fourth day after calving.

To produce 9,090 litres (2,000 gallons) of milk, the cow must secrete over 10,700 kg (9½ tons) of milk from the mammary gland, e.g. roughly about 12 or 14 times the weight of her whole body. (See MILK YIELD; 'LICKING SYNDROME'; MAMMARY GLAND; MILK; WEANING.)

Lactation, Artificial
The artificial induction of lactation may be brought about by means of hormones. For example, barren, anoestrus ewes have been rendered good foster-mothers to lambs by a single dose of 40 mg stilboestrol (not allowed in EU). Persistence of lactation in cows has been obtained experimentally by using bovine somatotrophin injections. (See also under SPAYING.)

Lactation Tetany
(See HYPOMAGNESAEMIA; ECLAMPSIA; HYPOCALCAEMIA; LAMBING SICKNESS IN EWES. See also MILK FEVER; MILK TETANY.)

Lactescent Serum, Plasma
Lactescent serum (Plasma) is milky in appearance because of high levels of triglyceride. It is also called lipaemic serum, and plasma. Especially if fasted, patients are at risk of developing acute pancreatitis and gastroenteritis (dogs) and skin eruptions (cats). Affected samples can still be used for serological tests after repeated centrifugation.

Lactic Acid
(See also MILK.)

VetBooks.ir

VetBooks.ir

Lactic acid is one of the VOLATILE FATTY ACIDS produced in the rumen from carbohydrate digestion. Excessive production of lactic acid in the rumen – such as occurs after cattle have gorged themselves with grain – is a serious condition, and is followed by absorption of fluid from the general circulation (with consequent dehydration), ruminal stasis, and often death. (See BARLEY POISONING.)

Lactic acid is produced in muscle by the breakdown of glycogen. (Oxidation of lactic acid provides energy for the recovery phase after a muscle has contracted.)

After strenuous exercise, excess of lactic acid can lead to CRAMP. It can be broken down by heart muscle which is important in recovery following exercise (see MUSCLE - ACTION OF MUSCLE).

Lactobacillus

Bacterial species that have been used to control and treat mainly alimentary disorders. Their main action is to lower the pH in the upper intestine thereby making the environment hostile for *Salmonella* species and *E. coli*. There are many strains of *L. acidophilus* used in animal species and man as PROBIOTICS. There is some evidence of endotoxin absorption and alteration of white blood cell activity.

Lactose

Sugar of milk. Lactose in cow's milk has a commercial value. Cows with low lactose production often have higher mastitis cell counts, a factor in deciding culling policy. Lactose intolerance is a cause of diarrhoea in cats. (See SUGAR.)

Lactulose

A synthetic short-chain sugar. Used as a laxative, a detoxifier of ammonia in the treatment of HEPATIC ENCEPHALOPATHY and as a vehicle for oral administration of medication to individual birds and reptiles. Alleged to have probiotic-enhamcing effects in the intestinal canal.

Lafora's Syndrome

An inherited, late-onset (usually over five years old), myoclonic EPILEPSY occurring in about 10 per cent of miniature wire-haired DACHSHUNDS. It is seen as generalised or complex partial seizures. These may be spontaneous or can be induced by sudden sounds, movements or flickering lights. The condition may progress to other neurological signs, such as BLINDNESS and ATAXIA. It is an inherited autosomal recessive condition caused by a mutation. There is a DNA screening test for the faulty gene.

Lagomorphs

A group of mammals that includes rabbits and hares.

Lagos Bat Virus

A rhabdovirus, carried by bats in Nigeria; it has similarities to rabies virus.

Lagotto Romagnolo Dogs

An Italian breed from the Romagna region. They are used as a gundog, especially as a water retriever, and used for truffle-hunting. They are a medium-sized dog weighing 10 kg to 16 kg (22 lb to 35 lb). The hair is white, off-white or roan and the dog is hypoallergenic. It is susceptible to JUVENILE EPILEPSY (DNA test available).

Lakeland Terrier

A small active dog whose coat resembles an AIREDALE TERRIER. Ununited ANCONEAL PROCESS may be inherited.

Lakes

(See ALGAE POISONING; LEECHES.)

Lamb Carcase Rejection

Lamb carcase rejection on inspection at abattoirs: causes include 'MILK-SPOT LIVER' (only the liver rejected); CYSTICERCOSIS; LIVER-FLUKES.

Lamb D-Lactic Acidosis

(See 'DRUNKEN LAMB SYNDROME'.)

Lamb Dysentery

Lamb dysentery is an infectious ulcerative inflammation of the small and large intestine of young lambs, usually under 10 days old, and characterised by a high mortality.

Cause *Clostridium perfringens* (formerly *C. welchii*) type B. This organism is one of the gas gangrene group. After birth the lamb runs every risk of getting infection from its mother's udder, from the soiled wool of the hindquarters, or from the soil itself.

Signs In the acute type nothing seems to be wrong with the lambs at night, but in the morning two or three are found dead. If signs appear during the day, lambs are seen to become suddenly dull and listless; they stop sucking and if forced to move, they do so stiffly. Later, the faeces become brownish-red in colour (sometimes yellow), semi-liquid, and are often tinged with bright red blood. After a few hours in this state, the lamb becomes unconscious and dies. In less acute forms, the lamb may live for two or three days.

Prevention Passive immunity is conferred through the ingestion of colostrum. Ewes are vaccinated using multicomponent vaccines protecting against up to eight clostridial infections, so that the lamb will be protected by antibodies in the co-

lostrum. The type of vaccine used depends on the infections prevailing in the area. (See also under VACCINATION.)

Lambing, Lambs

(See under SHEEP BREEDING AND MANAGEMENT.)

Lambing Difficulties

Abnormality of the fetus, or its malpresentation, accounts for a high proportion of 'difficult lambings'. The failure of the cervix to dilate is another frequent cause of difficulty, which can usually be overcome by a veterinary surgeon. (See 'RINGWOMB'; also VAGINA - RUPTURE.)

Lambing Sickness in Ewes

Lambing sickness in ewes, which is also called parturient hypocalcaemia, or milk fever in ewes, is a condition similar to MILK FEVER in cows. However it is almost always seen before lambing and is caused by stress e.g. gathering for clostridial vaccination, change of feed, change of weather, etc. The signs and treatment are the same. It may be mistaken for pregnancy toxaemia or louping-ill. (See 'MOSS-ILL'.)

Lambliasis

In USA the name is used for GIARDIASIS as the infection is known as *Giardia lamblia* or *G. intestinalis*.

Lamb Survival Research

(See SHEEP BREEDING AND MANAGEMENT.)

Lamella

1. Concentric circles surrounding the Haversian canal in bone.
2. A small disc of glycerin jelly containing an active drug such as atropine, cocaine, homatropine and physostigmine, for application to the eye. It is applied by inserting within the lower lid. This type of formulation has been largely replaced by eye-drops.
3. Thin scales or plates or folds, usually in groups, that increase surface area as in fish gills, the omasum of ruminants, etc. They are also seen in fungi such as under a mushroom or toadstool cap.

Lameness

Lameness consists of a departure from the normal gait, occasioned by disease or injury situated in some part of the limbs or trunk, and is usually accompanied by pain. In simple cases lameness is not difficult to diagnose; in obscure cases, however, and in those instances where more than one limb is affected, it may be extremely difficult for anyone, professional or otherwise, to determine the site of the lameness, and its cause.

It is important to remember that lameness in cattle, sheep, and pigs may be the first sign of FOOT-AND-MOUTH DISEASE.

Causes The main causes are given below, according to animal.

Cattle (See FOUL-IN-THE-FOOT, FLUOROSIS, LAMINITIS IN CATTLE, MUCOSAL DISEASE, 'MILK LAMENESS'.)

Lameness in cattle is of great economic importance to the dairy farmer. The pain arising from several forms of lameness can reduce a cow's milk yield to a significant extent. Economic loss can go beyond this, however, since premature culling and cost of replacement often have to be taken into account also. A survey of 1823 herds showed that the annual incidence of lameness was about 5.5 per cent.

About 88 per cent of this lameness was due to foot lesions, with foul-in-the-foot predominating – closely followed by abscess formation at the white line, and by ulceration of the sole.

A foreign body, such as a stone or piece of broken glass, lodged between the claws of the hind feet, can be a very common cause of lameness. In winter, mud at near freezing temperatures is apt to lodge there too, predisposing to foul-in-the-foot.

Results of another survey, involving 262 farms participating in a dairy herd health and productivity service operated by the Royal (Dick) School of Veterinary Studies, University of Edinburgh, showed that 'an astonishing 25 per cent of cows were treated for lameness, and 1 per cent culled because of it, in 12 months'.

The survey showed that faulty feeding of high-yielding dairy cows often predisposed to laminitis or coronitis, resulting in chronic, often incurable, lameness. Excessive steaming up, major changes of diet at calving, heavy feeding after calving, large single cake or barley feeds, and very acid silage can be causes.

Cattle housing can be a contributory factor to lameness; rough concrete surfaces can abrade the sole of the foot, as can worn slats; and bad cubicle design can also result in lameness. (See also FOOT-BATHS FOR CATTLE.)

Dairy cattle Some 25 per cent become lame every year; but for those kept in straw yards, the figure can be as low as 8 per cent.

The highest incidence of the latter is found where the cows are in cubicles. Digital dermatitis occurs in cubicle housing and straw yards.

Sheep Foot-rot. (See under DIPS AND DIPPING; also FOOT-ROT OF SHEEP.)

VetBooks.ir

VetBooks.ir

Pigs Bush foot, foot-rot, swine erysipelas; also a biotin deficiency.

In all species, fracture of a bone may be the cause; or injuries to joints, ligaments, tendons or muscles.

Dogs Lameness in the dog can be caused by many factors, including congenital developments, arthritis, fractures, skin disease and spinal problems. Dogs with acute kidney disease have a stilted, stiff gait. Athletic dogs can sustain dislocations and 'stress' fractures of the extremities. Road traffic accidents cause fractures which can result in lameness. (See BRACHIAL for lameness due to damage of the brachial plexus; INTERDIGITAL CYST.)

Horses The following remarks refer especially to the horse, but they are to a great extent applicable to the other four-footed animals.

Signs The most characteristic and easily seen feature of practically all forms of lameness is abnormality in the manner of nodding the head, either at the walk or at the trot. Normally, the horse's head rises and falls to the same extent at each step, and, in lesser measure, the point of the croup (i.e. the highest part of the hindquarters) follows the same course. If a horse is made to walk alongside a blank wall, the head is seen to describe a wavy line against the wall, the undulations of which are equal, provided that the rate of the gait is uniform. In a lame horse these undulations become unequal.

Fore-limb lameness The withers of a horse which is lame in one of its two fore-legs, rise when the lame leg is on the ground, and fall when the sound leg comes to earth. This rising and falling is transferred along the rigid bar of the neck to the head. Accordingly, when a horse is lame in this way, its head is said to 'nod' heavy on the sound leg, and rise on the lame leg.

Hind-limb lameness The croup rises when the lame leg is on the ground, and falls when the sound limb is there. But the croup is connected by a rigid bar, passing over a fulcrum (the withers), with the head: it will be seen, therefore, that any rising of the croup will cause a lowering of the head, since the spinal column acts as a lever working over a fulcrum. In the horse which is lame in one of its hind-limbs, therefore, the head falls when the croup rises, i.e. when the lame leg is on the ground: it rises when the sound leg is on the ground. In other words, it behaves in a manner opposite to its behaviour when the lame limb is situated in front; the diagonally opposite hind-leg is indicated.

Other signs The noise made by the lame limb falling to the ground is always less than the noise made by the sound limb, for obvious reasons. The lame limb may be lifted higher than the sound one during the walk, as in cases of sand-crack at the toe (often called 'symptomatic stringhalt' when affecting a hind-limb), or, more often, it is not lifted so high (in most cases of pain in joints or in flexor tendons). On soft ground the footprint made by the lame leg is never as deep as that made by the sound leg, although this fact is not of great practical importance. In most lamenesses of the hindmost pair of limbs, the point of the haunch (external angle of the ilium) is carried higher on the same side as the lameness exists. This is most pronounced in lamenesses which involve the joints in greater pain when they are flexed. The raising of the pelvis on the same side as the lameness enables the foot to clear the ground during the stride with a lessened amount of flexion than would otherwise be the case. Finally, there may be some peculiarity of the swing of the lame limb through the air. It may be carried outward (abducted), or it may be carried too near to the other limb (adducted).

Determining the lame limb The observer should see the horse walked away from him, towards him, and then past him at right-angles. The horse should then be trotted in the same way. If the observer watches the head carefully, he will see how it is nodding, and as soon as he gets the rhythm of the nods he should immediately commence nodding his own head at the same rate. When he is sure that he is nodding in time with the horse's head, he should at once drop his eyes to the horse's fore-feet, and determine which fore-foot comes to the ground when the nod of his head is downwards. Having decided which fore-leg corresponds with a downward nod of the horse's head, he can state that the horse is lame either on the opposite fore-leg, or else on the hind-leg of the same side.

He should now attempt to decide whether the lameness is in the anterior pair of limbs or in the posterior pair. To do this it is necessary to observe carefully in which pair of limbs there is some discrepancy in movement, either a long or a short step, a lighter noise, adduction or abduction (seen from in front and behind only), increased or diminished flexion, etc. By the aid of these rules practically all simple single-leg lameness can be determined. Where there are two or more limbs affected it is very much more difficult. The services of a veterinary surgeon should be obtained to diagnose the situation of the lesions and their extent and nature. (See also JOINTS; RICKETS; LAMINITIS; HORSES, BACK TROUBLES IN; LIGAMENTS; BRUCELLOSIS.)

Lamina

A thin plate or layer such as the dorsal part of the arch of the spinal vertebrae, or at the corium of the hoof.

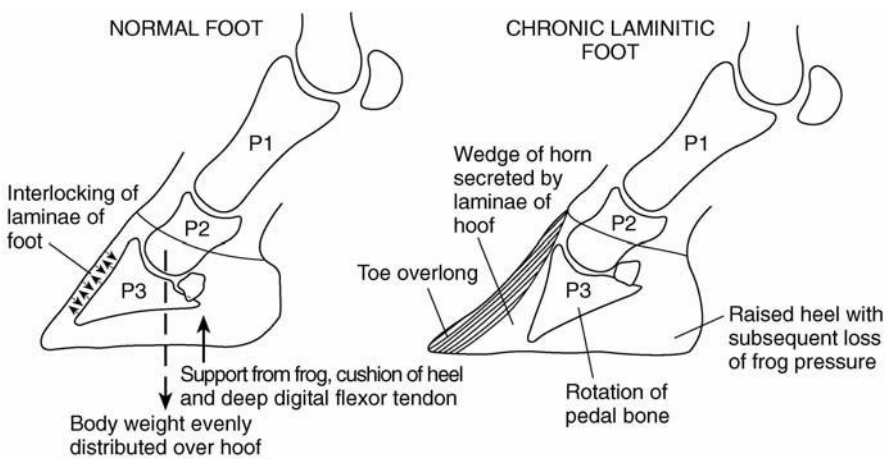
Laminectomy
A surgical treatment involving removal of the dorsal arch of a vertebra.

Laminitis
Inflammation of the laminae of the hooves causing lameness, often severe. It can be a serious problem in the horse. It is common in cattle, but less severe.

Laminitis in Cattle
Laminitis has been encountered in both adult and young cattle. For many years, overfeeding with barley has been regarded as a likely cause, and the disease has been described among cattle 4½ to six months old in 'barley beef' units.

Excessive steaming up, a change of diet at calving, large single concentrate feeds (especially of barley), overfeeding in the early stages of lactation, and acid over-fermented silage have also been cited as causes.

Laminitis in the cow is rarely the acute disease seen in the horse, but rather a milder, more insidious condition. 'A general tenderness of all four feet develops, usually soon after calving. This stage may go unnoticed. It may be followed sooner or later by more clearly recognised chronic secondary foot problems such as ulceration of the sole, separation of the wall from the sole, and horizontal cracks in the wall.' Infection usually complicates such conditions.



Laminitis in Horses
This has traditionally been defined as inflammation or oedema of the sensitive laminae of the hoof. It is now considered to be a transitory inflammation followed by congestion leading to breakdown of the union between sensitive and horny laminae.

Laminitis is most common in ponies, and in fat or unfit horses. Sometimes all four feet are affected; sometimes only the fore-feet; and occasionally only the hind-feet or one foot.

Causes
1. Excess carbohydrate intake ('grain overload').
2. Post-parturient metritis septicaemia.
3. Toxaemia – associated with enteritis, colitis X (exhaustion shock) and endotoxin shock.
4. Management and type – concussion in unfit horses or susceptible animal (e.g. fat pony).
5. Unilateral leg lameness putting excess strain on contra-lateral limb.
6. High-level corticosteroid administration.
7. Fatty liver syndrome.
8. Other suggested factors:
   (a) HYPOTHYROIDISM.
   (b) Allergic-type reaction to certain medication (e.g. anthelmintics, oestrogens and androgens).
   (c) High oestrogen content of pasture.
   (d) Cushing's syndrome. Between 24 per cent and 82 per cent of ponies have high ACTH levels which is often a precursor of equine Cushing's syndrome.

Laminitis should always be regarded as a serious disease, whether it arises secondarily during the course of a generalised illness, or whether it occurs independently of any other recognisable disease.

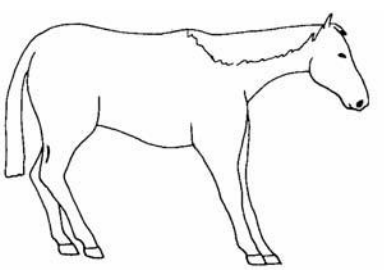
Intense pain results from acute laminitis, either from inflammation of the sensitive laminae or from changes in the circulation of the blood within the hoof. Prompt treatment is needed to relieve this pain, and to try to prevent permanent damage to the foot. In severe cases of laminitis, separation of the sensitive and horny laminae may occur, and any subsequent infection may put the horse's life at grave risk.

Diagnostic representation of forces involved in pedal bone rotation. (Reproduced by courtesy of the *Veterinary Record*, C. M. Colles and L. B. Jeffcott.)

VetBooks.ir

Signs Acute, subacute and chronic forms of laminitis are recognised. Signs, especially in acute and subacute laminitis, are both general, affecting the whole body, and local.

In acute laminitis the body temperature often rises to 40° C to 41° C (104° F to 106° F), breathing becomes rapid, and the pulse rate likewise (80 to 120 per minute). Pain may cause the horse to tremble, and profuse sweating may occur. Depression, a facial expression suggestive of pain felt, loss of appetite, and a reluctance to stand or move, together with an unnatural stance are other signs. Visible mucous membranes are often bright red, the pupils dilated.



If lying on the ground, the horse will be extremely reluctant to rise; and if standing will maintain the same position, and grunt or groan if forced to take a step.

The affected feet feel hot to the touch, especially at the coronet, and a bounding pulse in the digital arteries can be felt or even seen.

Tenderness is evident immediately any pressure is applied to the affected feet. The appearance of blood, or bloodstained exudate, at the coronary bands is usually followed by death within 24 hours or so.

Each time the affected foot is lifted from the ground, it is snatched up and held for a few moments as if contact with the ground were painful; later it may be rested out in front of the horse with the heel only on the ground. When two feet are affected it is always either the fore-pair or the hind-pair; diagonal feet are rarely or never involved. If the fore-feet are involved, the horse stands with these thrust out well in front of him, resting on the heels as much as possible, while the hind-feet are brought up under the belly in order to bear as much of the body-weight as possible.

In the chronic form, which often follows the acute, laminitis presents a slowly progressive change in the shape of the foot. The toe becomes more and more elongated, the heels and the pasterns become vertical, rings appear around the coronet and move slowly downwards as the horn grows, and a bulge appears in the concavity of the sole.

Laminitic stance – forelegs thrust forward, hindlegs drawn under the body and weight taken on heels. (Reproduced by courtesy of the *Veterinary Record*, C. M. Colles and L. B. Jeffcott.)

The line drawings show both the stance of the horse with laminitis of the fore-feet only, and also the rotation of the pedal bone which may take place during or after the acute stage.

Treatment The underlying cause of the laminitis must be addressed and treatment will depend on the cause of the condition. Palliative measures include blocking of the digital nerves with a local anaesthetic: this gives immediate relief from pain, enables the horse to stand and walk normally, and has a beneficial effect on the blood circulation of the foot; however, care must be taken that further damage is not caused to the laminae by exercise. For the relief of pain acetylpromazine is also used, and this drug tends to reduce blood pressure. Phenylbutazone is another drug which has been used. Similarly corticosteroids have in the past been used but are contraindicated; they can, in fact, produce the condition. Warm or hot water applications to the feet are regarded as preferable to hosing with cold water.

Green food in small amounts is good, and a little hay should be supplied.

In chronic cases the shoeing is of great importance and special surgical shoes may be needed. (See also CUSHING'S SYNDROME; EQUINE METABOLIC SYNDROME; 'FOUNDER'; HOOF REPAIR WITH PLASTICS.)

Laminitis in Other Animals

Laminitis in other farm species can vary from the acute disease as in horses to a milder, insidious condition, often presented as tenderness in all four feet.

Laminosioptes cysticola

A parasite causing small SUBCUTANEOUS cysts in poultry (chickens, turkeys). It is also called a cyst mite.

Lampas

A swelling of the mucous membrane of the hard palate of the horse immediately behind the arch of the incisor teeth in the upper jaw. It is often seen about the time when the permanent teeth are cutting through the gums, i.e. at 2½, 3½ and 4½ years, and for a short time afterwards. It is erroneously thought that it is the cause of a falling-off in condition which naturally occurs when the teeth are cutting; it is really rather an effect. It was the custom to lance 'lampas' in many parts of the country; this occasions unnecessary pain and discomfort to the horse, and if the incision is made towards 1 side instead of in the middle-line there is a serious risk of wounding the palatine artery on that side. On no account should lampas be lanced.

VetBooks.ir

Lampreys
Primitive fish that are parasites on other fish. There are saltwater and freshwater species, the freshwater species being larger (up to 50 cm long). They can be a problem for freshwater fish farms, particularly in the USA.

Lamziekte
Lamziekte is BOTULISM of cattle in South Africa which occurs as an enzootic in animals on phosphorus-deficient areas of the veldt. During winter, lack of phosphorus leads grazing cattle to chew the bones of animals (often cattle) that have died, in an endeavour to take phosphorus into the body to make good the deficiency. This condition of bone-eating (osteophagia) is actually only the result of a craving for minerals. Where the animals whose skeletons are left on the veldt harboured in their alimentary canals *Clostridium botulinum*, this organism invades the carcase, and both it and its toxin are present in the decomposing remains.

Prevention The researches of Sir Arnold Theiler and the workers at Onderstepoort showed that the best means of preventing lamziekte is to feed sterilised bone-meal to cattle during the winter months in areas which are naturally deficient in phosphorus. This is illegal in UK and an inorganic supply of calcium and phosphorus should be used. (See BOTULISM.)

Lancashire Heeler Dogs
A collie type of dog breed not common nowadays. It is susceptible to COLLIE EYE ANOMALY which is a recessive trait and to LENS LUXATION which may also be recessive.

Lancing
The act of surgery where an incision is made into a fluid filled LESION e.g. a CYST or ABSCESS.

Landrace Pigs
A large white, lop-eared pig used to produce commercial hybrid breeds. The pig was bred for pork production, in Denmark and following an improvement programme it made Denmark the chief bacon-exporting country. It is a long-backed breed and has about two more ribs than the average pig. For many years purebred breeding stock were not exported, but they have been imported into many countries including Britain. (See also BRITISH LANDRACE PIGS.)

Land Spaniels
These no longer occur but they tended to be called setting dogs. They crept forward and pointed at their prey. The WELSH SPRINGER SPANIELS is thought to be its successor.

Lanolin
A type of fat found in sheep wool. It is widely used in ointments and creams.

Lantana Poisoning
Lantana poisoning of cattle and sheep has occurred in Australia and New Zealand. *L. camara* is the species commonly involved; especially the red-flowered variety. It causes light sensitisation, with exudative dermatitis of teats and vulva. Deaths have occurred.

Laparoscopy
(adjective, Laparoscopic)
The use of optical instruments for viewing the interior of body cavities and organs such as the bladder, the interior of joints for signs of arthritis, etc., and for avian sex determination. It is used when performing ovariectomies in bitches using 'keyhole surgery'.

Laparotomy
Laparotomy means surgical opening of the abdominal cavity of mammals and the coelomic cavity of birds, reptiles and fish. The incision is either made in the middle line of the abdomen, or through one or other of the flanks. It can be used as a method of investigating or examining the abdomen and its enclosed organs (See EXPLORATORY LAPAROTOMY).

Lapinised
This term is applied to a virus which has been attenuated by passage through rabbits. An example is afforded by lapinised swine fever vaccine.

Large Black Pigs
This breed is mainly found in south west England. It is completely black and is useful in extensive farming systems. The breed nearly died out in the 1960s and is still on the rare breed vulnerable list.

Large Munsterlander
This dog breed is a recent introduction to the UK. Hereditary cataract occurs. It also is susceptible to HYPERURICOSURIA and BLACK HAIR FOLLICULAR DYSPLASIA.

Large White
This breed of pig contributes its genetics to many of the major commercial crossbred animals. It is a large breed with long face and with prick ears.

Larkspur Poisoning
Of the several varieties of larkspur, most of which occur in America in the ranges of the West, where they cause great loss to cattle owners, only one species is commonly found in Britain – *Delphinium ajacis*. The seeds are the most dangerous parts of

VetBooks.ir

the plant, although the leaves have proved fatal when fed experimentally. Horses and sheep are not as susceptible as cattle. The active principles are four in number: delphine, delphisine, delphinoidine and staphisagrine, and of these the first three are highly poisonous.

Signs Salivation, vomiting, colicky pains, convulsions and general paralysis.

Laryngeal Hemiplegia

A problem in large dogs, especially LABRADOR RETRIEVERS, in which one or both arytenoid cartilages of the larynx become misplaced and inhibit the passage of air through the larynx, resulting a characteristic hoarse respiration, similar to 'ROARING' IN HORSES.

Laryngeal Hypoplasia

The incomplete development or underdevelopment of the larynx. It is seen in SKYE TERRIERS.

Laryngeal Obstruction

Chronic obstruction of the larynx in cattle is characterised by difficult or painful inspiration, giving rise to 'ROARING' IN HORSES. The most common causes are calf diphtheria (necrobacillosis); but there is uncertainty as to the primary infective agent causing chronic laryngitis – *Fusobacterium necrophorum*, for instance, is unable to penetrate intact mucous membrane.

Laryngeal Paralysis

This can be acquired or congenital. It results from lesions of the VAGUS cranial nerve or the recurrent laryngeal nerve. It can result in HYPOTHYROIDISM in dogs. There is an inherited form found in BOUVIER DES FLANDRES dogs. The signs are of noisy respirations and obstruction of the upper respiratory airways lasting several months. (See also LARYNGEAL HEMIPLEGIA.)

Laryngeal Paralysis in Horses

The correct name is IDIOPATHIC LARYNGEAL HEMIPLEGIA or recurrent laryngeal neuropathy. Laryngeal paralysis in horses causes the abnormal inspiratory sound called 'roaring'.

The usual cause was for long regarded as vibration of the slackened vocal folds on one or both sides of the larynx, due to paralysis of the muscles which move the arytenoid cartilages outwards. Laryngeal paralysis is probably a hereditary condition transmitted by a simple recessive factor.

A large number of respiratory diseases may give rise to a temporary roaring due to inflammation and thickening of the mucous membranes lining the larynx. GUTTURAL POUCH DISEASE may have a permanent effect.

Treatment The traditional Hobday operation or tracheotomy is no longer advised. Laryngoplasty, often called a 'tie back', is used as a routine treatment. However the most modern treatment is laryngeal reinnervation. A nerve/muscle transplant is performed to restore function in the larynx.

Abnormal inspiratory noises during exercise, particularly in young horses which may have pharyngitis and laryngitis, should not be taken to indicate one-sided paralysis of the larynx. Similarly, normal respiratory sounds at exercise should not be regarded as implying soundness of the upper respiratory tract.

LARYNGOPLASTY is sometimes used for the treatment of roaring, especially in those horses not required to perform at high speeds. The operation involves securing the arytenoid cartilage in a lateral position, using prostheses to prevent intrusion of the arytenoid cartilage and vocal cord into the lumen of the larynx.

Poisoning In a case where contaminated mineral oil was used to dose horses, acute gastrointestinal signs were seen. About three weeks later bilateral laryngeal paralysis occurred, resulting in some deaths. Post-mortem examination revealed a severe loss of myelinated fibres from both recurrent laryngeal nerves. The acute clinical signs and delayed neurological effects were typical of ORGANOPHOSPHORUS POISONING.

Laryngeal Tie-Back

An operation to correct laryngeal hemiplegia.

Laryngitis

Inflammation of the larynx. (See LARYNX, DISEASES OF.)

Laryngoplasty

An operation used in horses with laryngeal paralysis in which a suture is applied to the diseased arytenoid cartilage to leave it permanently open. It has a reasonable success rate in racehorses but it is higher in draught and sports horses. It is also called 'tie-back'.

Larynx

The larynx is the organ of voice, and also forms one of the parts of the air passage. It is placed just between, and slightly behind, the angles of the lower jaw. Externally it is covered by the skin, by a small amount of fibrous tissue, and sterno-thyro-hyoid muscles.

Structure The cricoid cartilage is shaped somewhat like a signet ring and connects the rest of the larynx with the first ring of the trachea. To its upper part are attached the arytenoids and the posterior horns of the thyroids. A crico-tracheal

membrane unites it to the trachea, and a cricothyroid membrane unites it to the thyroid cartilage. The thyroid cartilage possesses a body which in man forms the protuberance known as Adam's apple. The epiglottis lies in front of the body of the thyroid and curves forwards towards the root of the tongue; it is shaped somewhat like a pointed ovate leaf. The arytenoids are situated one on either side of the upper part of the cricoid to which they are attached. (For functions, see under VOICE; for a similar organ in birds, see SYRINX.)

Larynx, Diseases of

(See also 'ROARING' IN HORSES; WHISTLING; COUGHING.)

Laryngitis is an inflammation of the larynx, but particularly of the mucous membrane which lines its interior. It is often associated with pharyngitis or with bronchitis and tracheitis, when it is usually due to the spreading of inflammation from one of these neighbouring structures.

In the horse it may occur during influenza. (See also LATHYRISM.)

Signs In ordinary cases there is a cough, difficulty in swallowing, pain on pressure over the larynx, extension of the head to relieve pressure on the throat (a condition that is aptly described in popular terms as 'star gazing'). A wheezing or roaring sound accompanies breathing if membranes become so swollen as to interfere with respiration. A slight rise in temperature and pulse-rate accompanies the milder forms, but when influenza is present, or if other specific diseases arise, the signs of fever are more distinct. Uncomplicated laryngitis usually lasts from a week to about a fortnight. Occasionally complications, such as roaring or whistling, follow recovery from the initial disease.

First-aid It is advisable to isolate all cases of laryngitis in a loose-box or other building, especially those arising in newly purchased animals, on account of the risk of contagious disease developing. (See NURSING OF SICK ANIMALS.)

Wounds of the larynx are not common, owing to its comparatively sheltered position in the body, but see under DRENCHING for a danger associated with the use of a drenching gun in pigs and sheep.

Lasalocid

A coccidiostat used as a feed additive in the prevention of coccidiosis in chickens, turkeys and game birds. It must not be used in breeding or laying birds; birds may be slaughtered only after 5 days from the last administration of the drug.

Laser

An acronym for light amplification by stimulated emission of radiation.

Lasers emit beams of intense, monochromatic, non-dispersing light, and can be used as powerful sources of localised energy. They are used in ophthalmic and other surgery and may be used instead of needles in acupuncture. Operators must wear protective glasses to shield their eyes.

Lassa Fever

This disease occurs in West Africa, and is caused by an arenavirus first isolated in 1969. In man the infection is likely to prove fatal. The virus has been isolated from the rat *Mastomys natalensis*, which (possibly with other rodents) acts as a reservoir of infection.

Lateral

An anatomical term signifying that an organ lies near the outside of the animal. The antonym is MEDIAL.

Lateral Cartilages

Lateral cartilages are rhomboid plates of cartilage which are attached, one on either side, to angles of the third phalanx (os pedis) of the foot of the horse. They extend above the coronet sufficiently to be felt distinctly at the heels and for a certain distance in front of this. In old age they often become ossified in their lower parts. When they ossify in their upper palpable margins, the name 'sidebones' is applied to the condition. In certain cases be cartilages may become injured from treads or tramps by neighbouring horses, or from the other foot; the cartilage, being poorly supplied with blood, undergoes necrosis. (See SIDEBONES; QUITTOR; FOOT OF THE HORSE.)

Lateral Line

A structure along the sides of fish that is sensitive to movement in the water, enabling the fish to detect the presence of other fish, currents, etc.

Latex, Natural Rubber

Hypersensitivity to this can result in contact urticaria, respiratory signs and shock. The main source of the allergens is the wearing of rubber gloves during surgery. Even a vaginal examination can result in an anaphylactic reaction in atopic people.

In the rubber-growing areas of Malaysia, the ingestion of latex by cattle, e.g. from buckets left by rubber-tappers, is a 'frequent occurrence', and can be fatal.

Latex from the tree *Hevea brasiliensis* can cause fatal illness in cattle.

Latex agglutination test This can be used for measuring the concentration of IgG_1 in the

plasma of newborn calves. The commercial test reagent (Ab-Ag Laboratories, Ely) is prepared by coating polystyrene latex beads with antibodies against bovine IgG_1.

Lathyrism, Lathyrus Poisoning

Lathyrism (lathyrus poisoning) is caused by feeding upon one of the various 'Mutter peas' – *Lathyrus sativus* principally, and *L. cicera* and *L. clymenum*, less frequently. The latter two samples of field peas grown in Southern Europe and North Africa, while *L. sativus* is imported from India mainly. They are poisonous to all the domesticated animals, but seem especially dangerous for horses. Many outbreaks have been recorded, and in most the percentage of deaths has been high, sometimes as much as 50 per cent of the affected.

Signs of poisoning may not appear until the lapse of as much as 50 days after the peas cease to be used as a food-stuff. The cause of lathyrism is the high selenium content of the plants. (See SELENIUM.)

Signs usually become visible when the animal is put to work or exercised. Typically, the chief signs are those of paralysis of some part of the body – usually the hind-limbs and the recurrent laryngeal nerve. This latter gives rise to the condition known as 'ROARING', and unless quickly relieved, the horse will die from asphyxia. In some instances the signs are so sudden in their onset that the horse drops while in harness and is unable to rise. In less severe cases there is staggering and swaying of the hindquarters, great difficulty in breathing, a fast, weak pulse, and convulsive seizures. The paroxysms may pass off in a few minutes, or the horse may collapse and die.

Treatment (See under LARYNX, DISEASES OF.) The antidote is ascorbic acid, added to the diet.

Laudanum

(See OPIUM.)

Laundry Detergent Pod Poisoning

These 'pods' are liquid capsules or sachets using polyvinyl alcohol film wrappings which dissolve on contact with water or moisture. As the liquid is concentrated it can cause severe signs, unlike with washing powder ingestion. In the USA in 2013 they were the second most common cause of fatal poisoning. They mainly result in ALKALI poisoning (pH 10 to 12) of a corrosive nature. They can cause MUCOSAL OEDEMA, PERFORATION and NECROSIS. Signs occur quickly and can include VOMITING, salivation, abdominal pain, respiratory signs and CNS depression. Treatment is symptomatic and may include OXYGEN, ANTIEMETICS, broad-spectrum ANTIBIOTICS, INTRAVENOUS fluids and ANALGESICS. SHOCK therapy may be required. PROGNOSIS is often poor.

Laurel Poisoning, Laurus Poisoning

The leaves of laurel shrubs and trees (family: Lauraceae) contain cyanogenic GLYCOSIDES which cause poisoning by HYDROCYANIC ACID.

Lavage

The process of washing out the stomach or the intestines. In gastric lavage, a double-way tube is passed down into the stomach either through the mouth or by way of the nose, and water or some medicinal solution poured or pumped through one channel in the tube. After a time this escapes by the other, carrying with it the contents of the stomach in small amounts. It is also used to wash out infected joints, abscesses, and infected thoracic and peritoneal areas. (See also ENEMA.)

Law

The law relating to the veterinary profession and veterinary practice, scientific research, domestic pets, farm animals, wild animals and zoos, is extensive and subject to frequent amendment. In the UK, Parliament implements laws for England and, following devolution, The Scottish Parliament, Northern Ireland Assembly and Welsh Government can implement their own acts, orders and regulations. Parallel legislation for the different parts of the UK exists for entries identified with an asterisk (*). It is important to note that new legislation may partially revoke previous legislation, a piece of legislation listed below may no longer be effective in its entirety.

Existing legislation includes the following (where appropriate, information on the topic, animal or disease covered by the legislation listed will be found under individual entries):

Abandonment of Animals Act 1960
African Swine Fever Order 2003*
African Swine Fever (Compensation) Order 1980
Agriculture Act 1970 [Sections 106, 110, 111, 113(1) and (2)]
Agriculture (Miscellaneous Provisions) Act 1968; Sections 4, 5 and 8 apply in Scotland
Agriculture (Miscellaneous Provisions) Act 1972
Agriculture (Poisonous Substances) Act 1952
Animal Boarding Establishments Act 1963
Animal Boarding Establishment Regulations (Northern Ireland) 1974
Animal By-Products Order 2003
Animal By-Products (Amendment) Order 2000*
Animal By-Products (Enforcement) (England) Regulations 2011
Animal By-Products (Enforcement) Regulations (Northern Ireland) 2011

Lawsonia intracellularis

The organism responsible for PORCINE INTESTINAL ADENOMATOSIS (PIA), also commonly called 'ileitis' in pigs. (See ILEITIS; see also Proliferative haemorrhagic enteropathy under HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Laxatives

SENNA, which has been recommended for pregnant sows; DIHYDROXYANTHRAQUINONE, useful in all domestic animals, including horses; EPSOM SALTS (magnesium sulphate), but of doubtful efficacy in ruminants; GLAUBER'S SALTS, but they may have ill-effects in pigs. LACTULOSE is useful in cats. Many laxatives are not licensed for use in animals in UK. (See also under PARAFFIN - USES.)

L-Carnitine

A vitamin of the B complex present in meat extracts and needed for fat oxidation. In human medicine it is claimed to improve exercise tolerance, and so might have a potential use in

racehorses. It can be combined with alpha lipoic acid to treat CANINE COGNITIVE DYSFUNCTION SYNDROME.

LD50

Ld_{50}value is a statistical estimate of the number of mg of a given substance per kg of bodyweight required to kill 50 per cent of a large population of test animals. The LD value of a compound may refer to oral or parenteral administration or to application to the skin.

LDA

(See LEFT DISPLACEMENT OF THE ABOMASUM.)

Lead Poisoning

Also called plumbism.

Acute form of lead poisoning

Cattle This is common in cattle which have eaten paint, licked out discarded paint tins, etc. (in spite of the fact that most paint is now lead-free), or which have eaten tarpaulins. It is frequently fatal and many cattle are unnecessarily lost each year from this cause. Cows have also been fatally poisoned after licking lead-rich ash from a burnt-down shed; and after eating silage contaminated by an old battery broken up by a forage harvester; also by eating roofing material from an old railway carriage.

In some instances cows have been poisoned after eating haylage made from grass in a field which had been used for clay-pigeon shooting. The haylage contained small particles of clay pigeons and lead shot. Dairy cows lose their appetite, become dull, and have diarrhoea. Some can develop stiff and swollen joints, become uncoordinated in their movements, with stillbirths or abortions.

Dogs They are sometimes poisoned through eating paint scrapings where a room is being redecorated, or after licking out a paint tin. Puppies often chew painted surfaces, leading to paint ingestion.

Cats can be affected by ingestion or inhalation of lead particles during home decoration.

Pigs are less sensitive than other farm animals. They can consume, without showing signs, a daily dose of lead which would kill a cow.

Geese Ten lead pellets can kill a goose.

Psittacines Due to their habit of pecking at their environment, birds can easily acquire lead from paintwork, especially from old joinery. (See also HEAVY METAL POISONING; 'NEW WIRE DISEASE'; ZINC POISONING.)

Swans Many cases have been reported of swans dying after swallowing lead weights used by anglers.

Signs Nervous signs are an important feature of lead poisoning, and may include excitement, ataxia, blindness, paresis and convulsions; affected animals may also show depression.

Cattle may bellow, charge around and, at intervals, press their heads against a wall or other fixed object.

Abdominal pain, sometimes with constipation followed by diarrhoea, are other signs; also anaemia in chronic or subacute cases.

In horses, 'roaring' (laryngeal paralysis) may be a sign, together with carpal swelling and posterior paralysis.

Treatment The treatment of lead poisoning was revolutionised by the introduction of the chelating agent, calcium disodium edetate (CaEDTA), which converts inorganic lead in the tissues into a harmless lead chelate which is excreted by the kidneys. In chronic cases, potassium iodide is given three or four times daily to hasten the elimination of the lead salt from the system. In cage-birds, calcium disodium edetate is alternated with penicillamine. Nursing involves the oral administration of magnesium sulphate and ispaghula husk (psyllium). (See also CHELATING AGENTS.)

Diagnosis of lead poisoning may be made by estimating the lead content of the blood, kidneys or liver.

A differential diagnosis must take into account other possibilities such as HYPOMAGNESAEMIA, ENCEPHALITIS, ACETONAEMIA, LISTERIOSIS, and poisoning by other substances.

Chronic lead poisoning The behavioural effects of lead poisoning in dogs may also include hysteria or aggressiveness.

This has occurred as a result of flaking paintwork in dog kennels, and also in the proximity of former lead-mining sites.

Falcons kept in painted cages developed lead poisoning after gnawing at the bars.

Lead poisoning is sometimes recorded in birds of prey that have consumed prey contaminated with lead shot.

Signs Chronic lead poisoning in horses results in recurrent laryngeal nerve paralysis and paralysis of the pharynx.

Leeches

Blood-sucking aquatic annelids of the class Hirudinea, within phylum Annelida (segmented worms).

VetBooks.ir

Leeches live in ponds, streams, and on damp vegetation. They have strong muscular suckers; the anterior one surrounds the mouth which, in several species, contains saw-like teeth used to pierce the skin of the host. Leeches secrete hirudin in their buccal cavity; this prevents clotting of the host's blood, on which they feed, and can cause a severe and sometimes fatal anaemia.

Limnatis nilotica is found in North Africa and Southern Europe. It reaches a length of 10 cm. The ventral surface is dark; on the dorsal surface are 6 longitudinal stripes on a brownish-green background. It cannot penetrate skin, but on being taken in with water by men and animals, it attaches itself to the buccal mucous membrane. This produces, constant small haemorrhages, which sometimes cause a serious anaemia.

L. africana and species of *Haemadipsa* are active in West Africa and in the tropical forests of Asia and South America, respectively.

H. zeylanica occurs in Asia and lives on land. It is a clear brown colour with a yellow lateral stripe on each side and a greenish dorsal stripe. It has five pairs of eyes and three teeth. It lives in damp weather on the lower vegetation. These leeches are small forms, about 2.5 cm long, but are very serious pests. The bite is painless but, as they occur in such enormous numbers, very deadly. They attack all vertebrates and many different species of mammals have been killed by them through sheer loss of blood.

Left Displacement of the Abomasum (LDA)

A problem mainly of dairy cows, but occurs occasionally in suckler cattle, sheep and goats.

Cause In the 1960s it was rare, but in the 2010s it is common especially in high yielding HOLSTEIN cows within a month of the third to fifth calving. It usually occurs soon after calving when the abomasum is FLACCID and can move in the ABDOMEN. It is MULTIFACTORIAL in cause but probably mainly the result of lack of dietary fibre and too quick transition to a high energy ration after calving resulting in varying degrees of ACIDOSIS.

Diagnosis The cow has an intermittent appetite often with forage intake occurring but concentrate intake reduced, resulting in unsatisfactory milk production. The left flank may appear sunken, rumen activity is usually normal and on left-side AUSCULTATION often a characteristic 'pinging' noise is heard. Cases, after a few days, may show diarrhoea.

Treatment Casting the cow onto her left side and slowly rolling into dorsal recumbency with kneading of the abdomen to reposition the abomasum. The animal is then kept on its left side before rising and giving forage. The success rate varies. Otherwise surgery is used such as fixation with a toggle, or a LAPAROTOMY using a bilateral, right lateral, left lateral or median incision and then replacing and fixing the abomasum.

Prevention Care is needed in feeding the cow in the dry period and transition to milking (See TRANSITION COW). In the early dry period, the diet can be mainly roughage, but in the late dry period, the cow will probably not be receiving sufficient energy for late pregnancy. A slow introduction of the milking ration should occur. Following calving, the cow should be in a group with other fresh calvers, and the feed energy level should gradually increase.

Legg-Calvé-Perthes Disease

It is sometimes called Von Perthes Disease, PERTHES DISEASE or Legg-Calvés Disease, OSTEOCHONDRITIS juvenalis or Avascular Necrosis. All are synonyms for a non-inflammatory aseptic NECROSIS of the femoral head and neck usually in dogs causing deformity. The animal is noticed to be lame. The condition may clear up spontaneously within six months, but during that time drugs to relieve pain are indicated. If it persists, the surgical removal of the femoral head may be indicated. It is a defect common in certain small breeds of dogs including BORDER TERRIERS, ITALIAN GREYHOUNDS, JACK RUSSELL TERRIERS, MANCHESTER TERRIERS, MINIATURE SCHNAUZERS, PUGS, SCOTTISH TERRIERS and WEST HIGHLAND WHITE TERRIERS.

Leghorn Chickens

This breed originates in Tuscany in central Italy and was named after the city of Livorno, known as Leghorn in English. There are many varieties but white is the most popular. Other colours include black tailed red, light brown, red, black, dark brown, blue, buff, Columbian, buff Columbian, barred, exchequer and silver. The birds are light and so not suitable for meat production but they are good layers producing 280 white eggs per year. The standard cock weighs about 5 kg (11 lb) and the hens weigh about the same. The bantam (light) type has cocks that weigh 4 kg (9 lb) and the hens 3.9 kg (8 lb). They are rather noisy, lively birds and are popular backyard or pet hens. The white leghorn has been used in the creation of broiler strains; the brown leghorn is often crossed with the LIGHT SUSSEX.

Legionella Pneumophila

This organism, first discovered in 1976, can tolerate hot water, and is spread by aerosols of it.

VetBooks.ir

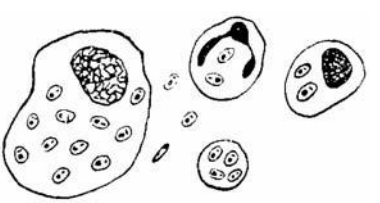
Contamination of humidifiers in air-conditioning units has been recorded. Fogging systems used to maintain high humidity in enclosures housing tropical species in zoological collections, especially those open to the public must be monitored for the organism. People, cattle, sheep, horses, pigs, goats, dogs and cats are all at risk of pneumonia caused by this infection (Legionnaires' disease).

Legislation

(See LAW.)

Legume Poisoning

This may occur when certain legumes are fed raw, and can result in death. Both navy beans (*Phaseolus vulgaris*) and jack beans (*Canavalis ensiformis*) contain a heat-sensitive toxin which can weaken the animal's resistance to coliform and other bacteria. Heat treatment of the beans renders them safe. (See also LATHYRISM; LUPINS, POISONING BY; POISONING.)

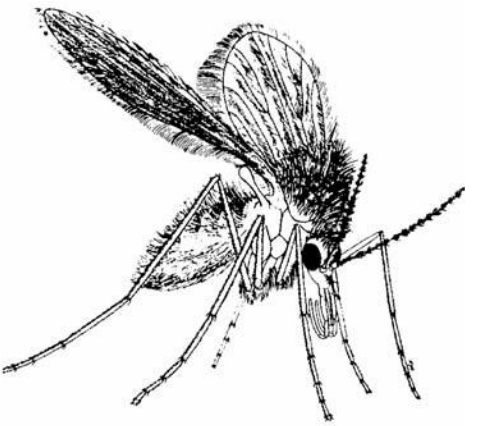


Leicester Longwool Sheep

The breed, produced in the Midland Counties of England in the 1700s, was developed by Robert Bakewell; it is also known as Leicester Bakewell, Leicester, New Leicester or Disley Leicester.

This is now considered a rare breed. There are no horns; it has a wedge-shaped head, with black lips and nostrils, and black specks on the face and ears. The hooves are black and the fleece is dense, with 'blocky' clumps of wool. The breed is present in the UK, USA, New Zealand and Argentina.

Leishmania



A genus of protozoon parasites. Each appears as a round or oval body with a micro- and a macronucleus.

Leishmania as seen in spleen cells.

Leishmaniasis

A zoonosis that is of considerable importance in man, but not in animals other than the dog and sometimes cat. Cutaneous leishmaniasis, or 'oriental sore', is seen in Iran, India, parts of Africa, and South America, and is caused by *Leishmania tropica*. Visceral leishmaniasis, called also kala-azar or 'dum-dum fever', occurs in the coastal countries of the Mediterranean, and is caused by *L. donovani*. (At least five other species, and several subspecies, are recognised.) Both forms are diagnosed by laboratory examination. A third form, affecting mucous membrane of mouth and nose, is caused by *L. brasiliensis*, and has a poor prognosis. The disease has been recorded in dogs returning from mainland Europe (mainly Spain) and must be considered by those travelling under the PET TRAVEL SCHEME (PETS).

A female phlebotomine sandfly, the vector of leishmaniasis. (Reproduced with permission from *The Leishmaniases: Report of WHO Expert Committee*, WHO Technical Report Series 701, WHO, Geneva.)

Signs in the dog include wasting, enlarged lymph nodes, keratitis and/or conjunctivitis, and alopecia or dermatitis. The ears are excessively waxy and the wax has a distinct and unusual smell. Dermatitis may develop.

Leishmaniasis is rarer in cats, causing skin ulcers, fistulae and enlarged lymph nodes with exfoliative and ulcerative dermatitis, particularly at the pressure points. Conjunctivitis is also seen in cats.

Treatment This is not recommended (as this is a zoonosis) (See FLIES - SANDFLIES). The incubation period in dogs may be up to two years; the prognosis is not good. The treatment of choice is allopurinol at 10 to 15 mg/kg bodyweight for six months at least; the treatment may actually take longer, depending on the response. Meglumine antimonite is used in USA, although treated animals may become symptomless carriers and a follow-up treatment with allopurinol may be required. A cure is rare.

Prevention Housing animals between 19.00 and 07.00, when the vector (the sandfly) is most active. Fitting dogs (not cats) with a 'flea collar' impregnated with a synthetic pyrethrin may help repel the flies.

Dogs are an important source of human infection in many regions.

VetBooks.ir

Lenses, Contact

Lenses, contact made of a softish hydrophilic material have been used in horses, dogs and cats with keratitis and/or penetration of the cornea. Such lenses can act more or less as a bandage for the cornea, and promote healing by reducing trauma from inflamed eyelids and so reducing pain. Ointment and eye-drops can be still used. The lens can be removed at the end of a week or so. The lens can be removed at the end of a week or so. Contact lenses have been used to treat HEAD SHAKING in horses where the adverse stimulus appears to be strong light.

Lens Luxation, Lens Dislocation

A condition in which the crystalline lens becomes displaced into one of the chambers of the eye. It occurs in dogs, especially terriers, and at first is very hard to recognise. One sign is that the animal bumps into stationary objects. Breeds involved include BORDER TERRIERS, CHINESE CRESTED DOGS, JACK RUSSELL TERRIERS, LANCASHIRE HEELERS, MINIATURE BULL TERRIERS, PARSON RUSSELL TERRIER DOGS, SEALYHAM TERRIERS, SMOOTH-HAIRED FOX TERRIERS, TIBETAN TERRIERS and WIRE-HAIRED FOX TERRIERS. Lens dislocation may be classified as congenital, primary, secondary, or traumatic. Surgery may restore some degree of vision and save the eye, but neglect of an anterior dislocation almost invariably results in the development of GLAUCOMA and the affected eye may have to be surgically removed. Some times lens luxation may occur following the development of a CATARACT. (See EYE, DISEASES AND INJURIES OF.)

Lens of the Eye

(See EYE - CONTENTS OF THE EYEBALL.)

Lentiviruses

Members of this group include EQUINE INFECTIOUS ANAEMIA; MAEDI/VISNA of sheep; and CAPRINE ARTHRITIS-ENCEPHALITIS, as well as the human AIDS virus and FELINE IMMUNODEFICIENCY VIRUS.

Leonberger Dogs

A breed of dog recently introduced to the UK. Hereditary CATARACT occurs but is of unknown mechanism and GLAUCOMA is also seen.

Lepeophtheirus

Lepeophtheirus is the sea-louse of salmonids. It is the most important disease problem for fish farming in sea lochs; the parasite literally eats the fish alive. Treatment is possible by feed medicated with azamethiphos or dichlorvos but uneaten feed attracts wild salmon to the cages. Wrasse (cleaner fish) have been suggested as a biological alternative to medication but there are doubts about the practicality. The Farm Animal Welfare Council published a report, *The Welfare of Farmed Fish*, in 1996.

Leporacarus gibbus

Formerly called *Listrophorus gibbus*, this mite is a benign ectoparasite of rabbits. It seldom produces clinical signs but can be observed as a 'pepper and salt' deposit on the fur. Sensitive human attendants may develop a mild PRURITUS when handling affected rabbits.

Leptin

A protein hormone that plays an important part in regulating energy intake and energy use by regulating (decreasing) appetite and (increasing) metabolism. Leptin is one of the most important adipose-derived hormones; white fat is the most important source, but it is also produced in brown fat, placenta, ovaries, skeletal muscle, stomach, bone marrow, pituitary, liver and mammary gland. Under normal conditions the body's fat cells are responsible for the constant production and release of leptin. Its production in the placenta means that leptin levels rise in pregnancy and fall at parturition.

Leptin acts on receptors in the hypothalamus of the brain where it inhibits appetite long term. It is reduced by MELATONIN during darkness. These receptors are associated with milk yield in dairy cows. Leptin-tt in the genotype of cows means they have increased appetite and higher milk yield. Genotypes with Leptin-cc have a lower appetite and produce less milk, while those with Leptin-ct are intermediate. A DNA test may be used to select high yielders.

Leptocephalus

An abnormally small head.

Leptomeningitis

Leptomeningitis means inflammation of the inner and more delicate membranes of the brain and spinal cord.

Leptospira

This genus comprises two species: a pathogenic one, *L. interrogans*; and *L. biflexa*, which is found in surface water and is regarded as a saprophyte. There are numerous serotypes and subgroups. The bacteria can survive for long periods in the kidneys and, outside the body, in moist, warm conditions. Leptospires are SPIROCHAETES.

Leptospira hardjo

A bacterium primarily of cattle and found as two main types *Leptospira borgpetersenii* serovariety *hardjo* and *L. interrogans* serovar *hardjo*. The infection normally enters a herd with infected cattle or sheep or contaminated water. Initially in a

herd some individual cattle may show a temperature rise and lose milk yield for a few days, so-called MILK-DROP SYNDROME or 'FLABBY BAG'. Then a few weeks later ABORTIONS can occur, usually in the last three months of pregnancy. Some animals show infertility or poor milk yields. Blood or milk (individual or bulk) samples can be taken for antibody. Antibiotics can be used to treat and there are vaccines available. It is a ZOONOSIS, mainly of those working with cattle and causing headaches, raised temperature due to non-suppurative meningitis.

Leptospire

A corruption or colloquial use for members of the genus *Leptospira*, a spirochaete.

Leptospirosis

Infection with *Leptospira* spp. Various types are non-pathogenic, but some can infect animal species including mammals, birds, reptiles and amphibians. Some strains have wildlife reservoirs and then cause infection in domesticated animals. Outside the body, it requires moisture to survive. Problems can occur in wildlife, resulting in periodic episodes of high mortality. Several leptospiral strains can infect humans.

Cattle This is an important infection which can give rise to a generalised illness, to mastitis, or to abortion. Jaundice may be one of the signs and, in the case of MASTITIS, discoloured milk. The leptospires tend to localise in the kidneys. Abnormal milk is a dominant sign. Abortion due to leptospirosis is not uncommon.

In one survey, a total of 406 cattle sera were collected at the Edinburgh abattoir from animals of 63 different herds in various parts of Scotland, the north of England and Northern Ireland, and tested against the following *Leptospira* serotypes: *icterohaemorrhagiae*, *canicola*, *pomona*, *bratislava*, *ballum*, *sejroe*, *grippotyphosa*, and *bataviae*; *saxaebing* and *hardjo* were included when testing the last 80 cattle sera. Of the total, 260 (64 per cent) sera had agglutinins to one or more of these 10 serotypes.

Cattle are the maintenance hosts of *L. hardjo*, the most common and important leptospire, which is a cause of abortion, milk drop syndrome and leptospiral MASTITIS, and also important from the public health aspect.

Leptospirosis of calves has been seen both in the UK (due to *L. icterohaemorrhagiae* and *L. canicola*) and overseas (due to other leptospires).

In Queensland an acute fever with jaundice and haemoglobinuria has been known in calves for many years. It is rapid in onset and death occurs within a few hours to four days after the appearance of signs; dullness, temperature of 40°C to 41.5°C (104°F to 107°F), dark red urine and pale and yellow visible mucous membranes. *L. pomona* was demonstrated in kidney sections on post-mortem examinations. Recovered calves continued to excrete leptospires for up to three months. Infection may occur through inhalation of droplets of infected urine splashing on concrete, or as a result of insect bites.

In the USA, where the important species are *L. pomona*, *L. grippotyphosa* and *L. sejroe*, abortion is reported to be the main sign of leptospirosis in cows. In Illinois, a survey covering over 23,000 animals showed 14 per cent to be affected.

In Kenya, outbreaks of acute illness due to infection with *L. grippotyphosa* have been reported in cattle, sheep, and goats. Jaundice is a sign in some 30 per cent of cases, and death has followed within 12 hours of signs being observed. Snuffling, coughing and holding down of the head are other signs. In cows, milk yield is reduced and is red in colour or otherwise abnormal. Urine varies from red to black. Temperature may rise to 40.5° C (105° F).

In Europe, *L. grippotyphosa*, *L. pomona* and *L. canicola* have been isolated.

Diagnosis The bacteria can be found in the aborted fetus but diagnosis is usually by detection of raised antibody levels.

Treatment Antibiotics, especially streptomycin/penicillin, or ampicillin, used at a high dosage can reduce levels of infection. Milk withdrawal requirements must be observed.

Control Vaccines are available for immunising cattle against infection by *L. interrogans serovar hardjo*. Two vaccinations are given four to six weeks apart with a single annual booster injection.

Wild animal hosts After an outbreak of abortion associated with leptospires in Scottish cattle, wild mammals were examined. Leptospires were isolated from 22 out of 108 rats, three out of 49 mice and one out of three hedgehogs; voles, mice and shrews were found to be infected on the farm where the leptospiral abortion had been diagnosed. Contamination of pastures by the urine of wild mammals may play a part in the spread of leptospirosis in cattle.

Public health People working in milking parlours have become infected with leptospirosis as a result of the splashing of infected cows' urine on concrete. Inhalation of a resulting aerosol is one means of transmission. Leptospires can penetrate abraded skin and intact mucous membrane – another mode of infection.

VetBooks.ir

Infection with members of the Hebdomadis serogroup has been identified as the most commonly diagnosed leptospiral infection of man in Britain. This serogroup includes *L. hardjo* and *L. sejroe*, which also cause mastitis in cows.

Two genotypes have been recognised: *hardjo bovis* and *hardjo prajitno*; the latter being less common but more pathogenic.

In one 12-month period, 72 cases of human leptospirosis, of which seven were fatal, were confirmed in the British Isles. In 30 cases the patient's occupation was associated with farming. Nine of the patients became infected through immersion in polluted water. Illness due to Hebdomadis serogroup infection was generally less severe than that due to *L. icterohaemorrhagiae*.

L. hardjo causes an influenza-like illness which can be severe and last several weeks. In rare instances there may be meningitis, kidney failure and death.

In New Zealand, high titres of antibodies were found in workers on farms where there was active *L. hardjo* infection of two- and three-year-old cattle. Conventional measures for protecting milkers from contact with infected urine appeared to be ineffective, and it was concluded that herd vaccination of cattle was the only means of protecting dairy farm workers.

Dogs Jaundice in dogs may be caused by *Leptospira icterohaemorrhagiae*. This organism also causes jaundice (WEIL'S DISEASE) in man, and illness (with or without jaundice) in a number of domestic animals, including pigs and calves. *L. canicola* (the cause of Canicola fever in man) is two or three times more common as an infection in dogs than *L. icterohaemorrhagiae*. The bacterium is the cause of much of the acute and subacute nephritis in younger dogs, especially between November and April.

Surveys in the UK have shown 37.6 per cent of rats infected.

Signs of infection with *L. canicola* are very variable. There may be loss of appetite, depression, and fever alone, or together with marked thirst and vomiting, loss of weight, and sometimes a foul odour from the mouth. In a few cases there is jaundice. Ulceration of the tongue may occur. Collapse, coma, and death may supervene.

The signs described above are related to leptospiral invasion of the bloodstream. This may be followed by invasion of, and damage to, the kidneys. This primary nephritis may be followed later by chronic interstitial nephritis, kidney failure, uraemia, and death. Infection with *L. icterohaemorrhagiae* follows a similar course with the target organ being the liver so JAUNDICE and petechial haemorrhages (especially in the mucous membranes of the mouth) are often clinical signs. (See PETECHIAE.)

Treatment Antibiotics have been used successfully in the early stage of *L. canicola* infection. Once the kidneys have been damaged, however, treatment is as for nephritis. In severe cases clinical signs of uraemia are evident and the animal dies, as a rule, despite all treatment. (See KIDNEYS, DISEASES OF; URAEMIA; NURSING OF SICK ANIMALS; HEART.)

Prevention Single and multiple vaccines are available; annual boosters are necessary to maintain immunity. Most vaccines contain *L. canicola* and *L. icterohaemorrhagiae*, but *L. grippotyphosa* and *L. australis* may be included.

Most of the dogs which recover from leptospirosis excrete the organisms in the urine for long periods (sometimes four to 18 months). This obviously makes control of the disease difficult.

Horses Leptospirosis in horses is usually a mild disease, though sometimes fatal in foals; but see PERIODIC OPHTHALMIA.

Pigs Cases of leptospiral jaundice in piglets due to *Leptospira icterohaemorrhagiae* and also to *L. canicola* have been reported in the UK. Signs in pigs include loss of appetite, fever, jaundice, and – in some cases – death. Pigs which have recovered excrete leptospires for some time afterwards. Indeed, infection in a herd may persist for years, with risk to human health. Infected sows may abort.

L. canicola can survive for 12 days in naturally infected pig kidneys kept in a refrigerator. (See CANICOLA FEVER, which farm workers may contract from pigs.)

L. pomona and *L. interrogans hardjo* may cause leptospiral abortion. *L. australis*, which in the UK has many free-living carnivore hosts, also infects pigs.

Sheeps and Goats In Britain, leptospirosis is rare in sheep, though serological surveys have shown evidence of infection. Three serogroups were implicated: Hebdomadis, Australis, and Pomona. Clinical signs are abortion and stillborn or weak lambs.

Clinical leptospirosis in sheep and goats in other countries has been characterised either by abortion, or by an acute, often fatal disease, with signs of JAUNDICE, FEVER, and HAEMOGLOBINURIA.

Lernea

The anchor worm. The female (only) is a parasite on fish. It attaches itself to the muscles by penetrating the skin. They may be seen round the vent. Affected fish are sluggish and grow poorly. There may be heavy mortality.

VetBooks.ir

Lesion
Lesion meant originally an injury, but is now applied to all changes produced by diseases in organs or tissues.

Let-Down of Milk
(See MILKING.)

Lethal Factors
(See GENETICS, HEREDITY AND BREEDING.)

Leucine
One of the essential amino acids. It is involved in tissue repair, especially skin and bone. It aids in lowering elevated blood sugar levels and is metabolised in muscle. It must be well balanced with the amino acids isoleucine and valine, as excess leucine results in increased metabolism of those two amino acids, leading to a greater requirement for them in the diet.

Leuco-
(See LEUKO-.)

Leucocytes
White blood cells. (See LEUKOCYTES.)

Leucoderma
(See LEUKODERMA.)

Leucogen
The proprietary name of Britain's first genetically engineered vaccine for use against FELINE LEUKAEMIA virus (a retrovirus).

Leucoma
(See WALL EYE.)

Leucopenia
(See LEUKOPENIA.)

Leucorrhoea
(See LEUKORRHOEA.)

Leucosis
(See LEUKOSIS COMPLEX.)

Leucotrichia
(See LEUKOTRICHIA.)

Leucovirus
(See LEUKOVIRUS.)

Leukaemia, Lymphosarcoma
Leukaemia (lymphosarcoma) is a malignant disease – a form of cancer – involving lymphoid tissue especially. It occurs in all the domestic animals, in which (as opposed to man) there is commonly but not invariably no increase in the number of lymphocytes in the bloodstream (an 'aleukaemic leukaemia'). Accordingly, lymphosarcoma is the better name.

In one form there may be a large tumour mass at the site of the thymus. Usually, many lymph nodes are involved, with enlargement of the spleen and infiltration of the liver. (See MULTICENTRIC LEUKAEMIA.) Tumours may occur in almost any organ.

Signs Enlargement of superficial or of mesenteric lymph nodes, depression, emaciation, anaemia and often diarrhoea.

In the dog, death commonly follows after three weeks, but the duration of illness varies from one to more than 60 weeks.

Leukaemia is the commonest malignant disease in the cat in Britain, and is caused by a virus. (See FELINE LEUKAEMIA.)

(For disease in cattle, see BOVINE ENZOOTIC LEUKOSIS.)

Treatment Cytotoxic drugs such as cyclophosphamide and vincristine may be used in dogs and cats. Half-body irradiation is also used in some cases. Treatment is highly specialised. The outcome is invariably fatal.

Vaccines are available for protection against feline leukaemia.

Leuko-, Leuco-
Leuko- (leuco-) is a prefix meaning white. 'Leuko-' is the spelling recommended by the EU.

Leukocytes
Leukocytes are white cells found in the blood and lymphoid tissue. (See BLOOD; LYMPHOCYTES; INFLAMMATION; PHAGOCYTOSIS; WOUNDS; IMMUNE RESPONSE.)

Leukocytosis
Leukocytosis is a temporary increase in the number of white cells in the blood. It occurs after a feed, during pregnancy, after exertion, and when the temperature is elevated. It is seen during infections, when neutrophils will be numerous; though in some infections monocytes will be more numerous than normal for a time. In parasitic infestations and some allergic reactions, eosinophils increase in number.

Leukocytosis is seen in some cases of poisoning, e.g. by potassium chlorate, phenacetin.

The usual proportion of red cells to leukocytes in the blood of the healthy mammal is about 1000:1.

In true leukaemia there is an abnormal increase of leukocytes in the blood – some being of abnormal shape. Myeloblasts may predominate in the final stages of leukaemia. (See LEUKAEMIA.)

VetBooks.ir

Leukoderma
Leukoderma means a condition of the skin and hair when areas become white as a result of injury or disease. It is seen on the backs of horses that have worn badly fitting saddles and collars, when it is called 'saddle-mark' and 'collar-mark', and after ringworm. In coloured horses, the white areas are used in freeze branding.

Leukoma
The presence of a dense corneal scar seen as an opaque patch or spots on the surface of the cornea. (See EYE.)

Leukopenia
A condition in which the white blood cells are less numerous than normal. It occurs during the course of several diseases, e.g. SWINE FEVER, LEPTOSPIROSIS of cattle. (See FELINE INFECTIOUS ENTERITIS.)

Leukorrhoea, Leukorrhea (US)
A chronic vaginal discharge, generally of a whitish or greyish colour. It is a sign of VAGINITIS or of metritis. (See UTERUS, DISEASES OF; 'WHITES'.)

Leukosis Complex, Leucosis Complex
Multiplication of leukocyte-forming tissues; it results in leukaemia. (See BOVINE ENZOOTIC LEUKOSIS; LEUKAEMIA; LEUKOSIS IN TURKEYS; MAREK'S DISEASE.)

Leukosis in Turkeys
Two distinct forms of leukosis infection are recognised in the UK and have caused serious and widespread economic loss among turkey flocks.

(a) Lymphoproliferative disease (LPD) affects turkeys from nine weeks of age and can cause a mortality of 1 per cent a week. It is characterised by sudden death of birds in good condition with gross enlargement of the spleen and tumours in the liver, lungs and elsewhere. The causative agent of LPD is suspected to be an oncovirus unrelated to recognised avian viruses of this group.
(b) Reticuloendotheliosis virus (REV) infection can be distinguished clinically from lymphoproliferative disease by the fact that it is associated with diarrhoea which frequently affects turkeys between 8 and 10 weeks of age. This is followed by the development of tumours resulting in mortality of up to 20 per cent. The most consistent post-mortem finding has been a large leukotic liver. The causative agent is an RE virus which can be replicated in tissue culture. Viraemia develops within two weeks of infection and antibodies persist for the lifetime of infected birds.

Leukotrichia, Leucotrichia
Whitening of the hair. It is seen in freeze branding.

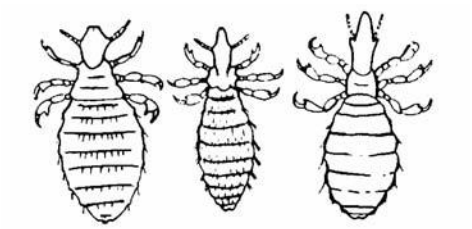
Leukovirus
This genus of virus includes the Rous sarcoma virus, feline leukaemia virus and fowl sarcoma virus.

Leurocristine
(See VINCRISTINE.)

Levamisole
A broad-spectrum anthelmintic. It can be administered orally, by injection or in the feed. Levamisole is also of value in stimulating the bodily defence mechanisms, when these have been depressed by, for example, viral infections, or by *Brucella abortus*. Any reduction of T-lymphocytes is apparently restored to normal, and phagocytosis increased, among other immuno-stimulant effects. (See ANERGY.)

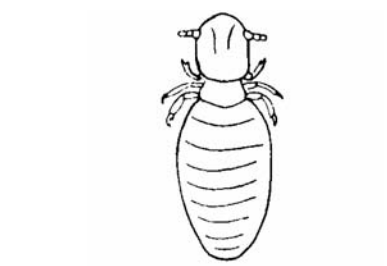
In dogs, levamisole is used mainly to treat heartworm infections. Its side-effects (vomiting, diarrhoea, loss of appetite) can be reduced by giving it with or after food. It has a low safety margin in camelids.

Leys, New
Highly productive pastures. Cattle grazing these are, generally speaking, more prone to hypomagnesaemia than when on permanent pasture. Clover-rich leys are also conducive to bloat, unless precautions are taken.



L-Forms of Bacteria
Those which can survive without a true cell wall. L-forms of staphylococci and streptococci have been recovered from cases of bovine mastitis. They are completely resistant to antibiotics such as penicillin which interfere with bacterial cell-wall formation.

Lhasa Apso
A small dog with long straight hair almost covering the face. The breed originates in Tibet. Renal cortical hypoplasia may be inherited and intervertebral disc disease may develop. HAEMOPHILIA B (coagulation factor IX deficiency) can be detected by DNA test. NICTITATING MEMBRANE GLAND PROLAPSE is common. They are also prone to KERATOCONJUNCTIVITIS SICCA.



Lice
Two distinct families of lice are found on domestic animals: the sucking lice and the biting lice. All the fowl lice belong to the latter family. Lice are

wingless insects which undergo a direct development. The egg is laid on the body, adheres to a hair or feather, and the young louse is, except for size, identical to the adult. There is no pupal stage, although several moults take place. Sucking lice belong to the order Siphunculata. Sucking lice can cause severe anaemia especially in young animals.

The biting lice belong to the order Mallophaga. The mouth parts of biting lice are very different from those of the sucking lice. They cannot suck blood, and the mouth parts consist of a pair of mandibles on the ventral side of the blunt head and are used to feed on skin debris.

Sucking lice. × 10. (Left, *Haematopinus*; centre, *Linognathus*; right, *Solenopotus*.)

Biting louse. × 15. (*Trichodectes*.)

Horses Only one species of sucking louse is found on the horse, called *Haematopinus asini*. Two species of closely related biting lice are also found: *Damalinia equi* and *D. pilosus*. Sucking lice are more generally found at the base of the mane and tail, while the biting species are commonly on the lower parts of the body. They cause poorness of condition, itching, and loss of hair.

Cattle Sucking lice include *Haematopinus eurysternus*, *H tuberculatus*, and *Linognathus vituli*. In addition, one species of biting louse occurs, *Damalinia bovis*. The sucking lice are found mainly on the head and shoulders; the biting lice can be found on any part of the body. They cause itchiness and scratching which may produce thickening of the skin, and cause mange to be suspected.

A fourth species of sucking louse, *Solenoptes capillatus*, is found in the UK, New Zealand, etc., but is not very common.

Sheep *Haematopinus ovillus* (on the body), *Linognathus pedalis* (on the foot) and *L. africanus* are sucking lice. *Damalinia ovis* is a biting louse.

Goats Sucking lice *Linognathus stenopsis* and *L. africanus* attack the goat. Biting lice include *Damalinia caprae* and *D. limbata*.

Pigs *Haematopinus suis*, a large species of sucking lice causing intense pruritus, which seriously interferes with fattening. Young pigs have been known to die from the loss of blood and the extensive irritation. The lice are usually found near the ears, inside the elbows and on the breast.

Dogs and cats Important species include a sucking louse, *Linognathus setosus*, and a biting louse, *Trichodectes canis*. The latter is an intermediate host of *the tapeworm Dipylidium caninum*.

Poultry and other birds All the lice affecting birds are biting lice, and include *Menopon gallinae* and *Goniodes gallinae*.

Lice can cause a severe anaemia in young animals especially.

Control involves two applications of a suitable insecticide at a seven- to 10-day interval, repeated if necessary. Permethrin and fibronil are suitable for dogs and cats.

For larger animals, sprays or dips, or ivermectin by injection, may be used. (See IVERMECTIN; BHC; FLEA-COLLARS; AEROSOL; BATHS - CATS.)

'Licked Beef'

'Licked beef' is that which shows greenish or yellowish tracks made by the larvae of warble-flies, with the formation of 'butcher's jelly'. This is of importance in food inspection. It has not been seen in the UK since warbles were eliminated.

Lick Granuloma

A tumour-like mass of granulation tissue on the skin of dogs which can form as a result of the incessant licking of a wound, ulcer, or even unbroken skin – in which case there may be a local neuritis causing itching of the spot, and so accounting for the licking. (See ACRAL PRURITIC NODE.)

Other parts of the body may be obsessively sucked, for example Dobermanns may produce a lick granuloma on a flank fold. The cause may be

psychotic or organic and its identification can lead to appropriate therapy.

Treatment An ELIZABETHAN COLLAR may be necessary to prevent the dog's access to the part. A corticosteroid may be used. In long-standing, intractable cases cryosurgery is usually the recommended treatment, but American experience suggests that two or three applications may be necessary, but that the owner is not always willing to persevere. (For a similar condition in cats, see EOSINOPHILIC GRANULOMA.)

'Licking Syndrome'

This is the name for a condition in which cattle tend to lick each other, or each other's urine, or the soil, in an attempt to obtain the extra salt they need, and is a sign of sodium deficiency. This occurs, in the absence of salt licks or the provision of sufficient salt in the feed, on sodium-deficient pastures.

Urine-drinking has been seen in yarded cows, even when given free access to salt and magnesium, and the habit may disappear once the herd gains access to spring pasture. Having drinking troughs placed too close together, or too few of them, in the yards can lead to dominant cows preventing others from approaching the sources of water and salt. (See under SALT — Salt licks; SODIUM DEFICIENCY; HAIR-BALL; METABOLIC PROFILE TESTS.)

Lidocaine

A local anaesthetic licensed for use in dogs, cats and horses (where it can be used on kits own or with XYLAZINE for caudal EPIDURAL ANAESTHESIA). A transdermal patch for humans has been used for acute pain in dogs although plasma lidocaine levels were lower than in humans. (See ANAESTHESIA, LOCAL AND REGIONAL.)

Lien

Lien is the Latin name for the spleen.

Ligaments

Ligaments are strong bands of fibrous tissue that serve to bind together the bones forming a joint. They are cord-like in some instances, flat bands in others, and sheets in the case of the joint-capsule which surrounds a joint. (See JOINTS.) Another type of ligament is composed of double thickness fold of PERITONEUM, which supports a VISCUS in the peritoneal cavity. The ligament takes its name from the VISCUS that it supports e.g. the ovarian ligament supports the ovary.

Inflammation of the fetlock annular ligament was diagnosed in 30 lame horses which had chronically distended digital flexor tendon sheaths, or plantar annular ligaments. The ligament was cut longitudinally in 25 of the horses; 16 returned to full work without difficulty and one became sound after a second operation.

Desmitis Inflammation of the fetlock annular ligament was diagnosed in 30 lame horses which had chronically distended digital flexor tendon sheaths, or plantar annular ligaments. The ligament was cut longitudinally in 25 of the horses; 16 returned to full work without difficulty and one became sound after a second operation.

Ligamentum Arteriosum

The fibrous remains of the *ductus arteriosus* of the fetus. It connects the left pulmonary artery to the arch of the aorta.

Light, Influence of

Adequate light is necessary for maximum fertility. This applies to poultry (see under NIGHT LIGHTING), to bulls – too often kept in dark places – and to sheep, etc. (See also LIGHTING OF ANIMAL HOUSING; RICKETS; VITAMINS - VITAMIN D; TROPICS, LIVESTOCK PRODUCTION IN THE.)

Light Beam Diaphragm

A device fitted to an anode tube of an X-ray machine used to limit the scatter of the emitted X-RAYS. The device emits a light beam to indicate the path that will be taken by the X-rays and can be observed while the operator adjusts the aperture to select the beam as required. (See also X-RAYS.)

Lighting of Animal Housing

Various kinds of glass substitutes have been put on the market, which are reputed to allow the ultraviolet rays of natural sunlight to pass through without appreciable absorption.

Adequate light is necessary to prevent rickets, and to ensure maximum fertility in poultry and other animals. Continuous light, however, may have harmful effects.

Artificial lighting of poultry houses is now a common practice. Red light is used in many broiler houses and in some laying houses in order to reduce cannibalism.

(See also NIGHT LIGHTING.)

Lightning Strike

Cattle, sheep and horses are most often affected. Struck animals are usually found dead. In some instances there are burn marks under the skin, but often there is nothing to see. Diagnosis depends on the presence of thunderstorms with lightning and sudden deaths of animals close to a potential conductor such as a tree, hedge, pylons, etc. (See

VetBooks.ir

under ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION.)

Light Sensitisation, Photosensitisation

Light sensitisation implies a predisposing factor, such as the eating of a particular plant, which has the effect of making certain cells in the animal's body abnormally sensitive – for the time being – to light. Strong sunlight is then capable of causing serious and extensive damage, with a good deal of distress.

In Australia this trouble is frequently caused, in cattle, sheep and pigs, through eating St John's wort. Elsewhere overseas, clover and buckwheat are often responsible. Occasional cases of light sensitisation occur even in the UK. To give an example, a British Friesian heifer was discovered in obvious distress. Over nearly all the white parts the skin was dead and had partly sloughed off. Appropriate treatment, which included temporary confinement in a darkened loose-box, was followed by a rapid recovery. Bog asphodel and rape cause light sensitisation in sheep in Britain, where pigs have also been affected (probably by St John's wort). In New Zealand, where the condition is called facial eczema, moulds have been incriminated. In Britain another plant involved is the GIANT HOGWEED.

It is the white, pigment-free skin which suffers. Thus, some breeds of livestock are never troubled with light sensitisation, while white or partly white cattle are susceptible. Similarly, grey and PIEBALD horses in the USA and elsewhere are sometimes affected.

Light sensitisation is associated with dysfunction of the liver, and the presence of porphyrins in the bloodstream. It also occurs in some cases of PORPHYRIA.

Light Sussex Chickens

(See SUSSEX LIGHT CHICKENS.)

Ligneous Membranitis

A rare condition of the eye resulting in chronic inflammatory disease of the mucous membranes associated with PLASMINOGEN deficiency. There is proliferative CONJUNCTIVITIS, GINGIVITIS and TRACHEITIS. It is seen in SCOTTISH TERRIER DOGS.

Lignocaine

A local anaesthetic agent used to produce nerve blocks, it has also been used to treat cardiac arrhythmias.

Lily poisoning

There are over 100 species in the *Lilium* genus, some of which are poisonous (as are *Hemerocallis* lilies, the daylily). All parts of the lily including the flower are toxic. Ingestion of less than one leaf can cause signs. The toxic mechanism is unknown but renal failure occurs from tubular epithelial necrosis; there is sometimes pancreatitis. The pollen of lilies can also produce toxic reactions in cats by ingestion directly from the plant or from the skin during grooming. Signs of poisoning include vomiting, anorexia and depression. This can progress to paralysis, respiratory problems, seizures and swollen paws or face. Treatment requires professional veterinary attention. There is often a poor outcome if therapy is delayed more than 18 hours post exposure. Gastric decontamination and aggressive iv fluid treatment are required.

'Limberneck'

An old, colloquial name for some of the signs seen in cases of botulism in poultry: a loss of power of the muscles of the neck, wings, and legs, affected birds first being dull and inactive. (See BOTULISM.)

Limbus

(plural, Limbi; adjective, Limbic)

A term used in anatomy to designate the border or edge of a structure, e.g. corneo-scleral limbus.

Liming of Pastures

If this is carried out to excess it can lead to a deficiency in copper in the grazing animal and so bring about INFERTILITY. Manganese deficiency is likewise a sequel when the soil becomes too alkaline. Cattle should be kept away from downwind of liming operations, or eye inflammation (conjunctivitis and KERATITIS) may result.

Limousin

A pure beef breed of cattle noted for high liveweight gains, high killing-out percentages, and freedom from calving difficulties.

Lincoln Longwool Sheep

Also known as the LINCOLN. The largest British sheep breed. developed for a fleece which was heavy, long and luxuriant, but coarse. The adult ewe weighs about 91 kg to 110 kg (200 lb to 240 lb). The fleece is now of low value and the breed is becoming rare, with only about 1,500 ewes registered.

Lincoln Red Cattle

A red breed originating in Lincolnshire. It was originally a draught animal and was crossed with the Durham type. Formerly a dual purpose breed, it is now used only for beef.

Lincoln Sheep

(See LINCOLN LONGWOOL SHEEP.)

VetBooks.ir

Lincomycin
A bacteriostatic antibiotic effective against Gram-positive bacteria, Gram-negative anaerobes and *Mycoplasma*. It is very effective against the latter when used at two parts of spectinomycin to one of lincomycin.

Linear Assessment of Dairy Cows
(See PROGENY TESTING - CONFORMATION.)

Liner, Teat-Cup
In selecting milking machinery equipment, one should avoid any liner with a hard mouthpiece. Liners must be changed after a maximum of 2,500 milkings. They can be made from rubber or siliconised rubber.

Linguatula serrata
This parasite, of the Order *Pentastomida*, has a flat body shaped somewhat like a tongue, but grooved. It is without appendages apart from two pairs of hooks at its anterior end. The adult lives in the nasal passages of dogs, cats and foxes, and is up to 2 cm in length. The eggs are expelled from the nose by sneezing; they may also be swallowed and excreted in the faeces. Sheep, cattle and rabbits swallow the eggs and become intermediate hosts. After the eggs hatch in the stomach, larvae migrate to the mesenteric lymph nodes, and encyst either there or in organs such as liver, lungs and kidneys. The life cycle is completed when the final host eats viscera containing the infective nymphs. (See MITES, PARASITIC.)

Liniments, Embrocations
Liniments (embrocations) are liquid preparations for external application (to unbroken skin), generally rubbed in, and having counter-irritant or analgesic properties. They are used for painful muscular conditions, strains and sprains.

Linognathus
A genus of sucking lice. (See LICE.)

Linoleic Acid
An essential fatty acid in most species; it is converted to arachidonic acid. In the conjugated form it reduces fat deposition and appears to have anti-cancer properties. Felidae cannot use it to produce arachidonic acid which must be obtained from their diet.

Linolenic Acid
An essential fatty acid in fish diets.

Linseed
The flax plant (*Linum usitatissimum*). After extraction of linseed oil from the seeds, the residue is made into linseed cake for feeding to horses, cattle, and sheep.

Linseed poisoning The flax plant contains a cyanogenetic glycoside in small amounts. An enzyme in the flax can act on the glycoside, with production of hydrocyanic acid. The enzyme is not always destroyed in the process of making linseed cake. Boiling for 10 minutes destroys the enzyme and renders linseed safe. However, linseed cake should be fed dry and not made into a mash with warm water – a dangerous practice owing to the formation of hydrocyanic acid. Linseed poisoning is not common.

Lionhead Rabbits
A small breed of rabbit with short ears and a mane over the head.

'Lion Jaw'
(See CRANIOMANDIBULAR OSTEOPATHY.)

Lipaemic Serum
(See LACTESCENT SERUM (PLASMA).)

Lipase
A fat-splitting enzyme found in the pancreatic juice.

Lipid Emulsion
It is a component of parenteral nutrition in humans and animals, and can be used as a carrier for drug delivery.

Lipids
Fatty or oily substances. Simple lipids are esters of fatty acids and alcohol, and include fats (esters of fatty acids and glycerol). Compound lipids contain, in addition to fatty acid and alcohol, carbohydrate or nitrogen or phosphoric acid, for example. Avian epidermal cells have a very high lipid content, very important to the protective function of the skin. (See SKIN.)

'Protected lipids' are those encapsulated in a protein envelope, which is then treated with formaldehyde. Because of their high-energy value, fats and oils and their fatty acids seemed worth including in cattle feed supplements; and 'protected lipids' offered the possibility of avoiding the disturbance of normal rumen metabolism likely to occur with free fats being present in the rumen.

Lipizzaner Horses
These horses came from the village of Lipizza, now in Slovenia, and were originally bred and trained in Vienna from 1580 by the Habsburgs as war horses. They are grey in colour, strong, stocky horses but not very tall; they are and are capable of very advanced dressage.

Lipocytes
Fat cells.

Lipofuscinosis
(See CEROID LIPOFUSCINOSIS.)

Lipoma
Lipoma is a tumour mainly composed of fat. They are liable to arise almost anywhere in the body where there is fibrous connective tissue, but are especially common below loose skin. They are occasionally seen in the abdominal cavity, where they develop in connection with the peritoneum, and sometimes encase the bowel and obstruct its function or attain a large size. (See TUMOUR.)

Lipopolysaccharides
These combine lipids and polysaccharides; they are liberated from dying bacteria and cause inflammation.

Lipoprotein
A complex of cholesterol, triglycerides, phospholipids and APOPROTEINS. An excess of lipoprotein in the blood – hyperlipoproteinaemia – occurs in some cases of diabetes, hypothyroidism metabolic disorders and inherited disease.

Lips
Lips are musculo-membranous folds which in the horse are covered on the outside with fine hairs, among which are longer, stouter tactile hairs, while some heavy draught horses have a 'moustache' on their upper lips. On the inside, the lips are covered by mucous membrane which is continuous with that of the mouth generally.

In the horse the lips are extremely mobile, and the upper lip especially contains a very dense plexus of sensory nerves which serve tactile purposes. In the ox the lips are thick and comparatively immobile. The middle part of the upper lip between the nostrils is bare of hair and is termed the muzzle. It is provided with a large number of tiny glands which secrete a clear fluid, which keeps the part cool and moist. Within the lower lip are numbers of horny papillae; its free margin is bare, but the under part of it is covered with ordinary and tactile hairs. The sheep possesses no hairless muzzle, but has a distinct PHILTRUM instead. The lips are thin and mobile. In the pig the upper lip is thick and short and is blended with the snout or nasal disc, while the lower is thin and pointed. (See also HARE-LIP.)

Liquefaction Necrosis, Liquefactive Necrosis
Tissue which undergoes death and then liquefies. (See also COAGULATION NECROSIS.)

Liquefying Expectorant
These reduce the viscosity of mucus in the respiratory system and thereby allows more easy removal of the material. BROMHEXINE HYDROCHLORIDE is used in many species.

Liquid Feeding
Liquid feeding of dairy cows in the parlour enables them to eat up to 6.8 kg (15 lb) of concentrates in seven minutes.

Liquid Paraffin, Medicinal
(See under PARAFFIN for its use as a laxative.)

Listerellosis
(Synonym for LISTERIOSIS, see below)

Listeriosis
A disease caused by *Listeria monocytogenes* which attacks rodents, poultry, ruminants, pigs, horses, dogs and man. As the bacterium tends to target the immune system the clinical signs can be very variable. Birds may be merely anorectic, with weight loss, but NEUROLOGICAL signs are sometimes seen and sudden death can occur from MYOCARDITIS. Listeriosis can occur in free-range chickens. In ruminants there are four manifestations: a septicaemic form that can cause sudden death, a genital form causing abortion in cattle and sheep, an encephalitis and an ocular form causing UVEITIS and blindness.

In cattle, the infection may be confused with RABIES or POISONING. The affected animal is seen to separate from the rest of the herd, and is later unable to stand without support. If walked, it usually moves in a circle. The head may be held back to one side, with salivation and a nasal discharge. Paralysis of one side of the face may occur. Some cows become violent in the terminal stages and bellow.

Other signs can include keratitis and conjunctivitis (*L. monocytogenes* is recognised as one cause of IBK), extreme dejection, and distressed breathing.

Listeria is a cause of IRITIS in cattle feeding at silage clamps. (See SILAGE.)

There is also a septicaemic form in adult sheep, which shows itself by depression, fever, weakness, and emaciation.

Pigs may have swelling of the eyelids, encephalitis, paralysis, or occasionally septicaemia.

Listeriosis is a rare cause of abortion in mares, and a common cause in other animals. It is an important cause of abortion in goats.

Infection may be spread by urine, milk, faeces, an aborted fetus and vaginal discharges.

Good hygiene helps to prevent the disease; antibiotics may be effective in treating early cases. Feeding extra vitamin E to turkeys until slaughter reduces recovery rates of *L. monocytogenes* at slaughter.

The disease is a ZOONOSIS and can be contracted from infected ewes or does at

VetBooks.ir

parturition or from unpasteurised milk or cheese (particularly soft). The organism can survive many weeks in refrigerated food. Pregnant women should not be in contact with parturient ruminants and should not eat unpasteurised products. In the USA it has been estimated that there are two human cases undiagnosed for every one reported.

(See also AVIAN LISTERIOSIS.)

Listrophorus gibbus

(See *Leporacarus gibbus*.)

Lithiasis

Lithiasis is the formation of calculi and concretions in tissues or organs. It is often used with a prefix to denote the type; for example, cholelithiasis means the formation of calculi in the gall-bladder. (See also under CALCULI; UROLITHIASIS.)

Lithium

Lithium antimony thiomalate has been used by injection to remove multiple warts.

Lithium poisoning has occurred in dogs that drink water for several months from swimming pools chlorinated with lithium hypochlorite. It can result in fits and diarrhoea, with weakness and dehydration. Recovery can be expected after providing fresh, uncontaminated water.

Lithontriptics

Lithontriptics are substances which are reputed to have the power of dissolving stones in the urinary system. (See HYALURONIDASE.)

Lithotomy

Lithotomy is the operation of opening duct or the bladder for the removal of a stone.

Lithotrity

Lithotrity is an operation in which a stone in the bladder is broken into small fragments and removed by washing out the bladder with a catheter.

Litter

(See DEEP LITTER FOR CATTLE; DEEP LITTER FOR POULTRY; BEDDING AND BEDDING MATERIALS.)

Litter, Old

Broiler chicks reared on previously used litter may, as a result of the ammonia fumes, develop a severe inflammation of eye-surfaces and eyelids. In one house, 3,000 broilers were affected. The birds cannot bear to open their eyes, and appear obviously dejected. Mortality is generally low, but the trouble is a serious one for all that.

The same condition occurs for the same reason in rabbits, which are extremely susceptible to the effects of ammonia. Rabbits will show clinical signs before human attendants can even smell ammonia.

Litter Size (Pigs)

In Britain the average is between 10 and 11 born alive; mortality 0.84. Gilts and sows having had over six pregnancies have smaller litters. Earlier figures showed that an average of 2.2 pigs per litter died between birth and eight weeks old. A litter of 34 has been recorded.

Liver

A solid glandular organ lying in the anteriormost part of the abdomen close up against the diaphragm. In birds and reptiles (which have no diaphragm) the liver occupies a similar space caudal to the heart, approximately in the second third of the coelom. Its colour varies from a dark red-brown in the horse and in most birds to a bluish-purple in the ox and pig, and it is often heavily pigmented with melanin in reptiles. It is soft to the touch though it is rather friable in consistency, and it constitutes the largest gland in the body.

Functions include the excretion of bile, the storage of glycogen and of iron, the breaking-down of old and worn-out red blood cells, and the breaking-down of toxic substances and of waste substances from the tissues of the body. It performs major nutritional functions in the conversion of fatty acids to glucose or volatile fatty acids (in ruminants); it builds up amino acids into proteins. It produces plasma ALBUMIN and its measurement is an indicator of liver function in animals on a normal diet without kidney or alimentary disease. From the liver, urea and uric acid find their way into the bloodstream and are excreted from the body in the urine by the kidneys. In most animals the bile is collected in the gall-bladder and the bile-duct before passing to the small intestine, where it assists the pancreatic juice in the digestion of food after a meal. The gall-bladder is absent in many species, notably the *Equidae* and also members of the avian Orders *Psittaciformes*, *Columbiformes* and *Struthiformes*.

Shape There are probably few organs which vary so much in shape as the liver, not only in different animals; but also in different individuals of the same species.

Horse It lies obliquely across the abdominal surface of the diaphragm, its highest and most posterior part being at the level of the right kidney. It possesses a strongly convex diaphragmatic surface which is moulded into the concavity of the diaphragm, and a posterior or abdominal surface

VetBooks.ir

which lies in contact with the stomach, duodenum, and right kidney, each of which organs forms a depression in the liver substance. It is only incompletely divided into three lobes in the horse. Lying mainly in the right lobe on its abdominal surface is the 'porta' of the liver, where the portal vein and hepatic artery enter and from whence the hepatic duct (bile-duct) emerges. Part of the posterior vena cava passes through the liver substance, whose blood it eventually drains. The liver is held in position by the pressure of other organs and by six ligaments. These are: the coronary, which attaches it to the diaphragm; the falciform, from the middle lobe to the diaphragm and abdominal floor; the round, to the umbilicus; the right lateral, to the costal part of the diaphragm; the left lateral, to the tendinous part of the diaphragm; and the hepatorenal or caudate, to the right kidney.

Cattle The liver lies mainly to the right of the middle-line through the body, and its long axis is directed downward and forward. Its diaphragmatic surface fits into the concavity of the right part of the diaphragm, and its posterior surface is very irregular. It presents impressions of the two main organs with which it comes into contact – the omasum and reticulum. There is only one distinct lobe – the caudate. There is no left lateral ligament, and the round ligament is found in the calf. A gall-bladder is present; it is situated partly in a slight depression on the posterior surface of the liver, and partly on the abdominal wall.

Sheep The bile-duct joins the pancreatic to form a common duct instead of opening separately as in other animals.

Pigs The liver is large, very thick, and very much curved. It lies in the anterior part of the abdominal cavity, occupying the whole of the anterior hollow of the diaphragm and more to the right than to the left side of the body. lt has four main lobes.

Dogs The liver is very large, being about 5 per cent of the whole bodyweight, and possesses six or seven lobes. The gall-bladder is buried almost completely in the space between the two parts of the right central lobe, only a very small portion of it being visible from the outside.

Ferrets The liver is of similar in proportion in size, shape and conformation to that of the dog. It has five lobes and a gall bladder.

Guinea pigs This posses a liver with four lobes and a gall bladder. It is large and prominent and easily ruptured by careless or rough handling.

Rabbits The liver has five lobes, one of which has a slender attachment to the main organ and is prone to torsion. The gall bladder is well developed as the rabbit excretes proportionally vastly more bile than a dog of the same weight.

Birds The liver is bilobed and held in close association with the heart (as there is no diaphragm). The organ is always infiltrated with lipid (from the yolk sac) in young birds until they start to eat a normal diet.

Chelonians The liver is bilobed and situated in the mid-coelom.

Lizards These possess a bilobed liver in the anterior coelom, close to the heart and lungs.

Snakes They have an elongated liver occupying approximately the second fifth of the snout to vent distance of the coelom. A gall bladder is present in every species of snake.

Minute structure The liver is enveloped in an outer capsule of fibrous tissue with which is blended the hepatic peritoneum. The hepatic artery, portal vein, and bile-duct divide and subdivide. Between the rows of liver cells also lie fine bile capillaries which collect the bile discharged by the cells and pass it into the bile-ducts lying around the margins of the lobules. The liver cells are amongst the largest cells of the body, and each contains one large nucleus. With careful special staining methods there can also be seen tiny passages or canals, passing into the cells themselves; some of these communicate with the bile-duct, and others with the ultimate branches of the portal vein. After a mixed meal many of the liver cells can be seen to contain droplets of fat, and granules of glycogen (animal starch) can also be determined. In addition to the cells above described, there occur at intervals along the walls of the sinusoids in a lobule stellate cells which represent the remains of the endothelium from which the capillary-like sinusoids are developed. They are known as 'Kupfer's cells'.

Liver, Diseases of

One of the commonly known signs of liver disturbance is JAUNDICE – a yellow coloration of the visible membranes. Gallstones, which are a complication of some liver diseases, are treated under GALL-BLADDER and GALLSTONES.

Hepatitis, or inflammation of the liver, may be acute, suppurative (in which abscesses are formed), or chronic. Acute inflammation produced by viruses, bacteria or poisons (of bacterial, vegetable, animal, or mineral origin), from the intestines, and

it is sometimes caused by the migration of parasites through the liver. The signs are pain on pressure over the abdomen, an elevation of temperature, suppression of the appetite, a disinclination to move, and often diarrhoea or constipation in the later stages. (See also CANINE VIRAL HEPATITIS.)

Chronic inflammation accompanies many diseases among animals, the commonest probably being infestation with liver-flukes, but it may also be present as a result of TUBERCULOSIS. Poisoning may be responsible. (See, for example, RAGWORT POISONING which gives rise to CIRRHOSIS.)

Signs of hepatitis include a gradual loss of condition, irregular appetite, a staring coat and a general unthriftiness; often oedema.

Abscess formation is due to the entrance into the liver of pus-forming organisms, and is usually secondary to some disease, e.g. tuberculosis. In the USA liver abscesses are found in about 8 per cent of all cattle slaughtered, and they are common in 'barley beef' animals in the UK. The lesions consist of abscesses in the substance of the liver. Signs are vague and diagnosis is often impossible.

Fatty liver (See FATTY LIVER/KIDNEY SYNDROME OF CHICKENS AND TURKEYS of cattle and poultry; also CEROIDOSIS.)

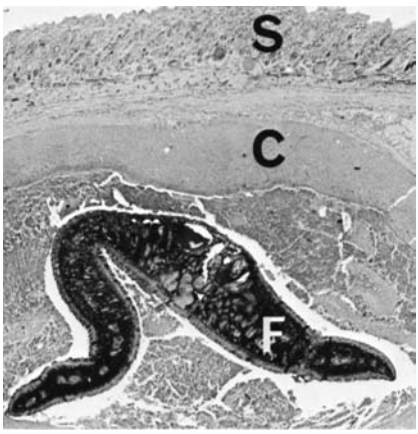
Liver/kidney syndrome (See under LIVER/KIDNEY SYNDROME OF POULTRY.)

Tumours include adenoma, carcinoma and haemangioma (see CANCER). The last type may bleed, show transient jaundice and eventually death from haemorrhage. Benign tumours may give rise to passive congestion, biliary obstruction with jaundice, or they may cause degeneration. (See under TUMOUR.)

Parasites (See LIVER-FLUKES; HYDATID DISEASE; HORSE BOTS; 'LIZARD POISONING' IN CATS.)

Rupture of the liver is by no means rare among old animals, especially dogs and cats. It may result from a blow, a kick, a traffic accident, a fall, or from violent struggling, when the liver is diseased. Even a small wound in such a vascular organ as the liver is likely to prove fatal. (See also 'MILK-SPOT LIVER' of pigs and sheep.)

Rupture of the liver in lambs, aged one to three months, may be the cause of sudden death. In a survey liver rupture in neonatal lambs from 16 farms exceeded 8 per cent. The liver surface was covered with haemorrhagic tracts made by migrating metacestodes of *Taenia hydatigena* (see TAPEWORMS).



Liver, Displacement of

The liver can be involved in diaphragmatic hernia and hiatus hernia; it can be displaced into the thoracic cavity, especially in cats following road traffic accidents.

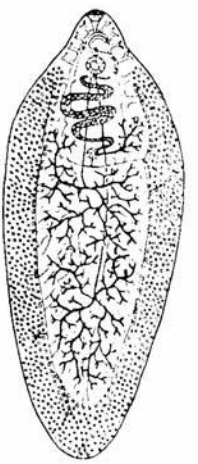
Liver-Flukes

Liver-flukes are parasitic flat worms which infest the livers of various animals, especially sheep and cattle. They may cause severe illness and even death.

Liver-flukes may increase the susceptibility of the host animal to *Salmonella* infection. (See SALMONELLOSIS.)

An adult liver-fluke implanted in a subcutaneous pocket in a rat. This technique showed that the rat gained thereby immunity to adult flukes without the complication of liver damage, and was part of the research carried out at the ARC's Institute for Research on Animal Diseases, Compton, into possible means of immunising cattle against liver flukes. (S = skin; C = subcutaneous tissue; F = liver fluke)

Life-history of a typical fluke The egg is usually passed to the exterior in the faeces of the host and under suitable conditions, chiefly of moisture and warmth, a small ciliated larva, called a 'miracidium', hatches from it. This larva, which is unable to feed and will die within some hours unless it finds a suitable host, gains access to the liver or some other special organ by actively penetrating the skin of an appropriate snail – usually a specific snail for any one parasite. In the snail's tissue it develops into a sac-like sporocyst which, by a process of budding from the internal lining of cells, gives rise to a number of elongated 'rediae'. Each redia is a simple, cylindrical sac-like organism which gives rise, by budding of cells, either to another generation of 'daughter rediae' or to 'cercariae'. The cercaria, which resembles a miniature tadpole in general form, leaves the snail and, after leading a free existence in



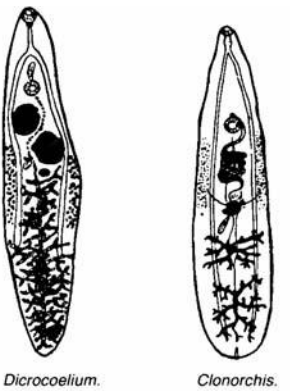
VetBooks.ir

water or on wet vegetation for a short time, comes to rest on grass or other objects, loses its tail and becomes encysted within a protective covering and remains in this state until it is swallowed by the final host, in which it becomes a sexually mature fluke.

Fasciola hepatica This is the common liver-fluke of sheep. (Other hosts are cattle, goats, pigs, rabbits, hares, horses, dogs, man, beavers, elephants, and kangaroos.) It is shaped more or less like a leaf, about 2.5 cm (1 in) long, but considerable variations exist, and elongated forms are found. It has been recorded in most herbivorous animals and in man; but it is in cattle and sheep that it is of most importance. It is generally found in the bile-ducts of the liver, but may be found in other organs.

The life-history is typical, the intermediate host being various species of *Limnaea* snails. Cercariae may be swallowed with drinking water or encysted on grass.

Infestation, sometimes called 'fluke disease', results in anaemia and hepatitis.



Fasciola hepatica.

Fasciola gigantica A parasite of cattle, sheep, and wild animals in the tropics and subtropics, and more pathogenic than *F. hepatica*.

Fascioloides This genus contains only one species, *F. magna*, the large American liver-fluke. In general anatomy, this species resembles the common liver-fluke, but differs from it in its larger size (up to 10 cm [4 in]).

Its larger size and its tendency to form cysts in the liver substance (not in the bile-ducts) make it a more formidable parasite. The cysts may become abscesses, and may be found in the spleen and lungs.

Dicrocoelium This genus is small and semi-transparent, the common species, *D. lanceatum*, being about 1.25 cm (½ in) long. It occurs in all herbivores and in man. It is less serious a pest than *F. hepatica*. It is carried by various land snails; a second intermediate host – the ant – is required, the ants being eaten by the grazing animal. *D. dendriticum* has similar hosts and a worldwide distribution. *D. hospes* occurs in Africa.

Dicrocoelium. Clonorchis.

Clonorchis *C. sinensis* is a common fluke of carnivores, pigs, and man in Asia. It is a small form.

The first part of its life-history is on general lines, the molluscan intermediary being a species of *Bythinia*. The sporocysts give rise directly to cercariae which escape and encyst on various freshwater fish. Infection to mammals is by eating infected fish which are either uncooked or imperfectly cooked.

Closely related flukes are found in the liver of dogs in Northern Europe and North America. (See also 'SALMON POISONING' IN DOGS; 'LIZARD POISONING' IN CATS.)

Incidence of liver-flukes Although surveys have reported a higher incidence of fluke in cattle (up to 40 per cent) than in sheep (13 per cent), this is because cattle show calcification of the bile ducts following exposure to the parasite. In sheep, this calcification does not occur and so only sheep with recent infections will be recorded.

Control measures To be effective, control requires a planned campaign rather than a single battle or weapon. In the sheep, infestation does not lead to subsequent immunity, and this fact gives very little hope of an effective vaccine (similar to the irradiated huskworm larvae vaccine) ever being produced. Not until 1971 was there any drug to kill all young, immature flukes within the body, and it is these which on their mass migrations through the liver can damage it so severely that sudden death inevitably follows.

VetBooks.ir

Triclabendazole (Fasinex) is very effective against flukes as it removes both immature and adult stages.

Other drugs used against liver-flukes include albendazole, closantel, nitroxynil and oxycyclozanide.

In the UK, over 60 per cent of cattle and 80 per cent of sheep are kept in the main fluke areas.

While sheep farmers are mostly fully alive to the fluke problem, it is suggested that most cattle farmers are not. It has been pointed out that on farms where mixed grazing is practised, it is a waste of time and money to dose only the sheep and not the cattle.

Profit margins in beef production have been improved by a combined anti-fluke attack, using routine dosing of the cattle together with a chemical spray (Frescon) on pasture to kill the host snails. In trials, 18-month-old beef animals finished 25 to 30 days earlier than controls, giving higher profitability through savings in feed. Returns were further increased by better carcase grading.

An 8 per cent drop in milk yield has resulted from low-grade infestations in dairy cattle, and it is claimed that autumn and winter dosing of dairy cattle helps to improve, or at least maintain, milk quality levels.

A vaccine against black disease – in which spores of one of the gas-gangrene group of organisms are stimulated into activity by young flukes in the liver – can prevent deaths from the resulting toxaemia. Against the liver-flukes themselves, routine dosing is essential on all farms where they are likely to occur.

Land drainage is still high on the list of control measures.

The use of snail-killers is a recommended part of the campaign against fluke disease, but is not a snag-free method. It is easy to miss small areas inhabited by snails, and this applies even when using a knapsack sprayer – the only possible method of spraying if the land is too wet, is to take a tractor. Snail-killers can be unpleasant to work with: the cheapest is sodium pentachlorophenate. N-trityemorpholine is expensive per acre but has the advantage of being relatively harmless to stock, so that grazing need not be delayed for a fortnight as after copper sulphate dressings or pentachlorophenate. All are poisonous to fish.

Running ducks over snaily land is not among the official recommendations but it might prove of some value. A few farmers have tried it in the past. In Zambia years ago, a large-scale duck-rearing scheme was introduced in areas flooded by the River Zambesi as a method of fluke-disease and bilharzia control. Hoof-prints, where the soil is exposed, are favourite habitats of the snails. (See also under ANTS.)

Public health Watercress is the chief source of infestation. Illness is most marked during migration of immature flukes. Eosinophilia is a pointer to aid diagnosis; eggs may not appear in the faeces for 12 weeks.

Symptoms in the human patient include urticaria, jaundice, enlarged and tender liver, and eosinophilia.

Cats (See under 'LIZARD POISONING' IN CATS; PANCREAS, DISEASES OF.)

Liver/Kidney Syndrome of Poultry (FLKS)

Fatty liver/kidney syndrome of poultry (FLKS) affects birds (chickens and turkeys) usually two to three weeks old. Signs may not be observed – or there may be depression for a day or two; occasionally trembling or paralysis of legs. Mortality: 1 per cent to 5 per cent. The whole carcase may have a pink tinge. It is the result of failure of the liver to synthesise glucose. The liver is pale, swollen and fatty. The kidneys may be very swollen. Biotin supplementation of the feed has been shown to alleviate the condition. (See also under FATTY LIVER/KIDNEY SYNDROME OF CHICKENS AND TURKEYS.)

The syndrome has to be differentiated from 'TOXIC FAT SYNDROME', GUMBORO DISEASE and NEPHROSIS, INFECTIOUS AVIAN.

Livestock Production

(See BEEF CATTLE HUSBANDRY IN BRITAIN; DAIRY HERD MANAGEMENT; TROPICS, LIVESTOCK PRODUCTION IN THE; and under PIGS and SHEEP BREEDING AND MANAGEMENT.)

'Lizard Poisoning' in Cats

This term is applied to infestation with the liver-fluke *Plarynosomum concinnum*, which has been reported from South America, the Caribbean Islands, Malaysia, the USA and, more recently, Nigeria. The life-cycle of the parasite involves a large land snail, a crustacean, and lizards, frogs, and probably other amphibians and reptiles. Signs in the cat include listlessness, fever, jaundice, diarrhoea, vomiting and emaciation; but sub-clinical infestations also occur.

Lizards

The largest group of reptiles. These ectothermic (cold-blooded) vertebrates, some of which are aquatic, are often kept as pets. The environment temperature and humidity must be kept within ranges appropriate for the particular type of lizard. It is essential to provide the diet recommended for the particular species. Most lizards require meat; crickets may provide a suitable source. Iguanas, however, are mainly, but not entirely, vegetarian. The keeper must learn about the natural history of the species and match this as closely as possible in

VetBooks.ir

captivity. This applies to diet, which tends to vary throughout the animal's life: often hatchlings are carnivorous or insectivorous but become herbivorous later in life. The adequate provision of light especially at the ultraviolet (UV) end of the spectrum is very important. All these requirements have to be balanced with hygiene, often a difficult feat as the conditions in a small vivarium are often ideal for bacteria and other pathogenic micro-organisms to multiply. Infections are therefore common in captive lizards, as are parasitic infestations. Laboratory examination of samples obtained from the vivarium (faeces, urine and urates) or from the animals themselves (skin scrapings, pus, blood, etc.) is an essential part of any diagnostic investigation. In many species the correct UV light must be available if normal bone development is to take place. Any lizard with a swollen limb may have osteodystrophy (bone disease), and the source of UV light should be checked and a calcium supplement provided. Chameleons and some other lizards have pigment cells (chromatophores) in their skin and can change colour to blend in with their surroundings. However, a colour change can be a sign of illness, particularly when the animal cannot blend in with its surroundings. Handling of many lizard species can result in them shedding their tails (see AUTOTOMY). This is a natural defence mechanism to stress and the tail will regrow.

The water in which aquatic lizards live must be kept fresh, otherwise a build-up of aeromonas or pseudomonas organisms may occur. Conjunctivitis is not uncommon; it shows as caseous (cheesy) discharge which must be gently removed before treatment can be given. When diarrhoea occurs it is usually as a result of infestation with protozoan parasites. Skin parasites can be removed by (for example) treatment with IVERMECTIN. The reptiles must be removed to a clean cage or tank while the original one is cleaned and treated with a suitable insecticide. Egg-binding is usually associated with a calcium deficiency but may happen if no suitable site for laying has been provided. Any heating device must be located so that the lizard does not come into contact with it. (See also ECTOTHERMY and POIKILOTHERMY.)

Llamas

Long-legged, long-necked domesticated animals widely used as pack animals and for wool and hide in the South American Andes. They belong to the order Camelidae, which includes also ALPACAS, GUANACOS and VICUNAS. They are farmed to a limited extent in the UK.

Importation of llamas and alpacas direct from South America into a Border Inspection Post is permitted. On arrival, each animal is examined for infectious or contagious disease. If no disease is apparent, the animals are quarantined for a month (to eliminate the possibility of FOOT-AND-MOUTH DISEASE) before going on to their destination. Do not look a llama directly in the eye as it will feel threatened.

Llanwenog Sheep

The breed was created in West Wales in the late 19th century from the horned Llanllwni (now extinct) and the SHROPSHIRE breeds. It is a medium-sized short wool breed with black legs and head, polled, and a tuft of wool on the forehead. It is used for meat production.

Lleyn Sheep

They originate from Llŷnyn Peninsula, Gwynedd, North West Wales. They are reasonably prolific and have about a 200 per cent lambing percentage and are used for meat. The wool is white. They can be used on upland and lowland grazing.

Lobe

Lobe is the term applied to the larger divisions of various organs, such as the lungs, liver, and brain. The term 'lobar' is applied to structures which are connected with lobes of organs, or to diseases which have a tendency to be limited to one lobe only, such as 'lobar pneumonia'.

Lobules are divisions of a lobe. The term 'lobular' is applied to disease which occurs in a scattered irregular manner affecting lobules here and there, such as 'lobular pneumonia'.

Local Anaesthetics

(See under ANAESTHESIA, LOCAL AND REGIONAL; ANALGESICS.)

Local Immunity

(Ssee under IMMUNE RESPONSE; ORIFICES, IMMUNITY AT; SECRETORY IGA.)

Lockjaw

(See TETANUS.)

Locomotor System

This is the MUSCULOSKELETAL SYSTEM.

'Loco Weed'

The legumes oxytropis and astragalus in the USA contain toxins that cause incoordination, and extreme excitability in animals grazing them. They are also TERATOGENIC and if consumed in sufficient quantity, abortifacient.

Longhorn Cattle

An ancient breed originating from Craven in the North of England and improved by Robert Bakewell. It is large, with a dark brown and white

VetBooks.ir

coat and long horns usually pointing forwards. It has increased in numbers over recent years and is used for beef.

Lonk Sheep

A 200-year-old breed from the Central and Southern Pennines in Lancashire and Yorkshire, England. The name is based on the Lancashire word 'lonk' or lanky. They are free-running agile animals, long and thin. Both sexes have horns, a white face with large black patches on nose and eyes, and long legs having irregular black patches on them. They produced wool for carpets, and meat. Rams weigh 75 kg to 91 kg (165 lb to 200 lb), ewes 45 kg to 54 kg (100 lb to 120 lb) with wool weighing 2.3 kg to 3 kg (5 lb to 6.5 lb) The breed was first registered in 1905.

Loose-Boxes

Individual enclosures for accommodating an animal; also called box-stalls. The best type has well-built brick walls lined on the inside to the roof with cement-plaster finished off smooth. Wooden boxes are harder to disinfect. The floor is of cement-concrete, grooved to facilitate the draining away of fluids and to provide a foothold, and the corners are rounded off with fillets of cement. The only fittings inside are hay-rack, water-bowl and manger – of iron, and rather larger than in the stall of a stable, so that cattle as well as horses may use them; in some cases one or two rings, to which animals may be tied, are provided. One or more windows, high up out of reach of the animals' heads, should be included, and the door should always be made in two halves, so that horses with respiratory diseases may stand with their heads out of the box, and so obtain a plentiful supply of fresh air. Wherever possible, loose-boxes should be built with a southerly aspect, so that full advantage can be taken of the disinfectant action of sunlight whenever sick animals are housed in the box.

Lop Eared Rabbits

Rabbits with very long ears that trail along the ground. They include the French Lop, English Lop, the Dwarf Lop (UK) or Mini Lop (USA), the American Fuzzy Lop and the Miniature Lop (UK) or Holland (USA).

Lordosis

Lordosis is an unnatural curvature of the spine, so that the concavity of the spine is directed upwards. It is seen in tetanus, sometimes in RABIES, and in many small rodents in oestrus.

Louping-Ill

Louping-ill is a disease of sheep, also called ovine encephalomyelitis; it is transmitted by *Ixodes ricinus*, the tick commonly present on hill pastures. It occurs in western Scotland, the North of England, and the Northwest of Ireland. There is a definite seasonal incidence, most cases occurring between March and June, and between September and October; only a few sporadic cases are met with at other times of the year. All breeds of sheep are susceptible. It occurs in cattle and has been recorded as affecting pigs, horses, deer and also dogs, in which the signs are fever, nystagmus, hyperaesthesia, and sometimes a tetanus-like rigidity. An inactivated vaccine is available for sheep with a single dose protecting for two years.

Cattle On upland grazings where ticks abound, louping-ill has become of economic importance in cattle. The animals become dull and uninterested in food, walk in an unnatural way, sometimes with their heads down, and occasionally become excited.

Pigs The first naturally occurring outbreak in pigs was reported in 1980 in Scotland. Young pigs show nervous signs, including reluctance to move, or wander aimlessly and press their heads into corners. Mortality in affected pigs can be high.

Cause A flavivirus. This is transmitted by the bites of infected ticks (adult or nymphal). The virus primarily multiplies in the blood, and in certain cases invades the central nervous system at a later stage in the infection.

It would appear that accessory conditions favour such invasion, e.g. tick-borne fever, a disease also transmitted by *I. ricinus*.

The ticks can survive, in the absence of sheep and cattle, on deer, rabbits, hares, voles, field mice, grouse, etc., and these animals may act as host of the virus.

Signs Two forms of the disease are recognised: an acute and a subacute form. In the acute form the signs may appear in from four to six days after the sheep is infested with the carrier ticks. The sheep becomes uneasy, lies down and rises frequently during the day. Its temperature ranges between 40° C and 41.6° C (104° F and 107° F) during the next week or 10 days, and it develops nervous signs. At first, it is merely more timid and more easily frightened than usual; later, the muscles of the jaws and neck begin to twitch and quiver, and there may be frothing at the mouth. It staggers when made to move rapidly or turn suddenly, and as the disease becomes firmly established it may be seen taking short spasmodic jumps, rising apparently from all four feet at the same time, and landing upon all four feet again, i.e. 'louping'. In this way an affected sheep can usually be easily noticed among a flock when the sheep are being

VetBooks.ir

driven or collected by a dog. In more advanced stages the animal becomes paralysed, unable to stand, and often has its head drawn round over its fore flank. Unconsciousness quickly appears, and the animal dies a short time afterwards.

In the subacute type the sheep is seen taking very high steps with its fore-legs; it holds its head very high, and sometimes carries it to one side (often the left); the pupils are dilated, and the expression of the sheep is one of extreme fear when caught. It may attempt to feed, but actually eats very little. Tremblings of the muscles, staggering and falling, and sometimes paralysis of one or more groups of muscles, are seen. As times goes on the sheep loses condition. If not fed by hand it dies from starvation.

Recovery from an attack confers a degree of immunity, which may last for life. (See also TICK-BORNE FEVER OF CATTLE and TICK-BORNE FEVER OF SHEEP).

Prevention Control measures should aim at the eradication of the infecting ticks from grazing lands. This is not easy, as the tick can live under rough herbage without access to the living sheep for as long as one year. A vaccine is available and affords good protection. Cattle should be vaccinated annually; sheep and goats every two years.

Sheep Vaccination of ewes confers protection in their lambs. Inoculations are carried out in spring prior to the season when ticks become active.

Cattle Investigations on hill farms where louping-ill is a problem have shown that cattle play an important part in the maintenance of virus. Hill cattle as well as sheep therefore should be vaccinated, not only for their own protection, but to reduce the transfer of virus to the ticks which are the only agents passing on the infection each year.

Public health Shepherds, farmers, and slaughter-house workers – as well as veterinarians – may become infected. The main symptom is fever. Meningoencephalitis has been recorded, and has sometimes proved fatal.

Lowchen Dog
A small dog with a long wavy coat.

Lower Respiratory System
This consists of the BRONCHIOLES and ALVEOLI of the lung. (See also UPPER RESPIRATORY SYSTEM.)

Lubricants
The type of lubricant used in pellet mills and other forms of machinery for processing animal feeding-stuffs may be of the greatest importance. Lubricants containing chlorinated naphthalene compounds and used on such machines may give rise to HYPERKERATOSIS in cattle eating the food so contaminated by the minutest quantity of lubricant. Bland gel lubricants such as KY Jelly are used when undertaking rectal or obstetrical procedures.

Lucerne
A valuable leguminous plant (*Medicago sativa*) for fodder and forage; it is also called alfalfa. It works best in naturally high pH soils that are free-draining, with annual dry matter yields of 12 tonnes/ha (4.8 tons/acre) of high protein forage. It usually requires a nurse crop for the first year. Lucerne-hay is highly valued for the feeding of horses if of good quality. (It is of little value when most of the leaf has been lost, or it is dusty or mouldy.) Lucerne is also a valuable crop for cattle, but for precautions and dangers, see BLOAT; also MUSCLES, DISEASES OF - NUTRITIONAL MUSCULAR DYSTROPHY. The fibre appears to give some protection against zearalenone mycotoxin (see MYCOTOXICOSIS).

Lucilia sericata
The 'GREEN-BOTTLE' FLY which is usually the initial cause of FLY STRIKE. It is commonly seen in sheep, but it can occur in other species when there are untreated wounds or the animal is debilitated. (See BLOW-FLY STRIKE; FLIES - ORDER DIPTERA - DIPTEROUS LARVAE OR MAGGOTS - MYIASIS; STRIKE.)

Lufenuron
A product (milbemycin oxime) used in the treatment and prevention of flea infestations in dogs and cats. The drug interferes with chitin formation and fleas ingest it with blood. It enters the flea eggs and viable offspring do not develop.

Lugol's Solution
A solution of 50 g (1 ⅓ oz) iodine and 100 g (3 ⅓ oz) potassium iodide in distilled water to 1000 ml. A 2 to 4 per cent dilution of the solution has been used for irrigation of the uterus in cases of bovine metritis; it is now rarely used as it can damage the uterine lining. It may also be added to drinking water for the treatment of goitre in budgerigars.

Luing Cattle
A beef breed evolved from Beef SHORTHORN and HIGHLAND cattle, and named after the island. Colour: red with a touch of gold; or roan (red and white mixed); or white. There are a breed society and herd book.

Lumbar
Lumbar is a term used to denote either the structures in or disease affecting the loins, i.e. the

region lying between the last rib and the point of the hip, from one side of the body to the other. There are lumbar vertebrae, lumbar muscles, etc.

Lumbosacral
Involving the area of the LUMBAR and SACRAL region, or related to the lumbar vertebrae and SACRUM.

Lumen
The space inside a tubular structure, such as an artery or intestine.

Luminal, Phenobarbitone
1. Luminal is a proprietary name for phenobarbitone (see BARBITURATES).
2. Related to a LUMEN.

Lumpy Jaw
(See ACTINOMYCOSIS.)

'Lumpy Skin Disease'
'Lumpy skin disease' is a NOTIFIABLE DISEASE throughout the EU. It is characterised by a discharge from the eyes and nose, lameness, and salivation may be observed – depending upon the site of nodules which sometimes involve mucous membrane as well as skin.

Oedema may occur, and involve the genital organs, udder, dewlap, and limbs. Sloughing of skin may occur. Exotic cattle may die.

The disease is caused by the Neethling pox virus; and a modified sheep-pox vaccine is used for protection.

'Lumpy Skin Disease, Pseudo-'
This is characterised by the formation of raised plaques on the skin, which exude a discharge and then ulcerate; and by fever. The cause is the bovid herpesvirus 2, which also causes mamillitis of cattle.

Lumpy Wool, Wool Rot
Lumpy wool (wool rot) is caused by a bacterium which attacks the sheep's skin during wet weather, causing irritation and the formation of a hard yellowish-white scab about 3 mm (⅛ in) thick. Healing soon occurs and the wool continues to grow carrying the hard material away from the skin as a buff or brownish zone in the wool. Severe infection may lead to loss of wool. (See BLUE WOOL.)

The bacterium causing this dermatitis is *Dermatophilus dermatonomus*. (See also DERMATOPHILUS; 'STRAWBERRY FOOT-ROT'; STREPTOTHRICOSIS.)

In America, this disease has been treated by defleecing with cyclophosphamide. Shearing the sheep assists with resolution plus, if necessary, the use of streptomycin and penicillin. The clippers need to be disinfected after each use in an infected flock.

Lung-Flukes, *Paragonimus* spp.
These flukes are plump oval forms infecting carnivores, pig and man. Generally, two flukes are found together in a cyst in the lungs. The presence of the flukes cause bronchitis and pleurisy. Lesions resembling tuberculosis may be developed. The flukes are found in America and Asia. Eggs are coughed up, swallowed, and passed out with the droppings. The CERCARIAE develop in snails, and afterwards escape and encyst on freshwater crabs or crayfish. These are eaten, and the adult flukes develop in the body. Treatment with NICLOSAMIDE and ALBENDAZOLE appears to be effective against *P. kellicotti*, which causes coughing and sneezing in cats. For the pancreatic fluke of cats, see PANCREAS, DISEASES OF.

Paragonimus.

Lungs
These two organs are the main ones concerned with respiration, in which carbon dioxide is exchanged for oxygen. The air breathed in is warmed before reaching the lungs via the AIR PASSAGES. Most snakes have only one lung – an adaptation to accommodate their elongated body shape.

Blood is carried to the lungs by the pulmonary artery, which divides and subdivides into tiny capillaries which lie around the walls of the air cells.

Functions Apart from their main function of gaseous exchange (see AIR), the lungs can release histamine, metabolise noradrenaline, and inactivate prostaglandins. Local immune mechanisms also operate in the lungs.

Lung is composed of very highly elastic tissue which consists of multitudes of tiny sacs arranged at the terminal parts of the smallest of the bronchioles, and which collapse when the balance of pressure between the air in the sacs and on the outside of the lung surface is disturbed. Thus a lung shrinks to about one-third of its normal size when removed from the chest cavity.

Horses The lungs occupy the greater part of the thoracic cavity, and are accurately moulded to the

VetBooks.ir

walls of the chest and to the other organs contained within it. The right is considerably larger than the left, owing to the presence of the heart, which lies mostly to the left side of the middle plane of the cavity. In the Equidae the lung is not divided into lobes as it is in some of the other animals. The apex is that portion which occupies the most anterior part of the chest cavity, and just immediately behind it is the deep impression for the heart. Behind this again, and a little above it, is the 'root' of the lung, which consists of the blood vessels entering and leaving the lung, lymph vessels, nerves, the bronchus, and here also are situated the bronchial lymph nodes. In cross-section each lung is somewhat triangular in shape, with one of the angles rounded. The rounded angle lies in the uppermost part of the chest, alongside the bodies of the thoracic vertebrae, and the more acute of the remaining angles lies along the floor of the chest.

Cattle The lungs are thicker and shorter than in the horse, and there is a greater disproportion in size – the right weighing about half as much again as the left. They are divided into lobes by deep fissures. The left has three lobes, and the right four or five. The foot in each case is almost immediately above the impression for the heart. The apical lobe (i.e. the most anterior of the right lung) receives a special small bronchus from the trachea direct.

Sheep The lungs show little lobulation.

Pigs The left lung is like that of cattle, but the right lung has its apical lobe very often divided into 2 parts. Otherwise there are no great differences. Three bronchi are present, as in cattle.

Dogs The lungs are thicker than in either the horse or the ox in conformity with the more barrel-like shape of the chest. There is no cardiac impression in the left lung. Each has three large lobes, but the right has a small extra mediastinal lobe, and there may be one or more accessory lobes in either lung.

Birds Avian lungs do not expand and contract like those of mammals. They form part of a respiratory system with anterior and posterior AIR SACS. They do not contain ALVEOLI like mammals but consist of many tiny tubes called parabronchi which connect at either end of the lung with the dorsobronchi and ventrobronchi. Air passes through the parabronchi into air vesicles which are called atria and here gaseous exchange takes place.

Colour In the perfectly fresh lung from a young unbled animal the colour of the lung is a bright rose-pink with a glistening surface, the pleural membrane; but in the lungs of older animals there is usually a certain amount of deposit of soot, dust, etc., which has been inhaled with the air and collected in the lymph spaces between the air cells.

Connections The lungs are firmly anchored in position by their roots to the heart and trachea, and by the pleura to a longitudinal septum running vertically from front to back, (the mediastinum) (see PLEURA). The pulmonary artery, carrying unoxygenated blood to the lungs, divides into two large branches after only a very short course. Each of these branches enters into the formation of the root of the lung, and there begins to divide up into a very large number of smaller vessels. These subdivide many times until the final capillaries are given off around the walls of the air-sacs. From these the blood, after oxygenation, is carried by larger and larger veins, till it eventually leaves the lung by one of the several pulmonary veins. These number six or seven or more, and leave the lungs by the roots. In addition to the blood carried to the lung for aeration a small bronchial artery carries blood to the lung substance for nutritive purposes. This accompanies the bronchi and splits into branches corresponding to the small bronchi and bronchioles. The lymph vessels in the root of the lungs are very numerous, and are all connected with the large bronchial glands for this part.

Minute structure The main bronchial tube, entering the lung at its root, divides into branches, which subdivide again and again, to be distributed all through the substance of the lung, till the finest tubes, known as 'bronchioles' or 'capillary bronchi', have a diameter of only about 0.25 mm. In structure, all these tubes consist of a mucous membrane surrounded by a fibrous sheath. The larger and medium bronchi have plates of cartilage in the fibrous layer, and are richly supplied with glands secreting mucus, which is poured out on to the surface of the lining membrane and serves to keep it moist. The surface of this membrane is composed of columnar epithelial cells, provided with little whip-like processes known as 'cilia', which have the double function of moving any expectoration upwards towards the throat, and of warming the air as it passes over them. The walls of the bronchial tubes are rich in fibres of elastic tissue, and immediately below the mucous membrane of the small tubes is a layer of plain muscle fibres placed circularly. To this muscular layer belongs the function of altering the lumen of the tube, and, consequently, its air-carrying capacity. It is a spasmodic contraction of the muscular layer that produces the characteristic expiratory 'cough' of true asthma.

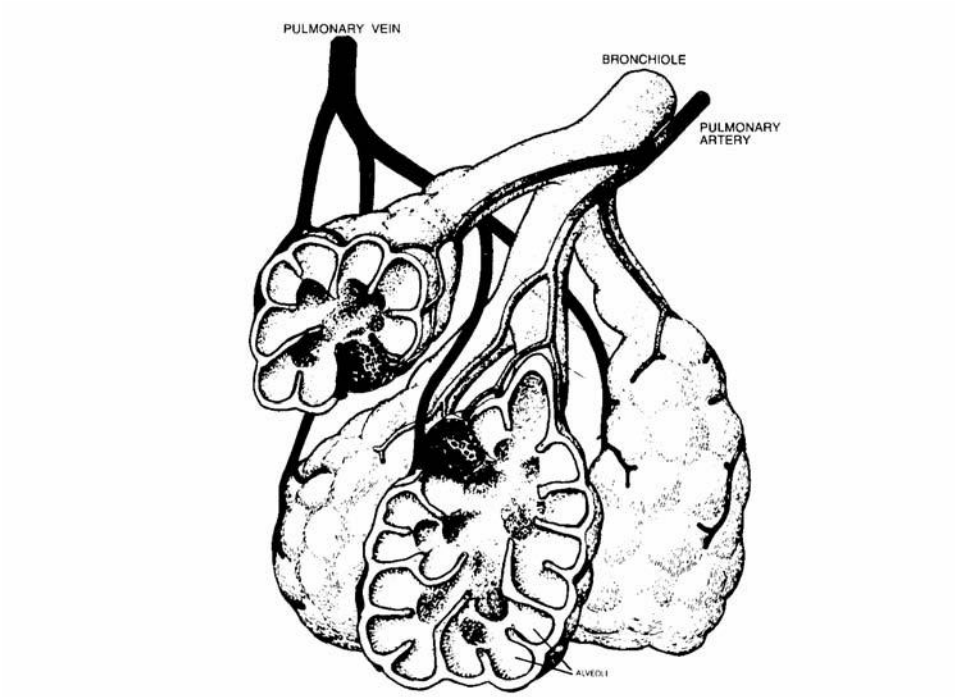
The smallest divisions of the bronchial tubes open out into a number of dilatations, known as

'infundibula', each of which measures about 1.25 mm across, and these are covered with minute sacs, variously known as 'air-vesicles', 'air-alveoli', or 'air cells'. An air cell consists of a delicate membrane composed of flattened plate-like cells, strengthened by a wide network of elastic fibres, to which the great elasticity of the lung is due; and it is in these thin-walled air cells that the respiratory exchange of gases takes place.

The branches of the pulmonary arteries accompany the bronchial tubes to the farthest recesses of the lung, dividing like the latter into finer and finer branches, and ending in a dense network of capillaries, which lies everywhere between the air vesicles, the capillaries being so closely placed that they occupy a much greater area than the spaces between them. The air in the air vesicles is separated from the blood only by two most delicate membranes, the wall of the air cell and the wall of the capillary, and it is through these walls that the respiratory exchange takes place.

Lungs, Diseases of

The chief of these is PNEUMONIA. (See also under PLEURISY; EMPHYSEMA; TUBERCULOSIS; MAEDI/VISNA; CALF PNEUMONIA; EQUINE RESPIRATORY VIRUSES; ENZOOTIC PNEUMONIA OF PIGS; CONTAGIOUS BOVINE PLEURO-PNEUMONIA; PARASITIC BRONCHITIS; PULMONARY ADENOMATOSIS.)



Congestion of the lungs Accumulation of fluid, or 'congestion', is the preliminary stage of several types of acute pneumonia. It also occurs in disease of the left side of the heart. FOG FEVER of cattle is another condition in which congestion of the lungs is seen.

'Hydrostatic (or hypostatic) congestion' of a lung is apt to occur if an animal which cannot stand, lies for too long on one side. Regular turning of the animal on to its other side is a necessary nursing procedure.

Pulmonary oedema This may occur during pneumonia (some forms), in disease of the left side of the heart, and (in cattle) in FOG FEVER, and in PARASITIC BRONCHITIS of cattle and sheep.

An acute and usually rapidly fatal oedema of the lungs occurs in animals exposed to smoke in a burning building; the animal almost literally 'drowns' in its own blood serum. (Administration of oxygen can be tried if an animal has been rescued before severe lung damage has been caused.)

Poisoning by PARAQUAT and ANTU results in oedema and consolidation of the lungs. (See also DIPS AND DIPPING; ELECTROCUTION.)

Relationship of alveoli to terminations of pulmonary artery and pulmonary vein. (From John A. Clements, *Surface Tension in the Lungs*. © Scientific American, Inc. All rights reserved.)

Pulmonary emphysema (See FOG FEVER.)

Pulmonary haemorrhage (See RACEHORSES.)

Allergic alveolitis Inflammation of the alveoli of the lungs of cattle exposed to mouldy hay or straw contaminated with micro-organisms such as *Thermopolyspora polyspora*, and resembling 'FARMER'S LUNG'.

Tumours of the lung are usually of metastatic origin, i.e. they are secondary growths which have started from another centre in the body, being carried to the lung tissue either by the blood- or lymph-stream. (See CANCER.)

Gangrene of the lung may be a complication of, or a sequel to, pneumonia, and is usually fatal. It is characterised by the presence of a foul-smelling, usually rusty-red, and almost always very copious discharge from both nostrils, in addition to the other signs of pneumonia. It is commonest in the horse as a sequel to ordinary pneumonia, and in other animals it may occur when the pneumonia has been produced through faulty administration of drenches. (See PNEUMONIA.)

Collapse of the lung The lungs are so resilient, in consequence of the elastic fibres throughout their substance, that if air is admitted within the pleural cavities the lungs immediately collapse to about a third of their natural size. Accordingly, if the chest wall is wounded and air gains entrance through the wound (pneumothorax), the lung collapses. After the wound has healed, and provided that no complications occur, the elasticity is restored as the air is absorbed. (See PNEUMOTHORAX.)

Torsion of a lung lobe, usually the right cardiac lobe, is seen rarely in dogs and cats; it causes dyspnoea, pulmonary oedema and death. The lobe may become twice its normal size and blackish.

Wounds of the lung Deep wounds of the chest involving the lungs are serious on account of the air admitted through the chest wall into the pleural cavity. This leads to collapse of the lung. Another serious factor involves haemorrhage, and the difficulty of checking it. The lung may be lacerated by the end of a fractured rib pointing inwards. (See 'FLAIL CHEST'.)

Parasites of the lungs Liver-flukes are sometimes found in the lungs of cattle and sheep; lung-flukes attack cats, dogs, pigs, and man in the Far East and the USA. Other parasites include LUNGWORMS. (See also HEARTWORM, for pulmonary dirofilariasis.)

Lungworms

(See PARASITIC BRONCHITIS; ROUNDWORMS; DONKEYS.)

LUPA

A European Commission project to collect DNA samples in many European countries to examine them for genetic diseases.

Lupin, Sweet

The sweet lupin (*Lupinus angustifolius*) can be added to livestock rations. The dehulled lupin is more nutritious than the whole lupin.

Lupins, Poisoning by

Lupins of different species have often been found to cause poisoning of sheep; sometimes also of horses, cattle and goats.

Poisoning by lupins is of two kinds: (1) due to alkaloids within the plant producing a nervous disease; and (2) due to infestation of the plant with a fungus which produces a toxin affecting the liver. This second type of poisoning is known as lupinosis, is usually chronic, and produces loss of appetite and weight, JAUNDICE, CIRRHOSIS of the liver, OEDEMA of the head, ASCITES and death. A few animals do recover but seldom thrive well afterwards.

In the USA great loss among sheep flocks has been occasioned by feeding on lupins by animals not accustomed to them. The toxic agents are the alkaloids which are present chiefly in the seeds.

Poisoning by the alkaloids gives rise to signs which include loss of appetite, laboured breathing, excitement, convulsions and death from respiratory paralysis. There is no jaundice or cirrhosis of the liver, and animals which recover are likely to do so completely.

Luprositol

A synthetic prostaglandin analogue for use in cattle, pigs and horses. It is used for oestrous control, oestrous synchronisation, LUTEOLYSIS in cycling animals.

Lupulone

An antibiotic extracted from hops (*Humulus lupulus*) which has activity against Clostridium species.

Lupus Erythematosus

An autoimmune disease of dogs and cats which occurs in two forms: (1) the cutaneous or discoid form, and (2) the systemic form.

The discoid form is characterised by symmetrical lesions on face, nose, and ears. ALOPECIA, loss of pigment, ERYTHEMA, and a scaliness may be seen. Exposure to sunlight worsens the condition.

VetBooks.ir

VetBooks.ir

The systemic form affects many tissues and organs. Autoantibodies against platelets, red and white blood cells may be present; with antibodies also in joints, kidney, skin and other organs. Signs include bilateral polyarthritis, fever, muscle pain, enlarged lymph nodes, and sometimes nervous signs.

Prednisolone is used in treatment.

Lusitano Horses

Magnificent dressage horses originating from Portugal. They are normally bay in colour, but any solid colour is allowed. They have Arab blood from the time of the Moor invasion of the Iberian peninsula.

Lutein

A natural pigment found in red, yellow, orange and green fruits and vegetables. It is extracted from marigolds and produced commercially from blue-green algae. It is an anti-oxidant and has been suggested that it may protect the eye against age-related macular degeneration in humans.

Luteinising Hormone (LH)

A secretion of the anterior lobe of the pituitary gland released by stimulation from GONADOTROPHIN-RELEASING HORMONE. LH controls the development of the CORPUS LUTEUM and its production of progesterone. In the male animal, LH stimulates secretion of testosterone by the testicle.

Luteolysis

Regression of a CORPUS LUTEUM. Two factors appear to be involved in luteolysis in most domestic animals – one being prostaglandin (PG) $F_2\alpha$ and the other being follicular oestrogen synthesis. It has been suggested that $PGF_2\alpha$ is the normal luteolytic compound, and that it is transferred from the non-gravid uterus to the ovary by some form of counter-current distribution between the uterine vein and ovarian artery. While the actual route for $PGF_2\alpha$ transfer is in some doubt, its physiological role is certain.

A number of procedures for inducing LUTEOLYSIS in domestic animals have been used. These range from the squeezing out of an established corpus luteum by rectal palpation in cattle, to the use of oestrogens. Synthetic prostaglandins are now used.

Luxation

(See DISLOCATION; SUBLUXATION.)

Lycopene

A chemical in tomatoes and carrots for which anti-cancer activity has been claimed.

Lyme Disease

This was first recognised in Connecticut, USA, in 1975; the vector of infection is *Ixodes* ticks on deer. Deer, hedgehogs and foxes all carry the bacterium.

The disease occurs both in the UK and in other EU countries; it also affects both adults and children.

Cause *Borrelia burgdorferi*. (See BORRELIA.)

Signs In humans, blurred vision, lethargy, headaches and arthritis. In a few cases meningitis or encephalitis or myocarditis result.

Lyme disease in dogs has been reported in the UK, other EU countries, the USA and Australia.

Lyme disease in horses results in them becoming lethargic. Diagnosis relies on paired blood samples showing a rising titre. Treatment consists of daily intravenous injections of oxytetracycline.

Treatment Antibiotics are likely to be beneficial if given early in the disease. NSAIDs may be used concurrently.

Control A vaccine has been developed for dogs.

Lymph

Lymph is a clear fluid which collects in the tissues which enters the lymph vessels and thence the bloodstream. It contains less protein than, but is otherwise similar to, the PLASMA. It also contains lymphocytes.

Lymph nourishes the tissues and returns waste products from them back into the bloodstream. There are certain tissues which are not provided with a blood supply at all, (e.g. the cornea of the eye, cartilage, horn, etc.) and in them the lymph is the only nourishing medium.

The lymph is derived in the first place from the bloodstream, of which the watery constituents exude through the fine walls of the capillaries into the tissue spaces. After meals, lymph from the small intestine may be milky in appearance due to the fat it contains. (See also LYMPH NODES; LYMPHOCYTE.)

The term 'lymph' was also applied to the material which collects in the vesicles of cow-pox and was used for vaccination.

Lymphadenitis

Inflammation of lymph nodes.

Lymphadenoma

(See HODGKIN'S DISEASE.)

Lymphadenopathy
Diseases of the lymph node(s).

Lymphangiectasia, Lymphangiectasis
The dilatation of the lymph vessels, which can be congenital of acquired. In BASENJIS intestinal lymphangiectasia is an inherited problem.

Lymphangitis
Inflammation of the lymphatic vessels, often resulting from a streptococcal infection.

In horses three infective forms occur: (1) EPIZOOTIC LYMPHANGITIS (caused by a yeast); (2) ULCERATIVE LYMPHANGITIS (bacterial); and (3) GLANDERS (bacterial).

The non-infective lymphangitis used to be called Monday morning disease, often being seen in horses after a weekend of no work and a protein-rich diet.

Signs Fever, lameness in one or more legs, with enlarged and tender lymph nodes. Later, doughy swellings, which pit on pressure, may affect the whole limb.

The appetite is lost for a day or two, but the horse is usually very thirsty. Under appropriate treatment, the severity of the signs abates in two or three days' time, or sooner; and although lameness still persists, perhaps for as long as a week, the general appearance of the horse rapidly improves. The horse is usually able to resume work in from 10 days to a fortnight.

Recurrences are likely, resulting in some permanent thickening of the limb.

Treatment Antihistamines may be tried. Antibiotics may be necessary; also diuretics to help reduce the swelling, and phenylbutazone, or some other analgesic, to reduce the pain.

Lymphatics
Lymphatics are the vessels which convey the lymph through the body. (See LYMPH.)

Lymphatic System
The lymphatic tissues of the body comprising lymph, lymphatics, lymph glands and lymphocytes.

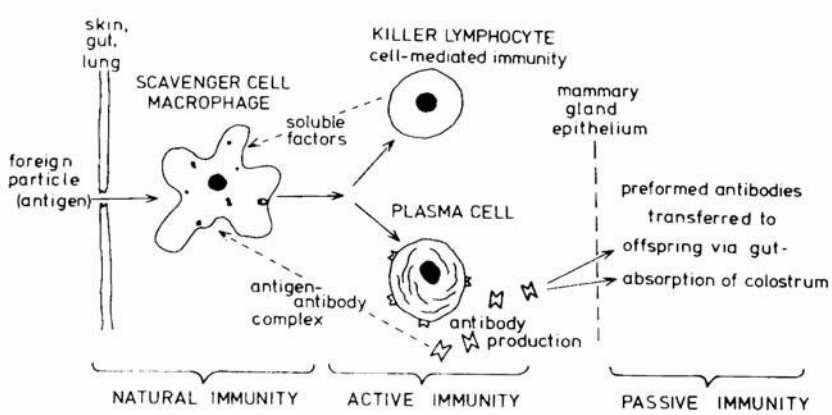
Lymph Nodes
Also called lymph glands, these are situated on the lymphatic vessels, act as filters, and have an important role in body defence by producing lymphocytes. (See also RETICULO-ENDOTHELIAL SYSTEM; IMMUNE RESPONSE; LYMPHOCYTES; PLASMA CELLS.)

Lymphocystis
A viral disease of fishes, which may give rise to whitish nodules on the cornea of the eye.

Lymphocyte
The main cell of the lymphatic system. Lymphocytes in mammals are of two main classes: thymus-derived, called T-cells; and B cells derived from bone marrow. Unlike polymorphonuclear leukocytes and monocytes, the white cells in this group have cell surface receptors for antigen, and they are not involved in PHAGOCYTOSIS.

T-cells do not secrete antibodies and act directly on foreign cells. B cells divide rapidly to form plasma cells which secrete antibodies. (See under BLOOD; B CELLS; IMMUNE RESPONSE; RECEPTORS.)

A much-simplified scheme of the relationship between antigens and some of the lymphoid cells of the body is shown in the diagram. Natural immunity is conferred by the natural secretions of the body surfaces. If these surfaces are penetrated, scavenger cells (macrophages) attempt to engulf and destroy the antigens. Macrophages have a central role in immunity and if they are successful no further effects of antigen may be detectable. The activity of macrophages is increased if the antigen is coated with specific antibodies. Macrophages are also attracted to areas where antigen is concentrated by soluble factors secreted by certain sensitised lymphocytes.



Large granular lymphocytes are a type of T-lymphocyte, stated to have a prominent role in modulating normal immune responses, and in eliminating virus-infected and transformed cells. It has been suggested that infection of these cells by the malignant catarrhal fever agent is the essential initial step in precipitating the disease.

(See also LYMPHOKINE.)

Lymphocytic Cholangitis
This is a probable auto-immune disease of cats. The signs include ASCITES, enlarged liver, POLYPHAGIA, ANAEMIA and in the later stages, JAUNDICE. The condition is treated with CORTICOSTEROIDS but progress is often slow. The human preparation ursodeoxycholic acid may be used under the 'Cascade' if all else fails.

Lymphocytic Choriomeningitis (LCM)
A viral disease of mice and laboratory and pet hamsters transmissible to human beings, in whom it may give rise to fever, headache, pain in muscles and, occasionally, death from meningoencephalitis. Dogs may act as symptomless carriers.

Lymphoedema, Lymphedema (US)
Swelling of an area with fluid as a result of blockage of the lymphatic vessels or lymph nodes. It can be congenital or acquired as a result of inflammation, injury or neoplasia. Inherited forms have been described in cattle, dogs and pigs.

Relationships between antigen and lymphoid cells illustrating the many stages at which antigen can be destroyed. If antibodies are formed they may be passed on from mother to young.

Lymphoid
Pertaining or relating to the lymphatic system.

Lymphoid Follicles
These are important structures in the intestines of birds that contain lymphocytes that undergo differentiation and specialisation.

Lymphoid Leukosis
Lymphoid LEUKOSIS COMPLEX of chickens is a form of cancer caused by a retrovirus, and initially affects B-lymphocytes in the BURSA OF FABRICIUS. It metastasises (see METASTASIS AND METASTATIC) to the liver and spleen, which becomes swollen. The tumours are nodular and yellowish-white. The disease is spread from hen to egg and hen to hen; the incubation period is about four months. Lymphoid leukosis is rare in mammals.

Lymphokine
Secreted by T-lymphocytes, and formed when sensitised cells react with antigen, lymphokines can attract other lymphocytes and monocytes, modify vascular permeability and activate macrophages. In man they are believed to play an important role in the development of rheumatoid arthritis.

Lymphoma
A common malignant tumour of dogs, representing 10 to 20 per cent of all cancers, which is genetic and can be influenced by environmental factors. It is also called LYMPHOSARCOMA and NON-HODGKIN'S LYMPHOMA. The most common form (80 per cent) affects lymph glands and in some cases the liver, spleen and bone marrow. The condition can affect the skin, alimentary tract and occasionally the nervous system. The glands swell and B or T LYMPHOCYTES can be involved. CYTOTOXIC DRUGS such as CYCLOPHOSPHAMIDE, DOXORUBICIN, and VINCRISTINE can be used in treatment.

Lymphosarcoma
A malignant tumour of the lymphatic system. (See LEUKAEMIA; also FELINE LEUKAEMIA; BOVINE ENZOOTIC LEUKOSIS; CANCER.)

Lymph Vessels
These are the vessels transporting lymph around the body. These vessels converge into two large ducts, right and left (thoracic) ducts which drain into the venous blood system at the junction of the right and left subclavian and jugular veins.

Lysine
Lysine is an essential amino acid. Synthetic lysine is added to pig feeds (concentrates) both to improve performance and to allow the quantity of added protein to be reduced. High levels increase the haemagglutination and agglutination titres (see CLOTTING OF BLOOD) of both IgG and IgA in chickens. A deficiency results in a loss of feather pigmentation in bronze turkeys. (See AMINO ACIDS.)

Lysis
Lysis has three meanings: (1) the gradual ending of a fever (as compared with crisis); (2) the destruction of a cell by an antibody; (3) the destruction of tissues. The affected tissue is identified by a prefix – e.g. OSTEOLYSIS is the destruction of bone, HAEMOLYSIS is the destruction of red blood cells, etc.

Lysosomal Storage Diseases
These are due to genetically determined deficiencies of specific enzymes; and are common

VetBooks.ir

in some breeds of dogs and cats. An accumulation of lipofusin (granular fatty deposits), and the related pigment ceroid, is a feature of some lysosomal storage diseases. (See FUCOSIDOSIS; CEROIDOSIS.)

Lysosomes

Lysosomes are structures within the cytoplasm of an animal cell which are surrounded by a membrane, contain enzymes and may carry out a digestive function for the cell, getting rid of bacteria, etc. They are involved in the metabolism of cellular products by producing enzymes. Deficiency of lysosomes and/or their dysfunction leads to by-product accumulation within cells. Deficiencies have been seen in specific breeds of cats. Lysosomes are particularly abundant in NEUTROPHILS, except those of rabbits, birds and reptiles. (See HETEROPHILS.)

Lysosomal storage disease These are due to genetically determined deficiencies of specific enzymes; and are common in some breeds of dogs and cats.

An accumulation of lipofusin (granular fatty deposits), and the related pigment ceroid, is a feature of some lyosomal storage diseases. (See CEROIDOSIS.)

Lysozyme

A basic protein that has non-specific antibacterial properties; it is an enzyme found in SALIVA, TEARS, OVALBUMIN, COLOSTRUM and other body fluids. It is also found in LEUKOCYTES. It is deficient in HETEROPHILS of species such as rabbits, birds, and reptiles and this deficiency is reflected in the solid PUS found in these species.

Lyssa

Lyssa is the name of a virus, similar but not identical to rabies, which is carried by certain European bats. The bite of a bat carrying the virus can infect man. Fatalities have been recorded in Finland and the former Czechoslovakia. In 1996, an infected bat was found in Southern England; as a result, the UK was not officially rabies free until summer 1998. Rabies vaccine will protect against Lyssa virus.

Lyssa Virus in Bats

The virus European Bat Lyssa Virus (EBLV) is seen in the UK, where it is rare, and Europe including the UK. The virus is a RHABDOVIRUS not dissimilar to RABIES in dogs. The bite of a bat carrying the virus can infect man. Fatalities have been reported in Finland and the former Czechoslovakia. There are two strains: EBLV1 and EBLV2. EBLV1 has been found in a serotine bat (*Eptiticus serotinus*) and two Natterer's bats (*Myotis nattereri*) in Southern England. In the UK 10 cases of EBLV2 virus have been found, eight in England and two in Scotland, all in Daubenton's bats. However, between 1986 and 2011 over 9,000 bats have been tested for the virus but it has not been found. This is a disease of wild bats and when it occurs and causes deaths it must be reported. As it is a form of rabies, those working with bats are offered vaccination. In 1996, an infected bat was found in Southern England; as a result, the UK was not officially rabies free until summer 1998. Human deaths from bites have occurred in Britain, the last in 2002 involved a person who refused vaccination. When handling bats, even apparently dead ones, thick gloves should be worn.

M

'M & B 693'
The code name given by the manufacturer May & Baker (now part of Merial) to sulphapyridine, one of the SULFONAMIDE DRUGS. It was the first sulfonamide to be introduced into the UK, in 1938.

Macaw-Worm Fly
This is a parasite of cattle and other animals in Central America. It is another name for the warble-fly *Dermarobia hominis*. (See under FLIES.)

Machrobrachia
An abnormal size or length of an arm.

Macrocephalus
An abnormally large head.

Macrocyclic Lactones (ML)
A group of broad spectrum endectocides. It includes members of the AVERMECTIN and MILBEMYCIN family of which moxadectin is a second generation member.

Macrocyte
Macrocyte is the term applied to an abnormally large erythrocyte especially characteristic of the blood in some forms of anaemia.

Macrodactylia
A congenital abnormality in which one or more digits are oversized.

Macroglossia
A congenital enlargement of the tongue.

Macrolides
A group of antibiotics including ERYTHROMYCIN, TIAMULIN, TILMICOSIN and TYLOSIN.

Macromelia
A congenital abnormality with an excessive size of an organ or a part, especially an extremity.

Macrophage
A former monocyte (type of white blood cell) which has migrated into the tissues and become larger. (See under BLOOD; INFECTION.)

Macrorhabdus ornithogaster
The organism causing a disease of cage-birds formerly called MEGABACTERIOSIS (synonym: AVIAN GASTRIC YEAST). Signs include loss of weight, difficulty in swallowing, vomiting, and diarrhoea. Birds that normally dehusk seed and swallow the kernel are seen to drop the seed (QUIDDING). Sudden death may occur due to haemorrhages. It also causes illness and death in ostrich chicks.

Macrotia
Congenitally abnormally large ears.

Macula
Part of the eye's retina found in humans and primates which is an area without blood vessels but is important in ensuring good vision. It is absent in domestic animals.

Macules
Macules are spots or stained areas of skin or mucous membrane, usually brownish, red, or purple in colour. They may be VASCULAR abnormalities or follow the release of blood cells or HAEMOGLOBIN into the dermis. Pressure with a glass slide will differentiate VASCULAR abnormalities from EXTRAVASATION of pigment.

'Mad Cow Disease'
(See BOVINE SPONGIFORM ENCEPHALOPATHY.)

Madness in Dogs
(See RABIES; ENCEPHALITIS; MENINGITIS.)

Maduramicin
A feed additive used to prevent coccidiosis in broiler chickens and turkeys. It is a fungus-derived ionophore and masks and goggles should be used when handling the product.

Maedi/Visna
A slowly progressive disease of sheep and goats, first recognised in 1939 in Iceland and believed to have been introduced into that country by karakul sheep imported from Germany. Iceland is now free from the disease, following two eradication programmes, but maedi occurs in the UK, continental Europe, North America, Africa and Asia.

Although maedi/visna has never been recorded in Australia, a retrovirus was isolated from goats there and shown to produce antibodies indistinguishable from those produced by maedi/visna virus in goats.

Cause A lentivirus. It is usually seen in animals over two years old. Transmission to the lamb is often via the ewe's milk.

'Maedi' is the Icelandic word for dyspnoea, and the disease is a type of pneumonia with a very long incubation period – one to three years or even more. An early sign is dyspnoea; after physical

exertion the breathing becomes very rapid and shallow. Later, breathing becomes difficult even when the animal is at rest, and death often follows.

'Visna' is a name applied to the same viral infection when the brain or spinal cord rather than the lungs are involved. DEMYELINATION occurs.

Diagnosis can be confirmed by microscopical examination of the tissues and by isolation of the virus. There is also an ELISA test.

MAFF

MAFF is the acronym for the Ministry of Agriculture, Fisheries and Food which, prior to 2001, was responsible for the control of NOTIFIABLE DISEASES, imports of animals and welfare of animals on farms. It was replaced in 2001 by the Department for Environment, Food and Rural Affairs (DEFRA).

Maggots

In many parts of the world, certain dipterous flies may lay their eggs on the wool of sheep during summer, and the eggs hatch into maggots which either live on the surface of the skin or burrow down into the subcutaneous tissues.

They cause great loss from wasting of flesh and destruction to fleeces, and sometimes result in the death of the affected sheep. The greenbottle flies (*Lucilla caesar* and *L. sericata*, in Britain, and *L. macellaria*, in both North and South America) are those responsible for this condition.

Maggots which have fed on carcases contaminated by *Clostridium botulinum* may contain a dose of toxin lethal to birds. This has caused deaths among domestic poultry, wild birds, and on game farms in the UK.

Maggots reared in a sterile environment are used to debride wounds.

(See BLOW-FLY STRIKE; FLIES - DIPTEROUS LARVAE OR MAGGOTS - MYIASIS; STRIKE.)

Maggots in Rabbits

Pet rabbits are frequently attacked by maggots in warm humid weather, usually in association with uterine and gastrointestinal disorders. The hindquarters of the animal are usually severely affected and treatment involves intensive nursing, identification and correction of the predisposing cause.

Maggots in Sheep

In many parts of the world, certain dipterous flies may lay their eggs on the wool of sheep during summer, and the eggs hatch into maggots which either live on the surface of the skin or burrow down into the subcutaneous tissues. They cause great loss from wasting of flesh and destruction to fleeces, and sometimes result in the death of the affected sheep. The green-bottle flies (*Lucilla caesar* and *L. sericata*, in Britain, and *L. macellaria*, in both North and South America) are those responsible for this condition. (See under MYIASIS and FLIES; FLIES - DIPTEROUS LARVAE OR MAGGOTS – MYIASIS.)

'Magic Mushroom' Poisoning

This is caused by psilocybin, a hallucinogen present in *Psilocybe semi-lanceate* and *Panaeolus foenisecii*. Consumption of the fungus by domestic animals can give rise to bizarre behaviour.

Signs In the dog, aggressiveness, ataxia, nystagmus and salivation plus a body temperature in excess of 42° C (108° F) have been noted.

A normally docile pony, which had been grazing in a field where 'magic mushrooms' were growing in profusion, became aggressive.

Magnesium (Mg)

Magnesium (Mg) is a light white metal which burns in air with the production of a brilliant white flame, leaving a white powder as a residue. The salts of magnesium used as drugs are the oxide, carbonate and sulphate. There is a heavy oxide, known as 'heavy magnesia', a light oxide called 'light magnesia', a heavy carbonate and a light carbonate. Both the oxides and the carbonates are antacids and slightly laxative. The sulphate of magnesium is commonly called 'Epsom salts'. (For blood magnesium, see under HYPOMAGNESAEMIA.)

Uses Magnesia, whether light or heavy, is usually prescribed for foals, calves and dogs when these require a mild antacid and laxative. The sulphate of magnesium is a saline purgative. (See under LAXATIVES.)

CALCINED MAGNESITE is used as a top-dressing for pastures in an attempt to prevent hypomagnesaemia (about 500 kg (10 cwt) per acre). For cattle, a daily dose of 50 g (2 oz) calcined magnesite is considered to be of great value in the prevention of hypomagnesaemia, but it should be fed only during the 'danger period'. This is because prolonged feeding of magnesium salts is apt to accentuate any latent phosphorus deficiency and may lead to 'milk lameness' or similar conditions.

A mixture of magnesium acetate solution and molasses has been used, being available on a free-choice basis to cattle from ball feeders placed in the field.

Magnesium oxide Too high a level in concentrate feeds for lambs and calves has led to urolithiasis. (See under URETHRAL OBSTRUCTION.)

Magnetic Field

Powerful force fields used in certain diagnostic machines. Operators must not go near the machine

VetBooks.ir

while it is on. Magnetic fields can cause serious problems to persons using electronic devices such as an artificial pacemaker. (See NUCLEAR MAGNETIC RESONANCE.)

Magnetic Resonance Imaging (MRI)

(See NUCLEAR MAGNETIC RESONANCE; DIAGNOSTIC IMAGING.)

Magnetotherapy

The use of magnetic fields to support therapy. There are claims that magnetotherapy has beneficial effects on painful conditions affecting the nervous and locomotor systems and on post-surgery healing. Two types of therapy are available, pulsed electromagnetic fields delivered by a remote device and activated for periods, and central reverse polarity magnets mimicking a pulse magnetic field and applied continuously.

Magnets

Magnets have been used to treat TRAUMATIC RETICULITIS and prevent TRAUMATIC PERICARDITIS in cattle. (See under HEART DISEASES.)

Maine-Anjou Cattle

Also called Rouge des Prés. It is a dual-purpose breed produced from local cattle crossed with Durham cattle in 1839 and by 1850 it was an established breed. It was centred on Maine Anjou region of West France and in 1908 a breeders society started. Colours: dark red and white (mainly on head, belly, rear legs and back but it can also occur elsewhere), and roan. The cattle are large, with bulls weighing 990 kg to 1,400 kg (2,200 lb to 3,100 lb) cows 680 kg to 865 kg (1,500 lb to 1,700 lb). They are now reared in North America and the UK. They have been used to improve muscling in the British BEEF SHORTHORN cattle.

Maine Coon Cat

A large-sized cat developed in New England, described as a long-haired breed in a variety of colours. The breed is prone to HAEMOPHILIA, HIP DYSPLASIA and FELINE HYPERTROPHIC CARDIOMYOPATHY. PATELLAR LUXATION and SPINAL MUSCULAR ATROPHY also occur.

Maize

A cereal plant (*Zea mays*) cropped and harvested all over the world where the crop can be protected from frost. Also called corn, miele and mealie, it can be fed to man and animals, depending on the variety and its treatment after harvest. Varieties have been produced that allow maturation in the southern half of Britain and the whole plant is used in silage especially for dairy cows and in other ruminants. It has a high energy and low protein content but is often deficient in some VITAMINS and MINERALS. (See PHYTIN; SILAGE.)

Maize Gluten

A by-product of various foods following production of maize starch and used in livestock feeds for ruminants, pigs and poultry. The analysis is variable usually with relatively high energy levels and variable protein content depending on source. Using the same source ensures little analysis variation. It is light brown in colour; if black it may have been overheated and should not be used.

Major Histocompatibility System (MHC)

One of the chromosomal regions controlling immune responses.

Histocompatibility antigens are inherited through a set of genes known as the major histocompatibility complex (MHC). Every animal possesses its own unique set of histocompatibility antigens.

Class I genes code for antigens that provoke the rejection of foreign grafts. Antigens of this class are of the cell-surface type, located on all nucleated cells, and concerned with cell recognition.

Class II cell-surface antigens are located mainly on B-cells, and are concerned with regulation of the immune response.

Class III antigens are located in serum protein, and regulate complement activity. (See COMPLEMENT.)

Following the demonstration at the Animal Breeding Research Organisation, Edinburgh, of an association between MHC type in cattle and their resistance to mastitis, it was suggested that it might be possible to select for AI bulls which pass on this resistance.

Malabsorption Syndrome

A group of disorders in which there is suboptimal absorption of nutrients and so excessive loss of nutrients in the faeces. It may occur in any species at all ages; it can occur in the runts of the litter and in older animals following alimentary disease. There is chronic diarrhoea and loss of weight. There is no cure in many chronic cases and it has to be managed by the diet. There are specially formulated diets for dogs and cats that contain high quality and easily absorbable protein.

Malachite Green

A dye used in the treatment of external fungal and protozoal infections of fish, and for the control of proliferative kidney disease. Only the zinc-free preparation can be used for therapy in fish.

Malacia

Softening of a part or tissue in disease, e.g. osteomalacia or softening of the bones.

VetBooks.ir

Malar Abscess
This is not strictly speaking an abscess, but a fistula from the root of a carnassial tooth of a dog to the outside of the face below the eye. The cause is an infected root. Pus is discharged from the root to the skin under the eye. Treatment is the removal of the affected tooth, allowing the infection to discharge and the area to heal by SECONDARY INTENTION.

Malaria
A disease of primates caused by *Plasmodium* spp., sporozoan parasites which are transmitted by mosquitoes. The parasite has an interesting method of neutralising the body's defence mechanisms: affected red blood cells bind to immature dendritic cells and prevent them from developing. Dendritic cells are essential in the process of developing immunity. (See under MONKEYS, DENDRITIC CELLS.)

'Malaria of Birds'
(See under PLASMODIUM GALLINACEUM.)

Malassezia, formerly *Pityosporon* spp.
A commensal yeast found particularly on the skin of dogs and some other animals including cage-birds, cattle, pigs and camelids. It sometimes produces a seborrhoeic dermatitis of dogs, a common complex, the signs of which it may exacerbate, and Malassezia dermatitis. It also causes a brownish-black deposit in dogs' ears. CHLORHEXIDENE digluconate shampoo can be used to treat it. (See SEBORRHOEA; SEBORRHOEIC.)

Malathion
An organophosphorus insecticide which has been used for the control of external parasites in cattle and as a crop spray.

Mal De Caderas, Maladie De Caderas
Mal de caderas (maladie de caderas) is a trypanosome disease of the horse, occurring in Brazil, Argentina, Bolivia, and Paraguay, being most serious in the latter country. It is caused by the *Trypanosoma equinum*. Suramin or quinapyramine have been used in treatment.

Mal De Playa
A form of poisoning in cattle by a plant, *Lantana camara*.

Mal Du Coit, Maladie Du Coit
(See DOURINE.)

Male Fern
The growing point of male fern (*Dryopteris felix-mas*) may attract cattle on bare pasture, and lead to poisoning. It usually occurs in beef animals on a limited diet and signs can include complete or partial blindness, weakness and recumbency. Recovery can occur following improved feeding. An extract has been used to treat TAPEWORM infestation. See also under FERNS.)

Maleic Hydrazide
A growth-retardant used on grass verges which has caused non-fatal gastritis in small animals.

Malformation
(See DEFORMITIES.)

Malignant
A progressively worsening condition. It often is used to indicate tumours (neoplasia) which become progressively larger and worse and eventually often result in death. Unlike benign tumours, many malignant tumours spread in the body.

Malignant Aphtha of Sheep
(See ORF.)

Malignant Catarrhal Fever
(See BOVINE MALIGNANT CATARRHAL FEVER.)

Malignant Histiocytic Disease
A rare condition resulting from an excess of histiocytes in the bloodstream. It affects some breeds of dog, e.g. BERNESE MOUNTAIN DOGS and FLAT-COATED RETRIEVERS and is thought to be inherited. There are three disease categories, benign cutaneous histiocytoma, reactive histiocytosis (cutaneous or systemic) and malignant histiocytic sarcoma complex. Clinical signs vary from anaemia and respiratory disease in the malignant form to itchy skin patches. The localised form has a single primary lesion with or without regional lymph node involvement. Treatment is surgical in localised forms, but in the malignant form possibly RADIOTHERAPY or more likely systemic chemotherapy.

Malignant Hyperthermia
(See HYPERTHERMIA, MALIGNANT.)

Malignant Jaundice of Dogs
(See CANINE BABESIOSIS.)

Malignant Oedema
(See GAS GANGRENE.)

Malignant Stomatitis
(See CALF DIPHTHERIA.)

Malignant Theileriosis of Sheep and Goats
A tick-borne disease caused by the protozoan parasite *Theileria hirci*, and occurring in Eastern Europe, the Middle East, Egypt and Sudan.

Signs include high fever, constipation, glandular enlargement, pale anaemic mucous membranes with later jaundice and death; however, the disease may be very mild in animals with some locally acquired immunity.

Mallein Test

Mallein test is a method of testing for the presence of GLANDERS in a horse.

Malocclusion

A dental condition in which the teeth do not properly meet their counterparts in the opposing jaw. Commonly seen in pet rabbits and chinchillas fed inappropriate diets, especially devoid of fibre. It is also encountered in dogs and cats with jaw deformities, especially congenital defects like prognathism (overshot or parrot-mouthed) and brachygnathism (undershot). (See BRACHYCEPHALIC, BRACHYGNATHISM, DOLICHOCEPHALIC SKULL, OCCLUSION, PROGNATHISM.)

Maltese Dogs

A small toy breed of white long-haired dog originally from the Central Mediterranean area. The breed is less popular now than formerly. There is no undercoat but the hair often requires much grooming to look presentable. They are cuddly, docile pets and weigh 2.5 kg to 5.5 kg (5 lb to 12 lb) although breed standards specify low weights. Tear staining is commonly seen and daily cleaning is required to prevent it. The breed often suffers from PATELLAR LUXATION. It is suspected that CHIARI-LIKE MALFORMATION and SYRINGOMYELIA may be inherited in the breed. Tear staining (CHROMODACTYORRHOEA) is commonly seen and means that daily cleaning is required to prevent it.

Mamilla

Mamilla is the Latin term for the nipple.

Mamillitis Inflammation of the nipple. Bovine herpes mamillitis is a recognised disease which can also affect the skin of the udder.

Mammary Gland, Udder

Structure

Cow The udder has four glands or 'quarters'. A strong septum divides the two right-hand glands from the two on the left side, but there is no such demarcation between fore and hindquarters on the same side of the body.

The gland is composed of lobes and lobules, held in position by fibrous tissue, and sending ducts down into an irregular milk sinus. This latter is large, and partly divided into compartments by folds of mucous membrane. From it leads one large lactiferous duct down the single teat to its apex, which possesses a sphincter muscle of almost 10 mm in width.

Mare The mammary glands are two in number, situated in the inguinal region.

Ewe There are two mammary glands, each of which has a single teat with a single duct. They are situated in the inguinal region, as in the mare and cow.

Sow The mammary glands number 12 in most sows (although a few have more), and are arranged in two rows reaching from just behind the level of the elbows along the abdomen to the inguinal region. As a rule, the glands which are situated towards the middle of the series are the best developed and secrete the most milk. Each teat has two ducts as a rule.

Bitch As in the sow, there are two rows of glands along the lower line of the abdomen. They are usually 10 in number, but in the smaller breeds

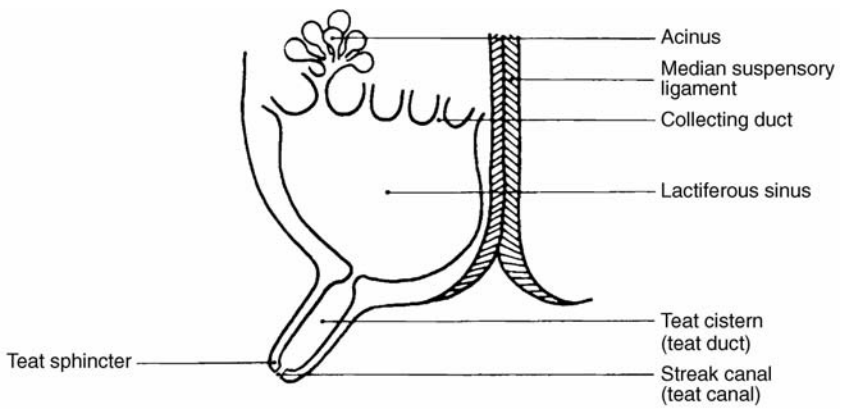


Diagram showing one-half of the cow's udder, and the median suspensory ligament which separates the 2 halves.

VetBooks.ir

VetBooks.ir

there may only be eight, and in the larger breeds there are sometimes 12. Each teat possesses from 10 to 12 tiny lactiferous ducts.

Secretion of milk This is a continuous process, initiated at parturition (or before) by the hormone prolactin (from the pituitary gland) and another from the thyroid. A number of other hormones may be involved, both in stimulating and in maintaining secretion of milk. Milk accumulates in the alveoli, upper channels, and milk cisterns; the rate of secretion decreases as internal udder pressure rises.

Milk 'let-down' in the cow, associated with the hormone oxytocin, is referred to under MILKING.

Colostrum is the name given to the first milk that is secreted by the udder.

(The importance of the newly born of any species of animal receiving an adequate supply of colostrum-containing first milk, soon after it is born, is explained under COLOSTRUM.)

(For other information concerning milk, see MILK.)

Conditions affecting the milk yield of cows

1. Breed.
2. Temperament. There is no doubt that a placid but not sluggish, alert but not highly nervous, cow makes the best milker.
3. Health. It is, of course, necessary that a cow should be in good general health if the best results are to be obtained from her.
4. Age. A cow in good health improves in her milk yield up to her seventh or eighth year, and remains at a high level until her 10th or 12th year. The milk of a young cow is much richer in fats and solids than that of an aged animal, so that the ideal position in a herd is to have enough young stock to counteract any possible deficiency in those substances from the milk of the old cows.
5. Lactation. A cow yields the greatest amount of milk between the sixth and eighth week after calving; thence she gives a smaller amount each day till about the 300th day, when she goes dry. Cows give best results when their lactation period does not exceed 8½ to 9 months, i.e. when they are dried off about eight weeks before they are due to calve, having settled in-calf at the first. (See also PROGENY TESTING; RATIONS FOR LIVESTOCK.)

Mammary Glands, Diseases of

Mastitis, or inflammation of the udder. All the domestic animals are liable to the disease, but it is commonest in the cow, ewe and goat. (See MASTITIS IN COWS.)

Abscess formation Antibiotics or sulfa drugs are indicated; lancing the abscess can give relief. (See ABSCESS: specific abscesses are considered under ACTINOMYCOSIS; TUBERCULOSIS.)

Tuberculosis of the udder (see TUBERCULOSIS).

Tumours include papillomas, fibro-adenomas, and adenocarcinomas. Some tumours of the bitch's mammary glands appear to be hormone-dependent and contain oestrogen receptor protein. In cats, mammary carcinoma is twice as common in the Siamese breed as in all other breeds combined. (See TUMOURS; CANCER.)

Hypertrophy of the mammary glands in the cat has been recorded both in pregnant queens and in neutered females treated with megestrol acetate for 14 months to five years. The condition has to be differentiated from neoplasia.

Wounds and injuries of the udder and teats are commonest in the cow and sow, owing to greater pendulousness than in other animals.

All wounds of the udder and teats are serious on account of the danger of infection and the development of mastitis. Bitches can also be similarly affected specially if the claws of the puppies are not trimmed when they become 'hooked'.

Treatment As a first-aid treatment, wounds of the teats and udder should be washed with warm water and an antiseptic, dry sulphanilamide powder subsequently applied.

When a teat has been torn or injured so that milk escapes from the canal, it is usually difficult to get the fistula, so formed, to heal until the cow goes dry. An operation is usually necessary to obtain healing. This procedure necessitates the cow remaining dry for at least 2 months. In some cases a cow with a fistula is better turned out to grass at once, and made to rear calves until her milk-flow ceases, when she can be taken in and undergo the operation.

Eruptions on teats may be specific, such as are seen during outbreaks of foot-and-mouth disease, cowpox, malignant catarrhal fever, rinderpest, etc. (See VIRAL INFECTIONS OF COWS' TEATS.)

Many teat sores, however, are caused through 'chapping', or 'cracking', of the delicate skin of the teat. (See under MASTITIS.)

Warts on teats (See WARTS.)

Teat obstructions Difficulty in milking may be caused by stricture of the sphincter, milk clots or (rarely) calculi in the teat canal; alternatively by the presence of warty growths inside the canal. The

latter condition is considered under WARTS. Cystic enlargement of the nipples of rabbits is sometimes seen related to womb disease (uterine adenocarcinoma).

Manchester Terrier
A medium-sized dog with pointed face, smooth black coat and brown markings on the face and legs. The breed may develop CUTANEOUS ASTHENIA, which is a dominant trait and LEGG-CALVÉ-PERTHES DISEASE which is inherited by an unknown mechanism. There is a DNA test for VON WILLEBRAND'S DISEASE.

Mandelic Acid
A urinary antiseptic, effective in acid urine.

Mandible
Mandible is the bone of the lower jaw. (See under JAW.)

Mandibular
Relating or pertaining to the MANDIBLE.

Mandibular Disease
(See SHOVEL BEAK.)

Mangalitza Pig
A Hungarian pig of the European pigs directly descended from wild boar. It has a heavy fleece like a sheep and is the only breed now in existence with this characteristic. They are large, round pigs originally bred for lard. They are now a rare breed.

Manganese (Mn)
A trace element, necessary in minute quantities for a healthy diet. It is important in the development and repair of epithelial tissue. Insufficiency in the pasture herbage, e.g. in Devon and Cornwall, UK, may cause infertility in cattle and deformed offspring.

In New Zealand calves deficient in manganese were born with very shortened limbs and enlarged joints. Some cases of CONGENITAL JOINT LAXITY AND DWARFISM have low blood manganese levels. (See TRACE ELEMENTS; 'SLIPPED TENDON'.)

Mange
A contagious skin disease caused by mites, which lay their eggs in the skin. The movement of the mites results in intense irritation. Damage to skin, hide or fleece is caused by efforts to relieve the discomfort. There are different types of mange, each caused by a different species of mite. Sarcoptic mange occurs in man (when it is known as scabies), dogs, cats, cattle, pigs, sheep and horses, etc. Psoroptic mange in the sheep is known as SHEEP SCAB. Chorioptic mange usually affects the tail and legs of cattle and horses. Demodectic mange (follicular or 'black' mange) is most common in dogs and hamsters. Details are given below. (For causal mites, see under MITES, PARASITIC.)

Mange in cattle

Demodectic mange Fairly common but often not noticed as clinical signs are few; nodular formation in hair follicles is the main sign, with resulting damage to the HIDE.

Sarcoptic mange is common in Britain and North America and is the cause of 'dairyman's itch'. It is usually found on the head and neck, but may occur on any part of the body. Bulls are particularly liable to this form of mange.

Chorioptic mange is usually confined to the base of the tail, but may spread to the legs, causing stamping and rubbing.

Psoroptic mange causes debility, failure to thrive and reduced liveweight gain.

Psoroptic mange is an important disease of feedlot cattle in the USA, and was once the most prevalent form of cattle mange in Britain, where it is now seldom seen. In an outbreak in Britain, in a beef herd comprising 306 animals, the infected areas of skin were thickened and scabby, with blood and serum oozing from the lesions. These extended along the back and down the flanks.

Treatment Ivermectin or similar products by injection; 'pour-on' products such as fenthion and phosmet.

Mange in the horse is relatively uncommon, but four varieties of mange occur. Ear mites are not seen in horses, but rarely they have psoroptic mange mites on the very edge of the pinnae. NB: Ear dressings should never be poured into horses' ears.

Sarcoptic mange In this type the parasites burrow into the epidermis and make treatment difficult. The disease commences by the hair dropping out in patches with the formation of papules and an intense continuous itching. The hair becomes thin and broken, and abrasions are present. The skin is hard and folded. Emaciation is progressive, and death may occur from exhaustion. It reaches its height in spring, and is at an ebb in late summer and autumn.

Treatment Gamma BHC is an efficient mite-killer, but its use in the UK is banned. The organophosphorus compounds, diazinon and fenchlorphos, are also effective. For the best results they should be applied by dipping or as saturating sprays, and for the sarcoptic manges particularly, two or more treatments may be necessary at intervals of 10 to 14 days.

VetBooks.ir

Psoroptic mange Two varieties of *Psoroptes* occur on the horse, one in the ear and one on the skin. The lesions on the skin are localised at first, and usually start near the dorsal line where the hair is long. The patches are generally barer than in sarcoptic mange. The parasites bite the epidermis, but do not penetrate the skin. The serum which exudes forms a scab in which the parasites live.

Treatment is on similar lines to that for sarcoptic mange. It is important to remember the presence of parasites in the ear, and to treat this part of the body also.

Chorioptic or symbiotic mange is usually confined to the legs or root of the tail. It is not notifiable. It causes great itching, stamping and rubbing of one leg against the other. Papules, scabs and even ulcers may be found. Treatment is as above. Ivermectin paste, 0.2 mg/kg, in two doses, two weeks apart, has been suggested as a control measure.

Demodectic mange (See description under 'Mange in dogs and cats', below.)

Mange in sheep

Sarcoptic mange is usually confined to the head, and is seldom found on the woolly parts of the body. It tends to become more generalised in the goat.

Chorioptic mange, caused by *Chorioptes bovis*, occurs in horses as well as cattle and sheep, and can be serious, especially in housed sheep overseas. It is not uncommon in the UK. Of 130 sheep received from South Wales at the Central Veterinary Laboratory, 33 per cent were found infested. Lesions occur on the pasterns and in the interdigital spaces.

Psoroptic mange or 'sheep scab' is caused by *Psoroptes ovis*. It occurs on all parts of the body covered with wool and in the ears. The life-cycle is typical, and can be completed in 13 to 16 days: the progress of the disease is in consequence very rapid. It is one of the worst of sheep diseases; it was formerly notifiable in Britain.

Itching is usually the first sign of the disease, and should be investigated **at once**. The skin becomes thickened and even ulcerated; the wool becomes detached and the sheep emaciated (see illustration below). The itching causes the animal to rub itself against fences and detaches the scab. This further spreads the disease, and permits secondary infections of the wound by bacteria.

Treatment is usually by means of double-dipping at an interval of about 8 to 12 days, but which depends on local circumstances. In Britain, a dip sanctioned by DEFRA must be used. It should be purchased only from a reputable manufacturer and used exactly as directed. Organophosphorus dips can only be purchased by persons who have attended a course on their usage and have received an appropriate certificate to confirm this.

Prevention (see IVERMECTIN).

The 'itch-mite' of sheep *Psorergates ovis*, which occurs in Australasia, Africa and North and South America, has not, so far, been found in Britain. This mite causes thickening of the skin and scurf formation. The growth of the wool fibre is affected and the fleece is further damaged by rubbing.

Mange in pigs

Sarcoptic mange is very common. It starts on the head and gradually spreads all over the body, especially attacking the thinner skin. There is intense itching, the hair falls out, and the skin becomes covered with scabs or with wart-like projections. It is found in the UK and North America.

Treatment Improved liveweight gains have followed treatment of sarcoptic mange. Amitraz, doramectin or IVERMECTIN may be effective.

Mange in dogs and cats

Sarcoptic mange is common in the dog; it generally starts on the muzzle and spreads backwards. The animal should be clipped and bathed with green soap. It may then be treated with phosmet. If the infection is generalised, treat one-half of the body, and the other half after two or three days.

Notoedric mange in cats is similar to the latter form in dogs. It is intensely irritating, affecting face, ears and occasionally legs and external genitalia. It is now very rare in the UK.

Otodectic or auricular mange occurs very commonly in dogs and cats. Otodectes is the most frequent cause of irritation in the ears; it causes scratching and shaking of the ear with resulting excoriation. There may be HAEMATOMA formation in one or both pinnae.

The eggs and larvae are very resistant, and survive under treatments which kill the adults. Treatment is usually repeated until the condition resolves.

First-aid Cat-owners may be able to provide a little temporary relief by means of a few drops of olive or vegetable oil, which will help to soften waxy deposits and kill some mites. A few drops of warm, soapy water (**not** dish-washing detergent

liquid) may achieve the same result. However, professional advice should be obtained without delay.

Owners should not poke around with cotton-wool wound round an orange stick or tweezers, as the wool will slip off, and the skin of the external ear canal is then likely to be abraded, or even the ear-drum punctured.

Professional treatment consists in the use of eardrops containing an effective mite-killer, plus an analgesic to reduce the irritation caused by the mites.

In neglected cases, or those complicated by bacterial or fungal infections, where a painful, suppurating condition is present, antibacterial or antifungal drugs must be used.

(See DEAFNESS and EAR, DISEASES OF; also HAEMATOMA.)

Demodectic mange of dogs Cigar-shaped mites invade the hair follicles, causing the hair to fall out in patches.

Demodectic mange (also known as follicular or 'black mange') is most common in dogs.

Signs Two types of demodectic mange in dogs have been described: (1) the squamous type, in which the skin becomes scaly, wrinkled and ringworm-like in appearance (and is sometimes mistaken for ringworm); and (2) the pustular type in which secondary bacterial infection occurs. This is always very serious, and constitutes an illness as well as a mere skin disease, since the dog suffers from toxaemia. Indeed, sometimes euthanasia becomes the only humane course, especially when extensive areas of skin are involved.

Cause *Demodex canis*.

Treatment is made difficult by the fact that the mites are sometimes living at a depth difficult to reach. However, IVERMECTIN and similar products (MACROCYCLIC LACTONES) by injection or 'pour-on' and 4 per cent PERMETHRIN are effective. AMITRAZ spray is used in some EU countries and can be imported under licence from the VETERINARY MEDICINES DIRECTORATE.

Diagnosis is made or confirmed by the examination of skin scrapings under a microscope.

The disease often appears in the dog when 8 to 12 months old, usually first on the head, around the eyes and nose, and on or near the feet.

Mange in goats There are four main causes of mange in goats. *Sarcoptes scabiei* cause intense PRURITUS and ERYTHEMA, usually starting around the eyes; in extreme cases it can lead to severe weight loss and a drop in milk yield. *Psoroptes cuniculi* is usually confined to the ear, and may cause local irritation. *Demodex caprae* may cause small non-pruritic palpable nodules or pustules, without loss of hair, in the skin anywhere on the body. Yellow caseous ('cheesy') material containing mites (seen microscopically) can be expressed from them. *Chorioptes caprae* is non-burrowing, and causes white or brown scabby lesions, in most cases confined to the lower leg.

Treatment Injections of AVERMECTINS are effective against *Sarcoptes* and *Chorioptes*. However, there are no products in the UK available which have a marketing authorisation for goats. AVERMECTIN injections are not licensed for use in milking animals. EPRINOMECTIN is licensed for use in cattle, with a nil milk withhold time. It is effective against sarcoptic and chorioptic mange and is widely used in the USA. In the UK, it is essential to seek veterinary advice before treating goats with mange. (See 'CASCADE'.)

Mange in fowls

'Depluming scabies' in fowls is caused by *Cnemidocoptes laevis*, which lives at the base of the feathers, and so irritates the fowl that it pulls them out. The stumps left may be seen to be surrounded with crusts. The affected spots and surrounding areas may be treated with IVERMECTIN.

'Scaly leg' is caused by *C. mutans*. The feet and legs become enlarged and crusted. The birds may become very lame and even lose a toe. Destruction of infected birds combined with rigorous disinfection is the most common method of eradication. If this procedure is not convenient, the scab should be removed with soap and water, the leg dried, and one of the preparations mentioned above used. This should be repeated in three or four days.

Dermanyssus gallinae is the chicken mite of Europe and North America. It is whitish to red in colour. The complete life-cycle takes about seven to ten days.

The mite lives exclusively on blood. It is nocturnal in its habits, living in crevices during the day.

Eradication of the mite must be thorough. All wooden structures must be disinfected. A painter's blow lamp is very useful for cracks.

Affected flocks may be treated by cypermethrin, as a dilute spray.

Although primarily a parasite of fowls, this mite will attack horses and other mammals, causing much irritation, with the eruption of papules and the formation of scabs. The mite, as it feeds only at night, may be overlooked as the cause of the

VetBooks.ir

disease. The proximity of fowls suffering from the mite may give a clue.

Ornithonyssus sylviarum, the northern fowl mite which is also common in Britain, causes scab formation, soiling of the feathers, and thickening of the skin around the vent. In contrast to the chicken mite, this parasite remains on its host.

In Israel allergic rhinitis and bronchial asthma have been caused by this mite among poultry farmers.

Liponyssus bursa, the tropical 'fowl mite', replaces the last species in the warmer parts of the world. Unlike it, however, this species is found on the fowls and in the nest. It may feed during the day. It also lays eggs and moults on its host. The signs are similar.

Mange in cage birds Cage birds may suffer from this infestation. *C. pilae* causes 'SCALY LEG' and TASSEL FOOT.

Manioc

An ingredient of some compound animal feeds which has been found unsafe for turkeys. It is also called cassava and tapioca. It is produced from the tuber of *Manihot esculenta*, a member of the *Malvaceae* family. It contains high levels of cyanogenetic glycosides and can cause poisoning of animals if fed raw. (See CASSAVA.)

Mannan Oligosaccharides

A group of polymerised mannose compounds found in yeast. They are added to feeds to ensure a healthy upper intestine and prevent pathogens such as *E. coli* from ascending the intestinal tract and causing disease.

Mannheimia

This is a Genus of bacteria reclassified in 1999. It contains several strains of organism commonly found in the respiratory tract. There are five species of which the most important is *M. haemolytica* (formerly *Pasteurella haemolytica*), causing respiratory disease especially in cattle and sheep.

Mannosidosis

The most widely recognised lyosomal storage disease of cattle, especially of Aberdeen Angus. It is due to a genetic deficiency of the enzyme mannosidase. Affected calves develop ataxia and become aggressive; finally, paralysis sets in.

Beta-mannosidosis, an inherited disorder of glycoprotein metabolism, has been identified in goats, and is rapidly fatal. Signs include inability to rise from a recumbent position, carpal contractures, pastern joint hyperextension, a dome-shaped skull and deafness. There is a DNA test for the problem in DOMESTIC SHORT-HAIRED CATS and PERSIAN CATS.

Manure Heaps

Manure heaps are potentially a source of infection and should be fenced off. Grass growing near manure heaps may also contain pathogens and parasites. New manure should be buried under older manure; the new manure will then heat up to about 70° C (158° F), destroying most pathogens, if left for a few days. (See also SLURRY.)

Manx Cats

A breed of cat that is without a tail, or has only a very short one. There are two varieties of coat length – long and short. The breed originated on the Isle of Man and the Manx government maintains a breeding colony. The lack of tail is due to a dominant mutation and is seen as a spinal deformity, a depression at the end of the spinal column. There may be associated defects in vertebrae, and malfunction of the sphincter muscle. If both parents carry the mutant gene, kittens die before birth. Early deaths in kittens may be due to malformations such as fused vertebrae or spina bifida. Manx cats with a short tail are called 'stumpies'; some are born with tails and are known as 'longies'. Manx cats have longer back legs than forelegs, causing an unusual gait.

'Many-Plies'

(See OMASUM.)

MAP

Mycobacterium avium subspecies *paratuberculosis* is the current name for the bacterium causing JOHNE'S DISEASE.

Marans Chickens

A medium-sized chicken originating from France. It is used for meat and eggs, laying 150 eggs (dark brown) per year. There are nine colours, with black copper (black with copper feathers on the neck) and cuckoo (barred feathers giving a black and white speckled appearance) the commonest; there are also golden cuckoo, black, birchen, wheaten, black-tailed buff, white and Columbian. All have red and orange eyes and white feet.

'Marble Bone Disease'

(See OSTEOPETROSIS.)

Marbofloxacin

A quinolone antibiotic. (See QUINOLONES.)

Marburg Disease

Also called 'Green Monkey Disease', this is a severe fatal disease of laboratory workers exposed to the

VetBooks.ir

virus carried by the green vervet monkey (*Cercopithecus aethiops*). Clinical signs in man are fever, headaches, general pains, vomiting and diarrhoea. Signs in experimentally infected monkeys include fever and anorexia. The cause is the Marburg virus, a Rhabdovirus. There is no effective treatment and no vaccine. (See MONKEYS, DISEASES OF.)

Marek's Disease (MD)

This contagious disease of domestic poultry was first described in Austria-Hungary in 1907. It was first recorded in America in 1914, and in Britain in 1929, and spread widely. The availability of vaccines, with good hygienic practice, has greatly reduced the losses from Marek's disease, which is a neoplasm caused by a herpesvirus. Turkeys are rarely affected as they normally harbour a different herpesvirus – one that affords protection against Marek's disease. The turkey virus has been used in a vaccine for chickens.

Formerly called fowl paralysis, Marek's disease had, before the advent of vaccination against it, become the most economically important disease of poultry in many countries, in terms of fowl mortality, carcase condemnation, and lost egg production.

At least two forms of Marek's disease are recognised: the classical form, in which paralysis – to a varying degree – is the outstanding feature; and an acute leukosis form, in which lymphoid tumour formation is the main feature, with nervous signs less in evidence. (See LYMPHOID LEUKOSIS.)

Cause A herpesvirus, which may persist for long periods in litter dust. There are three serotypes: 1. pathogenic strains, CVI/Rispens strain; 2. non-pathogenic strains; 3. HETEROLOGOUS strains HVT.

Once infected, birds may remain infected throughout life.

Signs The classical form affects birds commonly between the ages of three and four months, but cases have been recorded in broilers a little over three weeks old, and also in birds over a year old. It is frequently noticed that certain strains of birds are affected – in-contact birds of a different parentage remaining healthy. Affected birds may show lameness of one or both legs: this lameness becomes progressively worse, and general paralysis results. A common attitude for an affected bird to adopt is to lie about with one limb extended in front and the other extended behind. In spite of this the bird appears alert and will feed if placed beside a supply. Drooping of wings may be noted. In some cases the tip of the wing may touch the ground. Eye lesions may be seen.

In the acute form of Marek's disease, birds as young as six to eight weeks may be affected. Loss of appetite and depression are noticeable; tumours can often be palpated – these involving abdominal organs, muscles, skin and sometimes the comb. Paralysis is not the predominant characteristic of this form of the disease.

Mortality The mortality varies, but in birds six to eight weeks old may exceed 20 per cent. It is difficult actually to arrive at a satisfactory figure as this disease may co-exist with others, e.g. COCCIDIOSIS, TAPEWORM infestations, AVIAN TUBERCULOSIS and vitamin deficiency, etc.

Control measures Vaccination at one day old may be repeated at two to four weeks; it provides 80 to 90 per cent protection in the case of an outbreak.

On the disease being diagnosed, all affected birds should be destroyed as soon as the first signs are observed. The disease is always introduced to a farm by the purchase of fresh stock, in the form of eggs, day-old chicks, or adult birds.

Careful selection of the source of fresh stock is vital in maintaining disease-fee flocks.

Both the fowl tick, *Argas persicus*, and the darkling beetle can harbour the virus of Marek's disease.

Vaccines Freeze-dried and 'wet' cell associated vaccines are available. The latter are stored in liquid nitrogen; care is needed in handling as the ampoules may shatter or cause freeze burns. The manufacturers' instructions must be followed.

Mare Reproductive Loss Syndrome

A condition which occurred in several USA states in 2001, characterised by early and late abortions, weak and sickly foals with pericarditis and uveitis. The cause was suggested to be Eastern Tent caterpillars (*Molacosoma americanum*), but there also appeared to be other factors, such as fungi. Large numbers of *Streptococcus* spp., and *Actinobacillus* spp. may be present. Sows also abort when consuming these caterpillars.

Mares, Infertility in

(See under EQUINE GENITAL INFECTIONS IN THE MARE.)

Marie's Disease

(See HYPERTROPHIC OSTEOPATHY.)

Marijuana Poisoning, Cannabis Poisoning

Marijuana (cannabis) poisoning has occurred in dogs in the USA and the UK as a result of being

given homemade sweet biscuits containing the drug or scavenging discarded smoked 'joints', etc. Signs include acute depression, retching or vomiting, and a staggering gait. The dogs may be ill for 36 to 48 hours and vomiting may be frequent, with salivation and diarrhoea, muscular tremors, and weakness, comas, fits and unexplained (hallucinatory?) barking. Dilated pupils and mild urinary incontinence can also be seen. A few dogs develop severe signs and become agitated, having high blood pressure, distress and continually dribbling urine. Treatment depends on signs but may include fluid replacement and sedation.

Marine Toad
(See TOADS.)

Marketing Authorisation
Generally, medicines sold for animals must have a marketing authorisation (MA) for use in that species. These licences are granted by the licensing authorities, in the case of the UK, the VETERINARY MEDICINES DIRECTORATE, following submission of a dossier by the manufacturer concerned.

Markets
Markets are covered accommodation for the sale of animals. Shelter must be provided for dairy cows in milk, calves, lambs and pigs. Animals showing any sign of disease, or which are unfit, must be put in special pens and not offered for sale. Because of the contact between animals from different sources, disease can spread rapidly. Strict regulations apply to the running of a market and the transport of animals to and from markets. The legislation involved is the Welfare of Animals at Markets Order 1990 and the Welfare of Horses and Ponies at Markets (and Other Places of Sale) Order 1990.

'Marmite Disease'
A form of dermatitis encountered in piglets three days old and upwards. Some cases improved by giving Marmite. (See 'GREASY PIG DISEASE'.)

Marrow
The soft substance that is enclosed within the cavities of the bones. Yellow marrow owes its colour to the large amount of fat contained in it, while red marrow is of a highly cellular structure. Formation of the red blood cells (erythrocytes) takes place in the marrow, as also that of the blood platelets (thrombocytes). The marrow is also the source of lymphocytes (B-cells), monocytes, and other leukocytes. (See BLOOD; BONE; also MYELOCYTE.)

Marsh Gas
(See METHANE.)

Marsh Marigold Poisoning
The marsh marigold, or kingcup (*Caltha palustris*), has occasionally been the cause of poisoning, and is similar in its effects to BUTTERCUP POISONING.

Marsupial
A mammal of an order in which the young are born in an immature state and continue their development in a maternal pouch. Examples are kangaroos and opossums in Australia.

Marteiliosis
A disease caused by the Protistan parasite, *Marteillia refringens* that affects molluscs, especially oysters and is lethal for the European flat oyster (*Ostrea edulis*). It is a NOTIFIABLE DISEASE in the UK and throughout the EU. Infection is confined to spring and summer when water temperatures are above 17°C. The parasite develops mainly in the epithelium of the digestive gland causing poor condition index, emaciation and exhaustion of glycogen reserves, discoloration of the digestive gland and death.

Masham Sheep
The cross resulting from a TEESWATER ram crossed with either a DALESBRED ewe or SWALEDALE ewe. They are found mainly in Northern England. They are long coated with the ewes hornless.

Masitinib
A tyrosine kinase inhibitor used to treat canine MAST-CELL TUMOURS.

Mast Cell
Mast cells are a type of connective tissue cell containing granules that, when activated, can release HISTAMINE and HEPARIN, which cause an allergic reaction in susceptible animals (see ANAPHYLACTIC SHOCK and ATOPIC DISEASE). (See under BLOOD - COMPOSITION - WHITE BLOOD-CELLS; also REAGINIC ANTIBODIES.)

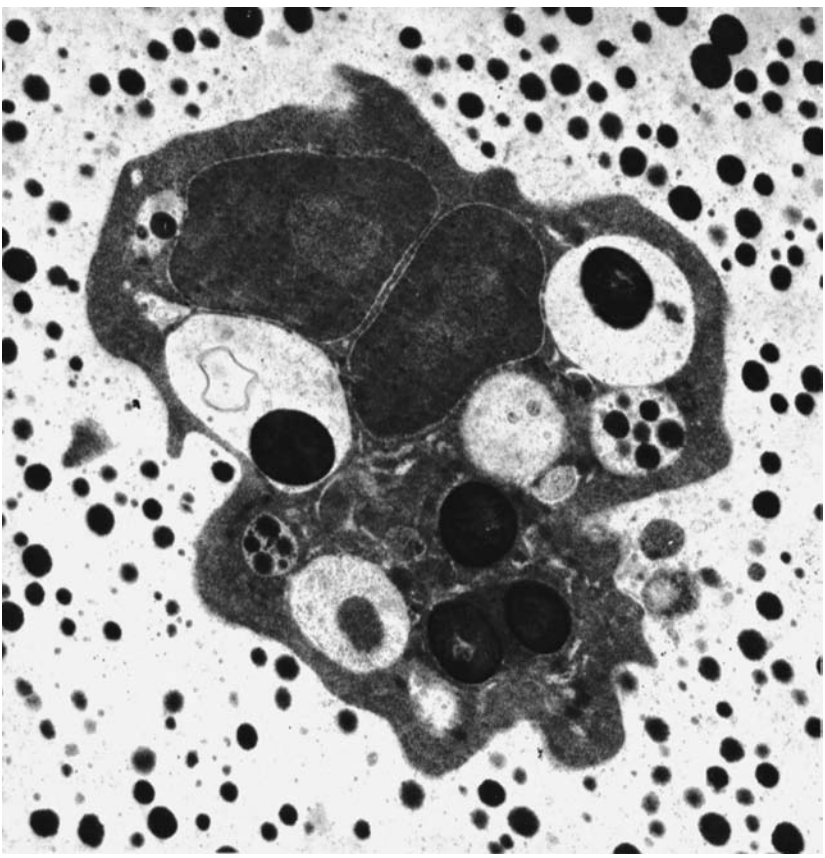
Mast-Cell Tumours
Nodular tumours of the skin which are common in dogs and uncommon in horses, cattle and pigs. They may be benign or malignant and variable in size and appearance. In horses they are normally benign but may become malignant in about 12 per cent of cases. Mast cell tumours are nearly always malignant in man and dogs. Manipulation may result in associated OEDEMA. Treatment is with tyrosine kinase inhibitors such as MASITINIB. (Synonym: MASTOCYTOMA.)

Mastiff
A very large, light-coloured dog with short coat, folded-over ears and a broad muzzle. Hip dysplasia may be present. PROGRESSIVE RETINAL

VetBooks.ir

ATROPHY is a dominant trait and the breed is prone to ECTROPION. They are susceptible to CRUCIATE LIGAMENT RUPTURE. CANINE MULTIFOCAL RETINOPATHY occurs (DNA test available). ENTROPION and GASTRIC TORSION are common.

Mastitis



Inflammation of the udder. (See MAMMARY GLANDS, DISEASES OF, for mastitis in animals other than the cow.)

Mastitis in Cows

Inflammation of the udder, involving the secreting cells of the mammary glands, or its connective tissue, or both.

Subclinical mastitis Mastitis may be unaccompanied by obvious signs. This form commonly reduces milk yields by 10 per cent or so, and is consequently of great economic importance. It has been stated that approximately one cow in three in Britain is affected by subclinical mastitis.

Cell count ranges (cells/cc)	Estimate of mastitis of problem	Estimate of milk production loss per cow per year
Below 250,000	Negligible	–
250,000–499,000	Slight	190 litres (42 gallons)
500,000–749,000	Average	330 litres (74 gallons)
750,000–999,000	Bad	760 litres (169 gallons)
1,000,000 and over	Very bad	885 litres (197 gallons)

In bovine mastitis, as in other inflammations caused by micro-organisms, neutrophils, a type of white blood cell (*leukocyte*), migrate from the blood into the inflamed tissue as the first line of defence. In this electron micrograph (magnification ¥ 7000) a neutrophil or phagocyte is shown to contain five staphylococci.

VetBooks.ir

Simple tests have been used to detect the presence of an abnormally high content of white cells in an ordinary-looking sample of milk, and so indicate the presence of mastitis. Once it is known that it exists, bacteriological tests can be used to identify the organisms responsible and to determine the best treatments. Sometimes an excess of white cells (more than 500,000 per ml) in the milk is the result of inflammation due to trauma and not to infection. Thus the CALIFORNIA MASTITIS TEST or Whiteside Test may draw attention to a faulty milking machine or bad milking technique.

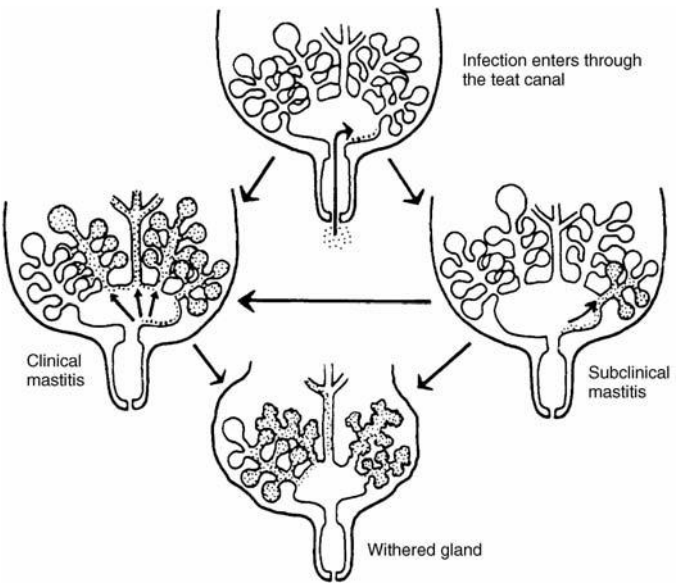
The mastitis situation in a herd can be monitored on a monthly basis by laboratories operating electronic cell counters. The table shows the ranges of white cell counts.

The graph shows the spread of mastitis in an autumn calving herd.

Mastitis tends to rise as the winter progresses and fall when the cows first go out to grass. The cell counts rise again in July and August chiefly because of the high proportion of the cows nearing the end of their lactation. Cell counts and mastitis levels fall again in September when some of the older cows are being culled and first calf heifers are coming into the herd. Mastitis levels rise again through the winter period.

Clinical mastitis should be regarded as a herd problem.

Acute Shivering may usher in the attack. Later, there is a rise in temperature; fast, full pulse; short, quick respirations; and an uneasy appearance. The animal paddles with her feet, but is usually afraid to lie down on account of the pain occasioned to



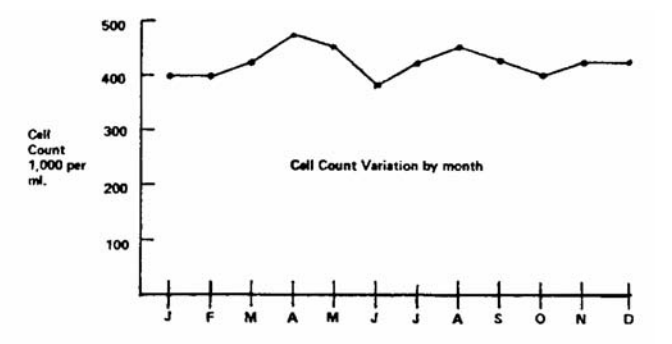


Diagram showing the relationship between the amount of mammary gland tissue involved and the form of mastitis which results.

The spread of mastitis in an autumn calving herd. (Milk Marketing Board.)

VetBooks.ir

the udder. She refuses food, and rumination is in abeyance. When the udder is examined it is found that one (or more) quarter is swollen, tense, reddened, and very painful to the touch; the cow may stand with her hind-legs straddled apart.

'Summer mastitis' (often involving gangrene of the udder) usually occurs either in heifers or in dry cows; however, it is seen occasionally in cows just after calving. It is now thought to be initiated by *Strep. dysgalactiae* and then caused by *Trueperella* (formerly *Arcanobacterium* and earlier *Actinomyces*) *pyogenes* and other pathogenic bacteria (e.g. *Peptococcus indolicus*).

'Summer mastitis' is something of a misnomer, in that, while it is most common in July and August, it is also seen in January and February.

If the gangrene affects a large part of the udder's quarter, or when more than one quarter is attacked, the condition of the cow is serious in the extreme. The animal may stand aloof from the rest of the herd, sometimes paddles with her hind feet, and is obviously in pain. On examination the trouble is soon located to the udder, where hardness – but not necessarily swelling – of a quarter is detected. Foul-smelling pus (grey, greenish-yellow or blood-stained) is present.

Treatment Antibiotics, by injection or intra-mammary administration, may save the animal's life, though use of the quarter is usually lost.

Prevention The injection into the teat-canal of long-acting intramammary antibiotic prior to turning out, repeated every three to six weeks depending on the product used, during summer. (In maiden heifers and in-calf heifers, this procedure may be difficult and not always practicable. Care is needed to avoid both damage to the teat and the introduction of pathogenic bacteria.)

Give such protection against flies as is practicable.

Subacute mastitis The disease runs a course not unlike that of the acute form, but the signs appear much more slowly. There is a greater difficulty in milking, the first drawn milk often containing little clots and always large numbers of shed epithelial cells; later, there is a gradually increasing pain and swelling in the affected quarter, accompanied by an alteration in the colour of the milk to yellowish or yellowish-grey. The amount of milk decreases. As a rule, appetite remains normal, pulse and breathing are unaltered, and if there is any rise in the temperature it is slight.

Chronic mastitis shows little general constitutional disturbance, and an almost complete absence of pain, a slowly progressing increase in the density of the gland, a diminution in the secretion of milk, and a gradual increase in the size of the affected quarter or quarters.

Pathological changes in the udder may render any antibiotic ineffectual. One such problem is the survival within phagocytes of staphylococci, where they are protected from the lethal action of most antibiotics. (See PHAGOCYTOSIS.)

Antibiotics can more economically be used when the cow is in the dry period. Long-acting antibiotics can then be given without aggravating the problem of antibiotic residues in milk. (See under MILK - ANTIBIOTICS IN MILK.)

Bacterial mastitis *Staphylococcus aureus*, *Streptococcus agalactiae*, *S. uberis* and *S. dysgalactiae* are among the main organisms responsible for mastitis. However, *S. dysgalactiae* is seldom a serious problem; *S. uberis* is more resistant.

A survey showed *S. uberis* to be the major pathogen associated with dry cow mastitis.

Coliform or 'Environmental' mastitis has become increasingly prevalent in recent years, and is common during the winter. This infection of the udder is often long-lasting, and the cow is ill with it, so that its economic effects may be greater than with streptococcal or staphylococcal mastitis. Many outbreaks have been linked with cold, wet weather; they are aggravated by damp bedding, sawdust, and muddy conditions underfoot when strip-grazing kale, etc. The above conditions would appear to favour the entry of *E. coli* through the teat-canal, but the organism may also reach the udder via the bloodstream in cattle that are scouring – often after a sudden change of diet – as a result of an active *E. coli* gut infection.

'Experimentally, severe cases of coliform mastitis can be produced only in early lactation following the stress of calving – a situation commonly prevailing in naturally occurring field cases.' (IRAD, Compton.) (See COLIFORM.)

Klebsiella spp. and *Enterobacter aerogenes* are other organisms involved in mastitic infections.

Leptospiral mastitis Leptospiral infection often causes agalactia rather than mastitis. However, in an outbreak in Northern Ireland, involving half a herd of 140 cows over a two-month period, signs included a sudden drop in milk yield, flaccid udders with all four quarters affected, thickish and sometimes bloodstained milk, fever (a temperature of up to 41° C [106° F]), and quickened breathing and pulse rates. The illness in individual cows lasted from one to four days. *Leptospira hardjo* was isolated from the milk and blood of cows with clinical mastitis. (See LEPTOSPIROSIS - CATTLE.)

Among other bacteria which may cause mastitis are *Bacillus subtilis*, which has been isolated from

VetBooks.ir

washing water, header tanks and teat-cup liners; *Pseudomonas*; and *Chlamydia*. *Campylobacter jejuni* has also caused mastitis.

Mycoplasmal mastitis occurs in Britain and many other countries, and may prove resistant to antibiotics. In an outbreak in North Wales over a five-week period, half a herd of 115 cows became infected, and 14 had to be sold for slaughter. The milk was at first brownish in colour. The mastitis was rapid in onset, producing a hard swollen quarter which was neither hot nor tender; the cows showed little sign of general illness. Unlike in other forms of mastitis, there was a rapid spread to other quarters of the udder. The first isolation of *Mycoplasma californicum* from cows with chronic, incurable mastitis in the UK was made in 1982 – 10 years after its first isolation in California. Other species include *M. bovigenitalium*.

Viral mastitis has been associated with VESICULAR STOMATITIS and INFECTIOUS BOVINE RHINOTRACHEITIS.

Mycotic mastitis More than 25 species of fungi have been implicated. The worst of these is called *Cryptococcus neoformans* and it can cause outbreaks of mastitis severe enough to lead to cows being slaughtered.

Algal mastitis A UK outbreak of severe indurative mastitis in newly calved cows, from which *Prototheca zopfii* was isolated, has been reported. (See ALGAE.)

Man-to-cow-infections Occasionally, mastitis in cattle arises from infection by human beings. The kind of streptococci which can give rise either to a severe sore throat or to scarlet fever can result in an outbreak of mastitis in a dairy herd, and several such outbreaks have been reported in various countries. The pneumococcus, a cause of human pneumonia, has been isolated from the udders of cows with streptococcal mastitis in Essex, Bedfordshire, and other counties, the source being the cowman's throat. *Campylobacter jejuni* has also been transmitted from man to cow. (See under MILK-BORNE DISEASE for *Corynebacterium ulcerans*, etc.; see also SALMONELLOSIS.)

The spread of infection Infection enters by way of the teat and can easily be spread from cow to cow by milkers' hands or the cups of the machine, but apparently less easily by the latter method. Udder cloths and towels are also commonly infected. It has also been shown that in an infected herd, a large proportion of sores or chaps harbour organisms, and these may be a source of infection of the udder itself in the same cow or in another. The skin of the teats and the milkers' hands may remain infected from one milking to another, and in a heavily infected herd the skin of the cows' bodies, milkers' clothes, floor, partitions, etc. become contaminated and may remain so for considerable periods.

Treatment Proper treatment depends upon a correct diagnosis and the use of suitable antibiotics in adequate dosage, introduced into the udder with aseptic precautions so as not to introduce further (and perhaps more virulent) infection. Adequate dosage is important, as otherwise strains of resistant organisms may arise. In some cases sulfanilamide may be used. Doubling vitamin E levels in the diet may reduce susceptibility to mastitis. (See ANTIBIOTIC RESISTANCE.)

The control of mastitis An important aid is teat-dipping. The liquid mainly used for teat-dipping is an iodophor – a type of disinfectant containing iodine but extremely mild in its effect upon the tissues. Good results can also be obtained with hypochlorite teat-dips containing 1 per cent available chlorine.

In rotary parlours with automatic cluster removal equipment and only one operator, teat-dipping is often impracticable and teat-spraying (probably less effective) is the only alternative.

A second recommendation is the wearing by the dairyman of smooth rubber gloves, which can be dipped in disinfectant before the udder is washed. They represent a partial solution to the problem created by the fact that hands cannot be sterilised.

Warm-water sprays may be used for udder-washing, and disposable paper towels for drying. The latter obviate cross-infections from udder cloths, which should not be used. (See also SPONGES.)

If warm-water sprays are not available, wash the udder (if very dirty) with plain warm water first, then with an udder wash; numerous proprietary formulations are available, based on benzalkonium, cetrimide, chorhexidine, solubilised iodine, etc. If none of these is available, a 1 per cent solution of cetrimide may be used.

It is significant that in herds with a low incidence of mastitis, udder-washing is avoided in 40 per cent and practised only in 11 per cent (but see MILK - SEDIMENT IN MILK).

Questions which the farmer must ask are as follows:

1. Is the person doing the milking capable of handling the cows properly, and keen to do so?
2. Are the vacuum gauges and cup-liners kept correctly adjusted?
3. Is hand-stripping avoided?
4. If a disinfectant is used, is it used at the correct strength?
5. Are there disposable paper towels?

VetBooks.ir

6. Are there any old, chronically infected cows in the herd which do not respond to treatment and would be better disposed of?
7. Is fly-control being practised in the milking parlour?
8. Is attention being given to the 96-hour rule regarding the withholding of milk from a cow after calving, whether treated with antibiotics or not?

Rough inexpert milking and stripping predispose to mastitis. With machine milking, the use of a badly designed teat-cup liner, for instance, or leaving the cups on an empty quarter, may lead to trouble. (See under MILKING MACHINES for faulty use of these, leading to mastitis.) Bruising is an important predisposing cause, and for this reason cows should never be hurried, especially before milking, as the udder may be injured. This applies particularly to older cows in which the udder is large and pendulous. Chilling must be avoided, and also chapped teats (the latter should be left dry after milking). Even the smallest injuries and sores on the teats should be carefully attended to, since the germs which gain entry to these so often gain entry to the udder later.

Routine use of the strip-cup is helpful. If flecks or clots are seen in the milk, segregate the cow(s) if practicable, and – in any case – milk after the others. When a strip-cup is used, care should be taken to see that neither the handle nor the fingers become a source of infection to clean cows. Use the cup **before** the udder is washed.

Dry-cow therapy It has been shown in large-scale field experiments that the best time to treat cows to eliminate infection from the udders is during the dry period. Particularly with staphylococcal infection, there is a better chance of removing infections at this time than during lactation, and better results are achieved when cows are treated in the subclinical phase of the disease rather than during a clinical attack. Treatment during the dry period not only eliminates most of the existing infection; it also prevents most of the new infections from occurring during the dry period, including 'summer mastitis'. Another advantage is that there is no problem of milk being contaminated with antibiotic(s), provided that a cow is dry for 6 weeks or longer. It is advisable to treat **all** cows. Preparations containing cloxacillin have proved very effective. Teat-dipping of dry cows is also useful in preventing summer mastitis.

Control measures summarised (The Six Point Plan)

1. Records Keep all details of cell-count figures on a monthly basis and use these to monitor the incidence of mastitis in the herd. Record also details of milking-machine testing and maintenance.

2. Milking machines Have machinery tested regularly and thoroughly at least once a year. At each milking check the vacuum pressures, pulsation rates, air bleeds and liners. Remember that machines are used 730 times a year and faulty machines can lead to a mastitis build-up.

3. Teat-dipping and hygiene Use an effective iodophor-plus-lanolin teat-dip on each quarter as the cluster is removed. Wear smooth rubber gloves for preference; use the fore-milk cup before washing the udders with clean, running water. Use clean paper towels – not a dirty cloth – to dry the udders.

4. Dry-cow therapy The farmer's veterinary surgeon will not only advise generally on mastitis control, but will also recommend the appropriate treatment at the end of lactation. This will include the infusion of a specially formulated, long-lasting antibiotic into each quarter, to destroy residues of infection and to counter new infections in the dry period.

5. Treatment Clinical mastitis can occur at any time and will need prompt attention immediately by the veterinary surgeon, who can advise on the correct treatment during lactation.

6. Culling Any cow which has several attacks of clinical mastitis in a lactation endangers the rest of the herd. Records of treatments and responses will identify those cows with recurring cases in one lactation and show which should be culled from the herd.

The cow's own protection 'Pathogens invading the mammary gland of the cow are subjected to non-specific resistance factors at two levels, either in the teat-canal or in the mammary gland itself. The teat-canal acts as a mechanical barrier, but in addition invading pathogens within the canal are subjected to the activity of antimicrobial fatty acids and cationic proteins. Pathogens breaching these barriers are then subjected to the defences of the mammary gland itself. In the early stages of infection there is a considerable increase in somatic cells in the milk, which is associated with an increased resistance to infection. During the early stages of the inflammatory reaction the invading pathogens are exposed to the action of neutrophils, locally produced humoral factors and proteins from the systemic circulation which pass into the mammary gland. These serum factors include the immunoglobulins, complement units and other antimicrobial proteins.' (Dr K. G. Hibbitt and Dr A. W. Hill, IRAD, Compton.)

Breeding for resistance to bovine mastitis may be possible in the future. (See MAJOR HISTOCOMPATIBILITY SYSTEM.)

VetBooks.ir

Mastitis in Ewes

Common causes are *Mannheimia* haemolytica, which can produce a peracute mastitis with gangrene, and *Staphylococcus aureus*. Once the ewes are separated from their lambs, dry-cow intramammary preparations may be used as a preventive measure. It is essential to use one tube per teat to prevent cross-contamination.

Mastitis in Goats

Mastitis in goats can be a problem in humans as the milk is often unpasteurised. Potential infectious organisms include *Streptococcus zooepidemicus*, *S. pneumoniae, Actinobacillus equuli, Mannheimia (Pasteurella) haemolytica* and *Staphylococcus aureus.*

Mastitis in Rabbits

Does have four or five pairs of mammary glands and teats. One or more gland may be affected and become swollen and painful. Causes can be infection, mainly *Pasteurella multocida*, hormonal imbalances or local infection of wounds or neoplasia. Treatment is with antibiotics, analgesics and fluid.

Mastitis Metritis Agalactia Syndrome (MMA)

Mastitis metritis agalactia syndrome (MMA), also known as farrowing fever, is a common problem in sows in the first two days after farrowing. The sow is off its food and the temperature rises; the udder may be partially or wholly swollen and painful. The piglets are restless.

Treatment involves antibiotics, possibly with anti-inflammatory agents. The piglets must be fed while the problem persists.

Mastocytoma

A type of TUMOUR which is common in the dog and involves skin and subcutaneous tissue; occasionally muscle. A mastocytoma may be malignant. It contains numerous MAST CELLS. In cattle this tumour is also regarded as potentially malignant. (See MAST-CELL TUMOURS.)

Maternal Antibodies

Their function in protecting the offspring from infections encountered by the dam is referred to under COLOSTRUM. Antibodies made by the dam pass to the offspring either by the COLOSTRUM (ruminants, horse) or sometimes across the PLACENTA (dog, cat). The immunity so produced and acquired by the young is a temporary one, and wanes but it can interfere with the effect of VACCINATION so that the timing of vaccinations to induce lasting immunity is crucial (see DISTEMPER - PREVENTION); for if carried out while the level of maternally derived antibody is significant, vaccination will fail. (See also MEASLES VACCINE; CANINE PARVOVIRUS.)

1. Abbreviation for MUCOSAL DISEASE. (See BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE.)
2. Abbreviation for MAREK'S DISEASE.

ME

(See METABOLISABLE ENERGY.)

Meadow-Saffron Poisoning

The meadow saffron (the autumn crocus, *Colchicum autumnale*), a common inhabitant of meadows, hedge bottoms, and woodland areas in England and Wales, is a cause of poisoning among horses and cattle. Pigs may sometimes eat the bulbous root (corm) and suffer, but sheep and goats are resistant. All parts of the plant are poisonous, both when green and when dried in hay, but the toxicity varies at different times of the year. Cases of poisoning are usually seen in the spring, when the leaves and seed-vessels are produced, and then again in summer and autumn (from August to October), when the flowers are formed.

The poison, (colchicine) is present in largest amounts in the seeds and corms; it is cumulative in its action.

Signs When only small quantities have been taken there is loss of appetite, suppression of rumination, profuse dribbling of saliva, and diarrhoea. The excretion of colchicine by the kidneys causes irritation in the urinary bladder, and induces the animal to pass urine in small amounts almost as soon as it is formed. Blood may be present in both the urine and the milk of dairy cows. Abortion is common in pregnant cows and heifers.

When large amounts have been eaten, the signs include ataxia and abdominal pain; death may occur in from 16 hours to 4 days.

The plant should be eradicated from pastures in the autumn when its striking pale purple crocus-like flowers can be easily seen. The bulbs should be dug out or cut with a hoe.

Meal-Feeding in Piggeries

This can result in a very dusty atmosphere under some circumstances, causing coughing and a feeling of tightness in the chest in people working there, and sometimes to a false assumption that the pigs are coughing because of enzootic pneumonia.

Meal-Worms

The inaccurate, but commonly used, term for larvae of the darkling beetle, *Tenebrio molitor*, a natural scavenger of grain stores. The larvae are often raised intensively and sold as a food source for captive reptiles, fish and birds. They are also sometimes used by anglers as live bait. They are a rich protein source but are often raised on bran and so require to be fed on nutritional supplements before they are fed to their intended consumers.

Mean Corpuscular Haemoglobin (MCH)

The volume of an individual red blood cell measured in femtolitres (fl or 10^{-15}L). It is used to define ANAEMIA with microcytic anaemia (small than MCV average), normocytic anaemia (average MCV) and macrocytic anaemia (large than MCV average).

Mean Corpuscular Haemoglobin Concentration (MCHC)

The concentration of HAEMOGLOBIN in a given volume of packed red cells. In ANAEMIA, the MCHC is low in hypochromic anaemia, normal in normochromic anaemia (where blood cells are large) and high in hyperchromic anaemia.

Mean Corpuscular Volume (MCV)

Measures red blood cell size. It is calculated by dividing the HAEMATOCRIT VALUE by the total volume of packed red cells. In ANAEMIA, values below MCV range indicate microcytic anaemia, within normal range normocytic anaemia, and above normal range macrocytic anaemia.

Measles

(See under MONKEYS; LEISHMANIASIS.)

'Measles' in Beef

The presence of the cyst stage (*Cysticercus bovis*) of the tapeworm *Taenia saginata* (which is a parasite of man). The cysts are found in the muscle fibres or connective tissue. (See TAPEWORMS.)

'Measles' in Pork

The cystic stage (*Cysticercus cellulosae*) of the tapeworm *Taenia solium* (which is a parasite of man). People are infected by eating the cysts in pork, but man can also harbour the cyst. (See TAPEWORMS.)

Measles Vaccine

An attenuated measles virus vaccine may be used in the dog to give protection against distemper. (See also under DISTEMPER.) Measles vaccine can overcome low levels of maternally derived antibodies and may be used from five weeks old.

Meat

(See PORCINE STRESS SYNDROME; HORSE-MEAT; DOGS' DIET, and below.)

Meat, Dark

Meat with limited fat cover and intramuscular fat appears dark. This is seen particularly in bull carcases, and horse meat is always dark in colour. Dark cutting beef is possibly the single biggest cause of loss to beef processors. It is caused by a deficiency of glycogen in the muscles of an animal at slaughter which prevents the normal decrease in pH post-mortem. As a result there is an increase in enzyme activity; this uses up the oxygen which would normally convert the dark myoglobin into pink oxymyoglobin and the meat appears dark. It also tends to be dry because of the higher water-binding capacity of muscle protein at a higher pH. The stores of glycogen are depleted principally by muscular exhaustion and stress, and these 2 factors must be avoided in the 48 hours before slaughter in order to minimise the risk of dark cutting beef. (See also PORCINE STRESS SYNDROME.)

Long fasting times are associated with a reduction in carcase yield in pigs and an increase in the incidence of dark, firm, dry (DFD) meat.

Meat, Knacker's

This was formerly used for the feeding of pet animals after being sterilised. (See MEAT (STERILISATION AND STAINING) REGULATIONS 1982; EARS AS

VetBooks.ir

VetBooks.ir

FOOD.) Unsterilised meat may be infested with viable hydatid cysts, or be infected with ANTHRAX or TUBERCULOSIS. It can therefore be a danger to public health. (See also SALMONELLOSIS; *E. Coli*; BOTULISM; AUJESZKY'S DISEASE; HORSE-MEAT.)

Meat and Bone Meal (MBM)

A product from rendering animal carcases that was formerly used as a feed for animals in the UK and parts of Europe. Following the appearance of BOVINE SPONGIFORM ENCEPHALOPATHY and its part in spreading the disease, it has been banned from ruminant and other farm animal feeds in the EU. It was a useful CALCIUM source for animals and is used in gardens.

Meat and Livestock Commission (MLC)

The Meat and Livestock Commission was set up following the Agricultural Act of 1967. Its role was to provide research, improvement and recording of the 'red meat' species (cattle, sheep, pigs) by improving genetics and rearing method, to improve meat slaughter and production and to promote meat consumption. It was funded by a levy of all animals slaughtered. On April 1st 2008 it became part of the AGRICULTURE AND HORTICULTURE DEVELOPMENT BOARD, which included the BRITISH PIG EXECUTIVE and the ENGLISH BEEF AND LAMB EXECUTIVE. (See also HYBU CIG CYMRU; QUALITY MEAT SCOTLAND.)

Meat DNA Testing

Meat can be tested for species present (horse, cattle, pig, sheep, poultry) and in some cases the breeding (e.g. ABERDEEN ANGUS). Other testing can help detect meat and bone meal or FISH-MEAL.

Meat-Handlers' Occupational Hazards

Many of the infectious diseases that affect animals can be transmitted to abattoir workers and may cause illness. They include infection by beta-haemolytic streptococci, which can infect cattle, sheep, pigs and chickens. People involved in the slaughter of these animals may be exposed to ringworm and impetigo, and any cuts on their hands may become infected. (See also under ZOONOSES; *also under* specific examples such as ORF; LEISHMANIASIS

Meat-Hygiene Regulations

Requirements for the production, inspection, cutting, storage and transport of fresh meat for domestic use and export are set out in the following legislation: The Fresh Meat (Hygiene and Inspection) Regulations 1995; The Poultry Meat, Farmed Game Meat and Rabbit Meat (Hygiene and Inspection) Regulations 1995; The Minced Meat and Meat Preparations (Hygiene) Regulations 1995; The Meat Inspection Regulations 1987 (amended 1990); The Slaughterhouses (Hygiene) Regulations 1977; The Slaughterhouses (Hygiene) and Meat Inspection (Amendment) Regulations 1991. (See also LAW).

Meat inspection in all UK licensed abattoirs is controlled by the Meat Hygiene Service, a government agency.

(See also FOOD INSPECTION.)

Meat Irradiation

This is used in the USA as a safe and effective food-safety technology in meat and poultry. Because of American legislation problems, irradiation is considered to be a 'food additive'. Maximum ionised irradiation levels are set for each type of meat and its duration. It is most effective against organisms with large amounts of DNA, thus parasites and insect pests are rapidly killed; more irradiation is required to kill bacteria, and viruses are resistant to irradiation at the doses used. The process increases the keeping time of meat by acting as a 'pasteurisation of solid foods'. Currently the process is not permitted in the EU.

Meat Pathogen Inhibitors

Meat can become contaminated by food-borne pathogens. Various additives can inhibit or reduce bacterial growths, including sodium nitrate and sodium NITRITE, CELERY juice, and OLIVE powder.

Meat Scraps, Bones

These can be a source of foot-and-mouth disease or swine fever infections. They should never be fed to pigs. (See SWILL; also under TUBERCULOSIS.)

Meat (Sterilisation and Staining) Regulations 1982

These require all knacker's meat to be sterilised before being supplied to owners of pets, kennels, etc. In 1982, new controls on the trade in meat unfit for human consumption came into force. If not sterilised, meat must be stained; likewise offal. Poultry meat is exempt. The colouring agent used is black PN or brilliant black BN.

Meatus

Meatus is a term applied to any passage or opening; e.g. the external auditory meatus is the passage from the surface to the drum of the ear.

Mebendazole

A broad-spectrum anthelmintic used in herbivores including horses and donkeys.

Meckel's Diverticulum

Meckel's diverticulum, of human pathology, apparently has a veterinary equivalent – a finger-

VetBooks.ir

like projection from the small intestine, recorded as a congenital abnormality in the dog and found in poultry.

Meclofenamic Acid
A NSAID used in horses for inflammatory leg conditions and for pain relief after trauma and surgery.

Meconium
Faeces present in the rectum of a newborn animal. They should in all cases be discharged soon after birth. In the first milk of the dam there is a natural purgative for this purpose. (See also ILEUS.)

Medetomidine
A sedative and chemical restraint used in dogs and cats. It can be combined with KETAMINE in the cat as a pre-surgical medication and in the dog before general anaesthesia with PROPOFOL.

Medial
An anatomical term signifying that an organ lies near the midline of the animal. Antonym: LATERAL.

Median Facial Cleft
A fissure that can affect the lips, and maxilla or the palate.

Mediastinum
Mediastinum is the space in the chest which lies between the 2 lungs. It contains the heart, the aorta and vena cava, the gullet, the extremity of the trachea, the thoracic duct, the phrenic nerves, and other structures of lesser importance.

Pneumomediastinum The presence of air in the mediastinum, following damage to lung alveolar tissue near its root.

Medicated Feedingstuff Prescription (MFS Rx)
The type of prescription written by a veterinary surgeon for incorporating medicines in solid or liquid feeds. These are normally supplied as medicated feed premixes. Most veterinary medicated products (VMP) except anthelmintics are classified as POM-V. This replaces the Veterinary Written Direction. MFS containing anthelmintics can be supplied to a keeper of animals on receipt of MFS prescription written by a veterinary surgeon, pharmacist or SQP.

Medicines
(See ACTIVE MEDICINE, ALTERNATIVE MEDICINE, CAUSAL MEDICINE, COMPLEMENTARY MEDICINE, CONSERVATIVE MEDICINE, EMPIRIC MEDICINE, EXPECTANT MEDICINE, PALLIATIVE MEDICINE, PREVENTIVE MEDICINE, PROPHYLACTIC MEDICINE, RATIONAL MEDICINE, SPECIFIC MEDICINE, SUPPORTIVE MEDICINE, SYMPTOMATIC MEDICINE.)

Medicines Act 1968
The Medicines Act 1968 was designed to control many aspects of the manufacture, testing and marketing of medicines for human and animal use. In particular, its aim was to bring safety standards up to those already enforced by the leading companies. The Act required wholesalers, importers and manufacturers to obtain licences. (See also VETERINARY PRODUCTS COMMITTEE.)

The Act classifies those medicines which may be sold to the public only on a veterinary prescription (PM), and those which may be purchased from pharmacies (P) and from other outlets (GSL). It is now mainly superseded by the VETERINARY MEDICINES REGULATIONS which can be altered annually.

Medicines Act Veterinary Information Service
(See MAVIS.)

Medicines (Labelling of Medicated Animal Feeding-Stuffs) Regulations 1973
These set out the detailed particulars required on labels of containers or packages of medicated animal feeds. The Medicines (Labelling) Regulations 1976 covered the labelling of containers and packages for medicinal products.

Mediterranean Fever
A tick-borne disease of cattle and the water-buffalo, occurring in Southeast Europe, Africa and Asia, and caused by the protozoan parasite *Theileria annulata*.

Signs Fever, loss of appetite, a discharge from eyes and nose, anaemic pallor of mucous membranes and constipation followed by diarrhoea. Survivors recover very slowly.

Mediterranean Spotted Fever
A human disease.

Cause *Rickettsia conori*, transmitted by a dog tick.

Signs Fever, nausea, vomiting, headache, muscle pain, and a rash.

Medroxyprogesterone
A drug the acetate form of which is used orally to interrupt or prevent oestrus. It should not be given to immature or pregnant bitches, animals with a history of abnormal reproductive cycles or animals with neoplasia (see NEOPLASM) or DIABETES MELLITUS or where PYOMETRA is a possibility.

Medulla Oblongata
That part of the brain which connects to the spinal cord (see BRAIN).

Medullary Cavity
Marrow cavity of bones.

Meerkats
Also known as suricate (Suricata *suricatta*), these are small mammals of the mongoose (*Herpestidae*) family found in southern Africa. They usually live in clans, mobs or gangs of about 20. They normally survive 12 to 14 years. The wild animals possess commonly many ECTOPARASITES including ticks, fleas (including a new species *Echidnophaga suricatta*) and mites (*Demodex* spp.); gastrointestinal parasites also occur frequently.

Mega- and Megalo-
Mega- and megalo- are prefixes denoting largeness. Strictly speaking, mega indicates a multiple of one million times, as in megabyte.

Megabacteria
These very large bacteria cause illness and death in ostrich chicks, canaries and budgerigars. In the latter the signs include loss of weight, difficulty in swallowing, vomiting and diarrhoea. Sudden death may occur due to haemorrhage. (See *Macrorhabdus ornithogaster*.)

Megabacteriosis
An infection with MEGABACTERIA.

Megajoules (MJ)
A measurement of energy in feeds for ruminants and poultry. It is 1,000,000 (10^6) joules and equals 0.239 calories.

Megakaryocyte
A giant cell of the bone marrow or spleen which produces blood platelets.

Megaloblast
(adjective, Megaloblastic)
It is an enlarged red blood cell still containing a cell nucleus or it remnants, as opposed to a NORMOBLAST. It is seen in PERNICIOUS ANAEMIA and FOLIC ACID DEFICIENCY.

Megaloblastic Anaemia
This is seen as PERNICIOUS ANAEMIA in man and animals and is due to Vitamin B_{12} deficiency due to a lack of secretion of intrinsic factor necessary for the absorption of the vitamin in the ileum. It is also seen in FOLIC ACID DEFICIENCY. (See also ANAEMIA.)

Megalocardia
An increase in size of the heart with a massive hypertrophy. Also called CARDIOMEGALY.

Megalocephaly
Abnormal largeness of the head.

-Megaly
An abnormal enlargement, e.g. of the spleen (which may attain four or five times its normal size in, e.g., babesiosis (red-water) in sheep).

Megaoesophagus
Megaoesophagus implies usually a pathological enlargement of the oesophagus, such as may be seen in FELINE DYSAUTONOMIA and 'FLOPPY' LABRADORS. It can occur in some other dog breeds including GERMAN SHEPHERD DOGS, IRISH SETTERS, RHODESIAN RIDGEBACKS and SHAR-PEIS.

Megestrol Acetate
A hormonal product used in bitches as an oestrus suppressant, in cats for the treatment of miliary dermatitis (eczema), and in male cats and dogs to modify aggressive behaviour. Contra-indications are cats with diabetes or genital disease. Prolonged dosage or overdosage may adversely affect the uterus or result in hypertrophy of the cat's mammary glands. (See also OESTRUS, SUPPRESSION OF; DIABETES MELLITUS.)

Meglumine Antimonate
A drug which is used in the treatment of LEISHMANIASIS in dogs. It is administered by subcutaneous injection and can accumulate in tissues; dogs should be monitored for antimony poisoning in prolonged treatment.

Megrims
(See EPILEPSY.)

Meibomian Glands
These are minute sebaceous follicles situated in the eyelids: also called tarsal glands. They produce meibum, an oily substance which prevents TEAR evaporation. Inflammation may develop around an eyelash, and later there may be suppuration with the formation of a STYE.

Meiosis, Reduction Division
Meiosis (reduction division) occurs during the formation of ova in the female and of spermatozoa in the male, and reduces the number of chromosomes by one-half, to the haploid number. (See also MITOSIS.)

Meishan Pigs
A Chinese breed of pigs, of small to medium-size, with large drooping ears and a wrinkled black skin. The breed has large litters, of 15 to 16 piglets. It has been imported to the UK and USA because of

its fecundity for use in hybrid pigs. The breed is not much used on farms because of poor growth and excessive fat.

Melaena
The passing of dark tarry faeces, usually due to bleeding from the stomach or small intestines. The blood undergoes chemical changes as the result of the action of the digestive process, which produces large amounts of sulphide of iron.

Melamine
A chemical containing a high nitrogen content and, as crude protein is measured as its nitrogen content, it has been added to human and animal foods to make it look as though the food contains a high protein level. It has resulted in severe problems in all species where it has been ingested as part of the diet.

Melanin
A dark pigment that occurs naturally in the retina, hair, skin, feathers, etc. In the skin, it protects against harmful ultraviolet radiation and is responsible for the darkening effect of suntan. It is also believed to have a role in governing the natural circadian rhythms.

Melanism
Excessive deposition of melanin in the skin or its appendages. In birds it is often associated with the male.

Melanocyte
The pigment-producing cell found in various tissues, especially the skin.

Melanoma
A tumour containing the pigment MELANIN. Melanomas are potentially malignant, and not uncommon in old horses that have been grey and are turning whiter. CIMETIDINE has been used with some success in the treatment of such tumours. Excision is the treatment of choice in small animals.

Melanotic
Melanotic is the adjective deriving from MELANOMA.

Melatonin
Melatonin is a hormone secreted by the PINEAL BODY. It is derived from serotonin during periods of darkness. It is a 'messenger' of day length by which animals recognise the seasons; levels are higher in the winter than the summer. Experiments in housing sheep using artificial light in winter showed that melatonin levels increased.

An implant of melatonin can be used to stimulate onset of reproductive activity and improve fertility early in the season.

Melia, Dhrek
The fruits and leaves of this Asiatic tree, *Melia azedarach*, are poisonous to farm livestock. Abnormal gait, trembling of hind-limbs, paresis, and abdominal pain have been reported in the pig.

Melioidosis
A disease resembling glanders, caused by *Burkholderia pseudomallei* (also called *Pseudomonas pseudomallei*, *Bacillus pseudomallei* and *Pfeifferella pseudomallei*), and occurring in rodents – occasionally in human beings and farm animals – in the tropics. Diagnosis is by complement fixation test and/or identification of the organism. Outbreaks have also occurred in Europe, in zoos. Antibiotics may be useful in treatment.

Melophagus ovinus
(See SHEEP KED.)

Meloxicam
A NSAID licensed as an injection for use in horses and cattle and as a tablet for dogs.

Membrana Nictitans
(See NICTITATING MEMBRANE.)

Membrane
A thin layer of tissue covering the surface of an organ or forming the lining of a natural cavity or dividing a cavity. (See PLACENTA; BRAIN; MENINGES; MUCOUS MEMBRANE; SEROUS MEMBRANES.)

Membranous Nephropathy
A progressive disease of the kidneys of dogs and cats, affecting the glomeruli, and leading eventually (sometimes after several years) to kidney failure. Most cases in the cat are first seen when showing the nephrotic syndrome. There is persistent excretion of protein in the urine, too little protein in the blood, and subcutaneous oedema and/or ascites. (See KIDNEYS, DISEASES OF - NEPHROSIS/NEPHROTIC SYNDROME.)

Meniere's Disease
Spontaneous attacks of loss of balance, particularly recorded in foals. It is caused by the pressure of endolymph in one or both ears. There is some evidence that some cases are due to damage by HERPESVIRUS.

Meninges
The three coverings of the brain and spinal cord: dura mater, arachnoid membrane and pia mater. (see BRAIN – Structure.)

Meningioma
A tumour affecting the meninges, and perhaps the commonest brain tumour in the cat.

VetBooks.ir

Meningitis
Inflammation affecting the membranes covering the brain (cerebral meningitis) and spinal cord (spinal meningitis), or both (cerebrospinal meningitis). When the outer membrane is affected, the condition is called 'pachymeningitis'; when the inner membrane is it is known as 'leptomeningitis' – although it is not often that these distinctions can be determined clinically, for inflammation readily spreads from one to the other.

Causes Meningitis frequently develops in association with viral or bacterial diseases of animals, such as RABIES, TUBERCULOSIS, SWINE ERYSIPELAS and DISTEMPER.

In lambs it may be caused by *Mannheimia* haemolytica; in pigs by *Streptococcus suis* or encephalomyocarditis virus. (See GID; TAPEWORMS.) It may be produced through an external injury which fractures the skull and allows entrance to organisms, or it may appear during the course of other head injuries in which there is no fracture. It accompanies most cases of encephalitis caused by viruses.

Signs As a rule the first signs are those of restlessness and excitement. The animal moves about in a semi-dazed fashion, and stumbles into or against fixed objects. Neighing, bellowing, squealing, and barking, apparently at nothing, may be noticed, and at times the animal exhibits a wild frenzy. After an attack of delirium or frenzy the animal becomes dull and quiet; the head hangs, the eyes stare, the expression is vacant. Other signs, such as turning in circles, falling over, rolling along the ground, turning forward and backward somersaults, resting the head upon any convenient fixed object, such as a loose-box door, lying curled up in an unusual attitude, etc., may be seen in some cases. Paralysis of one side of the body (hemiplegia), of both hind-limbs (paraplegia), or of a group of muscles is not infrequent in the smaller animals.

Treatment Absolute quiet in a dark place is advisable pending professional advice.

Dogs A form of spinal meningitis occurs in which bony tissue is laid down in the spinal canal towards the posterior part of the vertebral column. It is called 'chronic ossifying pachymeningitis' as a consequence. It mainly affects old dogs, and causes inconvenience only when severe. It may lead to complete paralysis of the hind-limbs, accompanied by urinary and faecal incontinence.

In all animals in which meningitis follows injury, the skull should be examined for fractures.

Meningocele
A congenital defect: the protrusion of meningeal membrane through an abnormal opening in the skull or spinal column.

The defect occurs in calves, foals, puppies, kittens, piglets, etc.; it is also a human abnormality.

Treatment is surgical.

Meningoencephalitis
Inflammation of the brain and meninges. There is fever, pain and rigidity, as seen in meningitis; and muscle tremors, hyperexcitability, convulsions and paralysis, as seen in encephalitis. Most cases result from bacterial infection, including *Listeria monocytogenes*, especially in cattle and pigs, *Pasteurella multocida* in newborn calves, streptococci in newborn piglets and *Streptococcus zooepidemicus* in deer.

Signs include walking in circles, pressing the head against a wall, champing of the jaws, convulsions.

Meniscus
Meniscus is a crescentic fibro-cartilage in a joint.

Meorrhachischisis
A congenital fissure of part of the spinal cord: SPINA BIFIDA.

Mepacrine Hydrochloride
An antimalarial drug which has been used in the treatment of coccidiosis in cattle.

Meperidine
An OPIOID. (See PETHIDINE.)

Mepivacaine
A potent local anaesthetic licensed for use in horses; it does not cause vasodilation so does not require ADRENALIN to prolong its effect.

Mepyramine Maleate
An antihistamine which is given by mouth, by intramuscular injection, or applied to the skin as a cream. It has been used in the treatment of LAMINITIS, AZOTURIA and URTICARIA, etc. (See ANTIHISTAMINES.)

Mercurochrome
An antiseptic, and a stain for spermatozoa. It is a proprietary name of a preparation of merbromin, and an organic compound of mercury.

Mercurous Chloride
(See CALOMEL.)

Mercury (Hg)
Also known as quicksilver and hydrargyrum, it is a heavy silver-coloured liquid metal. In this form it was once used as an ingredient of ointments and even purgative powders.

The salts of mercury are of two varieties: mercur*ic* salts, which are very soluble and powerful in action; and mercurous salts, which are less

VetBooks.ir

VetBooks.ir

soluble and act more slowly and mildly. Mercuric salts are all highly poisonous; as organic compounds less so. In strong solution they may be caustic, and in weaker solutions are irritant.

Biniodide of mercury, or red iodide of mercury, made up into an ointment, formed the base of the common 'red blister'. With this and other mercury dressings, it is essential that care be taken, for the drug may enter the system by absorption from the skin, or by the animal licking itself.

Mercury poisoning With the possible exception of calomel as a laxative, preparations of mercury have given way to safer and more effective drugs. Consequently, mercury poisoning is now far less common than it was.

However, feeding seed corn dressed with phenyl mercuric acetate has caused sudden death in cattle; with extensive internal haemorrhages seen at necropsy. Deaths have also occurred in cattle accidentally exposed to mercurous chloride in plant spray. (See also under SEALS for mercury poisoning in those creatures.)

In Japan, the eating of fish with a high mercury content led to an outbreak of illness, with nervous signs, in cats.

Acute poisoning results in vomiting, diarrhoea, and abdominal pain, with death from shock. (Cattle may show only diarrhoea as the first sign.) Stomatitis and salivation may also occur. Severe purgation occurs in the smaller animals, together with signs of acute abdominal pain. Lips and mouth may become white.

Chronic mercury poisoning (mercurialism): salivation; swelling of tongue, which bleeds readily; loosening of the teeth. Nervous signs may develop, e.g. ataxia, blindness.

First-aid Give white of egg.

Antidote A CHELATING AGENT such as dimercaprol. Absorption of mercury can be reduced by adding a binding agent such as zeolite to the diet.

Human cases can occur from inhaling mercurial fumes; dental amalgam is a source of mercury vapour.

Mercury, Dog's

Both dog's mercury (*Mercurialis perennis*) and annual mercury (*M. annua*) are poisonous plants, especially when seed-bearing. Cows are most often affected. Animals may not show signs until from 7 to 10 days after the plants are first eaten.

Signs Diarrhoea. Urine is passed frequently, accompanied by painful straining, and is of a blackish or blood-red colour, as is the diarrhoea. Other signs are severe anaemia and semi-coma. Deaths have occurred.

First-aid The animal should be given strong black tea or coffee.

Merino Sheep

A breed originating from Spain. There are polled Merinos but most have long tight curled horns. They are of intermediate size and have a fine soft fleece of 3 kg (6.6 lb) to 6 kg (13 lb). They were introduced to Australia in 1788 but are found in Britain and other parts of Europe.

Merle

A colouring found in dogs: there is a solid base colour, usually black or red/brown, with lighter blue/grey or reddish patches giving a mottled or speckled appearance. It is common in some breeds especially the SHETLAND SHEEPDOG and WELSH COLLIE. Merle in dogs has been associated with susceptibility to AVERMECTIN toxicity. There is a tendency for DEAFNESS in merle animals, due to suppression of the pigment cells (MELANOCYTES) in the stria vascularis of the inner ear (COCHLEA) and also the iris, which leads to BLUE EYES.

MERS

(See MIDDLE EAST RESPIRATORY SYNDROME.)

Mesalliance

(See MISALLIANCE.)

Mesaticephalic

A normal sized head, as opposed to DOLICHOCEPHALIC (long-headed) and BRACHYCEPHALIC (short headed).

Mesembryanthemum

A succulent plant of the Aizoaceae Family, originating in South Africa, but it can be grown in temperate climates and is also known as 'midday flower', 'pebble plant' or 'ice plant'. The flowers are white or pink and are low growing. It appears to be tolerated by many herbivores including tortoises in small amounts but OXALATE toxicity in sheep is recorded.

Mesencephalon

Mesencephalon is the mid-brain connecting the cerebral hemispheres with the pons and cerebellum.

Mesenteric

Related or pertaining to the MESENTERY.

Mesenteric Hernia

(See HERNIA.)

Mesentery
Mesentery is the double layer of peritoneum which supports the small intestine, suspending it from the roof of the abdomen.

Mesh Grafts
(See SKIN GRAFTING TRANSPLANTATION.)

Mesna
An organosulphur compound from human medicine used in animals to protect the kidneys and bladder from the effects of CANCER chemotherapy, such as with CYCLOPHOSPHAMIDE.

Mesocolon
Mesocolon is the name of the fold of peritoneum by which the large intestine is suspended from the roof of the abdomen.

Mesogenic
Of medium virulence. Often used to indicate the degree of virulence of, e.g., strains of NEWCASTLE DISEASE.

Mesometrium
Mesometrium is the fold of peritoneum running from the roof of the abdomen to the uterus. It consists of two layers, between which run the blood and lymph vessels, and the nerves to the uterus, and it acts as an elastic suspensory ligament supporting the uterus in position. During pregnancy it gradually stretches under the weight of the fetal contents, but retracts again under normal conditions, after parturition.

Mesosalpinx
Mesosalpinx is the suspensory ligament of the oviduct.

Mesothelioma
A tumour developing from the mesothelium covering membrane surfaces.

Mesovarium
Mesovarium is the suspensory ligament of the ovary.

Mesulphen
A parasiticide which allays itching, used in cases of sarcoptic mange.

Metabolic
Relating to metabolism.

Metabolic Bone Disease
This is a complex condition of reptiles. It is due to a lack, or imbalance, of CALCIUM, PHOSPHORUS and VITAMIN D, insufficient ultra-violet light and protein deficiency. Lizards develop soft ribs and their legs are unable to bear their body weight. The mandible and limbs may become swollen. In long-standing cases in chelonians the carapace may appear lop-sided and may appear too small. It may be soft or appear pyramidal. The beak may be deformed and the limbs bent. Diagnosis is by assessing bone density on radiography. Treatment involves correcting the deficiencies and providing ultra-violet light.

Metabolic Profile Tests
Tests devised at the Institute of Animal Health, Compton, to assist management of the feeding of high-yielding dairy cows in order to achieve optimum production. They are based on the principle that imbalances between feed input and production output are reflected in abnormal concentrations of key metabolites in the blood. To be effective, metabolic profiles must take into account the age, stage of lactation, condition score and milk yield of the cow, and also the milk's constituents. The diet being used, and its composition, must also be considered.

As a first step, 'normal values' for the main metabolites were established by analysing 2,400 blood samples from 13 herds, a base continually extended over time. Then samples from herds with known production disease problems were assessed so that abnormalities in the blood could be linked to identifiable nutritional shortcomings; where appropriate, a change in diet could then be instituted to correct the problem.

Low haemoglobin levels in cows sampled at the end of winter indoor period warn of lack of iron in the diet and the need for turnout to spring pasture, or supplementation, to avoid clinical anaemia.

Low serum magnesium levels can indicate impending outbreaks of HYPOMAGNESAEMIA; magnesium dietary supplements can avoid the risk. In one case where cows were thought to be dying from calving injuries, magnesium deficiency was the actual cause.

Used prudently, metabolic profiles can cost-effectively identify deficiencies – or excesses – of blood metabolites linked to actual or potential clinical problems, which can then be corrected or avoided.

Metabolic Syndrome (MS)
A syndrome of metabolic problems in dogs that are obese. The problem is resolved by successful weight loss.

Metabolisable Energy (ME)
Metabolisable energy (ME) is defined as the available energy produced by food after deducting the energy used in the production of faeces, urine and methane. The unit of ME replaced – under metrication – the starch equivalent for calculating

VetBooks.ir

the composition of livestock rations. ME is measured in joules instead of calories. The ME energy requirement for maintenance of a dairy cow is about 60 million joules or 60 megajoules (MJ) per day.

Metabolisable Protein (MP)

A part of the rationing system used in Britain for rationing ruminant livestock, particularly cattle, which tries to balance the energy and protein available, in order to ensure maximum utilisation of both within the animal. In the USA, a computerised system known as the Cornell Net Carbohydrate and Protein System (CNCPS) is used and is based on relatively the same philosophy. The system determines the available proteins and divides them into quickly degradable protein, slowly degradable protein, non-digestible protein, and rates of their digestion in relation to the carbohydrate part of the diet.

Metabolism

Metabolism includes all the physical and chemical processes by which the living body is maintained, and also those by which the energy is made available for various forms of work or production. The constructive, chemical, and physical processes by which food materials are adapted for the use of the body are collectively known as 'anabolism'. The destructive processes by which energy is produced with the breaking-down of tissues into waste products is known as 'catabolism'. Basal metabolism is the term applied to the amount of energy which is necessary for carrying on the processes essential to life, such as the beating of the heart, movements of the chest in breathing, chemical activities of secreting glands, and maintenance of body-warmth. This can be estimated when an animal is placed in a state of complete rest, either by observing for a certain period the amount of heat given out from the body or by estimating the amount of oxygen which is taken in during the act of breathing and retained.

Metabolites

Any product of metabolism.

Metacarpal

This region is the part of the limb lying between the carpus and the phalanges or digits, and in the horse is commonly called the region of the 'cannon' on account of the comparatively straight tubular form of the large or third metacarpal bone. There are three bones here, of which the central or third is the largest, and the inner (second) and outer (fourth) are rudimentary. In the ox there are two large metacarpals fused together; the sheep is similar; the pig has four separate from each other; and the dog possesses five bones in this region.

In the bird the metacarpal and carpal bones are fused to form the carpometacarpus to which the flight feathers are attached.

Metacercaria

The cyst (dormant) stage of flukes such as *Fasciola hepatica*; when ingested by an animal, the life-cycle is resumed.

Metaldehyde Poisoning

Metaldehyde poisoning has been encountered in the dog and cat following the eating of metaldehyde pellets and tablets used for killing garden slugs. Signs may include excitement, vomiting, muscular TETANY, NYSTAGMUS in the cat, partial paralysis and stupor. The animal should be kept quiet in the dark pending veterinary aid, when anaesthesia may be required: PENTOBARBITONE SODIUM, intravenously or intraperitoneally, or DIAZEPAM, by intravenous injection. These have largely been replaced by PROPOFOL.

Metaldehyde poisoning has occurred also in horses, cattle, sheep, and birds.

Cattle An estimated 0.90 kg (2 lb) of slug pellets sufficed to kill six calves which had broken into a store shed. In another incident, ten suckler cows were found dead in a field. In a third case, three out of five milking cows died after consuming, between them, about 9 kg (20 lb) of slug pellets.

Signs in these cows included a staggering gait, profuse salivation, scouring, partial blindness and hyperaesthesia. Later, muscular spasms were observed.

Horses A hunter died after showing similar signs (but without diarrhoea or partial blindness) after helping itself from a pile of pellets spilled in a field and not cleared up.

Metal Detector

This instrument is put to veterinary use sometimes to confirm a tentative diagnosis of a metal foreign body in the reticulum.

Metalflumizone

An anti-flea treatment for dogs and cats applied directly to the skin; at the back of the neck in cats and between the shoulder blades of dogs.

Metaphase

The second phase of cell division (mitosis or meiosis) in which the chromosomes are maximally contracted and the duplicate chromatids align along the midline of the cell prior to division.

Metaphyseal Osteopathy

A condition seen in large dog breeds, usually in puppies three to six months old. The bone

VetBooks.ir

metaphyses are painful to the touch and there may be fever, diarrhoea and gum bleeding. Treatment is by close supervision of the diet in puppies to ensure adequate levels of minerals, vitamins and energy are present in the diet, although excess must be avoided. Some claim that extra VITAMIN C is helpful but this has not been proved.

Metaplasia
Metaplasia is described as 'the change of one kind of tissue into another; also the production of tissue by cells which normally produce tissue of another sort'. These changes are usually benign but seldom reversible. However, they are sometimes encountered in malignant tumours, e.g. mammary tumours in the bitch.

Metastasis and Metastatic
These are terms applied to the process by which a disease transfers from one organ to another. Often used in describing NEOPLASIA, where a malignant tumour spreads to distant parts of the body, and gives rise to secondary tumours similar to the original or primary tumour. Thus a sarcoma in one part of the body may spread to another part by pieces of tumour or clusters of cells breaking away from the parent growth, and being carried by the bloodstream to the lungs, etc., and setting up new sarcomatous growths there. (See CANCER.)

Metastasise
To spread, as applied to malignant cancerous growths.

Metastatic
Relating or pertaining to METASTASIS.

Metastrongylus
A genus of nematodes which infect the lungs.

Metastrongylus apri Lungworm of pigs where earthworms act as the secondary host.

Metatarsal Bone
Metatarsal bones are those bones and structures lying between the tarsus or hock and the digit of the hind-limb. It corresponds to the metacarpal region in the fore-limb, and has a somewhat similar arrangement of bones.

In birds there is a single bone, the TARSOMETATARSUS.

Methadone
A synthetic OPIOID analgesic licensed for use by intravenous or intramuscular injection in dogs for the relief of moderate to severe pain; the effect lasts for about four hours. It is also licensed for use as a premedication in combination with a neuroleptic drug.

Methaemoglobin
Methaemoglobin is a modification of haemoglobin, the red pigment of blood – the iron being in the form of ferric rather than ferrous sulphate.

Some methaemoglobin is normally present in the blood; but various poisons can increase the amount found in blood, and sometimes in urine – a particular case is PARACETAMOL toxicity in cats. Administration of large doses of certain drugs, such as acetanilide, can produce methaemoglobin and it is found also in some diseases. Chemically, methaemoglobin is the same as oxyhaemoglobin, except that it cannot part with its oxygen as readily as can the latter.

Methane, Marsh Gas
Methane (marsh gas) has the chemical formula CH_4. Large quantities (up to 250 litres per day) may be formed in the rumen of the healthy cow from carbon dioxide and hydrogen, as a by-product of rumen fermentation. It occurs in the production of acetate and butyrate but not proprionate or valerate. Low fibre and high concentrate diets result in less methane production. The gas is inflammable and is considered to be one of the more important ones involved in global warming. In New Zealand reducing the number of ewes but increasing number of lambs reared and increasing average carcase weight reduced the carbon footprint of lamb by 17 per cent. (See SLURRY.)

Methicillin, Meticillin
A semi-synthetic penicillin resistant to penicillinase.

Methicillin Resistant *Staphylococcus pseudointermedius*
(See MRSP.)

Methicillin Resistant *Staphylococcus aureus*
(See MRSA.)

Methimazole
Another name for THIAMAZOLE.

Methiocarb
A snail-killer used in agriculture. Poultry and other animals must be kept away from treated areas for at least a week.

Methionine
A sulphur-containing AMINO ACID; it is an essential part of any animal's diet. The inability of cats to metabolise methionine to taurine means that taurine must be provided in the diet (as it is in most proprietary cat foods). Excess methionine in the diet produces renal hypertrophy. Deficiency

leads to lymphocyte reduction and, in birds, atrophy of the bursa.

Methocarbamol
A centrally active muscle relaxant that is administered by intravenous injection or as a tablet orally or by enema.

Methohexital
A short-acting barbiturate anaesthetic for use in cats and dogs. It is administered intravenously.

Methoprene
An INSECT GROWTH REGULATOR used as an ingredient of flea collars for dogs and cats. It acts by preventing the young flea from developing to the adult stage.

Methoxyflurane
A volatile anaesthetic administered by inhalation; it is relatively slow in action and provides good analgesia and muscle relaxation.

Methyl
Methyl is the name of an organic radicle whose chemical formula is CH_3, and which forms the centre of a wide group of substances known as the methyl group. For example, methyl alcohol is obtained as a by-product in the manufacture of beet-sugar, or by the distillation of wood; methyl salicylate is the active constituent of oil of winter-green; methyl hydride is better known as marsh gas. Methyl groups are important in switching on or off the activity of genes.

Methylated Spirit
Methylated spirit is a mixture of rectified spirit (methanol 4 per cent and ethanol) with 10 per cent by volume of wood naphtha, which renders the spirit dangerous for internal administration. (See ALCOHOL POISONING.)

Methylene Blue
Methylene blue, given intravenously at a dose of 10 mg/kg of a 4 per cent solution, is an antidote to nitrate poisoning, and also to chlorate poisoning. In cats it was formerly used as a urinary antiseptic but gave rise to Heinz-body anaemia (see under HEINZ BODIES).

Methylprednisolone Acetate
A glucocorticoid licensed for use in dogs and cats. It is used in a variety of allergic and inflammatory conditions. In horses intra-articular injections are used for OSTEOARTHRITIS.

Metoclopramide Hydrochloride
It is used to control vomiting in GASTRITIS in dogs and cats, ruminal atony and treat RIGHT DISPLACEMENT OF THE ABOMASUM.

Metoestrus
Metoestrus is the period in the oestrous cycle following ovulation and during which the corpus luteum develops and lasts until the start of DIOESTRUS. Usually this is about two days but in the bitch it is considered to last the whole of PSEUDO-PREGNANCY (40 to 90 days).

Metritis
(See UTERUS, DISEASES OF.)

Metrocele
A hernia of the uterus.

Metronidazole
An antimicrobial (nitroimidazole) drug effective against anaerobic bacterial infections including *Bacteroides* spp., *Fusobacterium* spp., *Spirochaetes* spp., and also protozoal infections such as TRITRICHOMONIASIS and GIARDIASIS. It is used in conjunction with spiramycin in periodontal and other oral conditions in dogs and cats. There is a synergistic activity between the two antibiotics.

Meuse-Rhine-Ijssel Cattle (MRI)
A dual-purpose breed of cattle from the Netherlands and Germany. The Ijssel (Issel or Yssel) is also called Rotbubt, Roodbont, Red Pied Dutch, Dutch Red and White. It has good milk yields (up to 10,000 litres – 2200 gallons) and high butterfat (up to 4 per cent) and milk protein (4 per cent). Its herd book was started in 1874. They are medium sized cattle with bulls about 1,050 kg (2,300 lb) and height at tail-head 143 cm (57 in); cows weigh 675kg (1,500 lb) and height 132 cm (53 in).

Mexican Hairless Dogs
A small breed of dog which has no hair, except on the head, feet and tip of the tail. It is similar to the Chinese Crested dog. The body temperature is 40° C (104° F), which is higher than the normal dog range. The breed is also prone to SUNBURN. They weigh 5 kg to 6 kg (11 lb to 13 lb).

MFS Rx
(See MEDICATED FEEDINGSTUFF PRESCRIPTION.)

MHC
(See MAJOR HISTOCOMPATIBILITY SYSTEM.)

Mice
Mice are rodents in the suborder Myomorpha; they may be kept as pets and, in laboratories, for research purposes. Wild mice are vectors of several diseases (see under LYMPHOCYTIC CHORIOMENINGITIS; RODENTS). Polyoma viruses of mice and mouse hepatitis virus are other infections important in laboratory mice. In pet

VetBooks.ir

mice, RINGWORM, BARBERING, NEOPLASIA and ulcerative dermatitis are sometimes encountered. (See also ECTROMELIA (mouse pox); PETS, CHILDREN'S AND EXOTIC.)

A mouse is handled by grasping the tail before gripping the scruff over the withers.

Miconazole
An ectoparasiticide used in preparations to treat otitis externa (inflammation of the outer ear) wholly or partly due to the presence of *Otodectes cyanotis*.

Micro-
Micro- is a prefix meaning small.

Microcardia
An abnormally small heart.

Microcephaly
Microcephaly is abnormal smallness of the head.

Microchips
In the animal field, the name is given to electronic chips about the size of rice grains that can be encoded with an identification number and implanted permanently under the skin by a veterinary surgeon. The number can be read with a special electronic scanner and lost or stolen animals thus identified. More than 150,000 pets were microchipped in the 5 years up to 1996.

The scheme has been used for identifying the animals re-homed from RSPCA centres and other animal charities.

Under the scheme, a register of the numbers of all animals 'identichipped' is held by Pet Log, a national computer database launched by the RSPCA and the Kennel Club. As from 6 April 2016, all dogs in the UK are required to be microchipped, and owners found without such identification by local authorities or the police could be fined. Microchips are also used to identity small rodents and reptiles.

Microchiria
A congenital abnormal smallness of digit (synonym for Microdactyl).

Micrococcus
(plural, Micrococci)
A small round bacterium. Many belong to the family *Micrococcacae*.

Microdactyly
A congenital abnormal smallness of digit (synonym for Microchiria).

Microglossia
A congenital condition where there is an abnormally small tongue.

Micromelia
A congenital problem where the extremities are very short.

Micron
A micron is 0.001 mm; it is the unit of measurement in microscopical and bacteriological work. Its symbol is μ.

Micro-Organisms
(See BACTERIA; VIRUSES; MYCOPLASMA; RICKETTSIA; CHLAMYDOPHILA, FUNGAL DISEASES.)

Microphthalmia
An abnormal smallness of the eyes, accompanied by blindness; it may be unilateral or bilateral. In piglets and calves it is believed to be associated with a VITAMIN A deficiency. When present in newly hatched chicks and poults, it usually indicates VITAMIN A deficiency in the parent stock.

Microscope
The ordinary microscope with oil-immersion lens gives magnification up to 1500 diameters. (See also ELECTRON MICROSCOPE.)

Microsporum
A group of fungi responsible for ringworm.

Microstomia
A congenital condition where there is an abnormally small mouth.

Microtia
A congenital condition in which there are unusually small external ears or auricles.

Microvillus
(plural, Microvilli)
These are microscopic protrusions from the surface membrane and increase the surface area of organs such as the VILLI of the SMALL INTESTINE.

Micturition
The act of passing urine.

Midday Flower
(See MESEMBRYANTHEMUM.)

Middle East Respiratory Syndrome (MERS)
A human infection due to a CORONAVIRUS that originated in 2012 on the Arabian Peninsula. The virus has been found in bats and antibodies have been found in dromedaries.

Middle White Pig
A short-faced breed with white skin. Originating from Yorkshire, it is smaller than the LARGE

WHITE and is docile; used as a pork producer. It can be kept outside.

Middlings
A by-product of wheat milling used as a protein supplement for cattle and pigs. (See WEATINGS.

Midges, Biting
Species of *Culicoides* including *Culicoides obsoletus*, *C. dewulfi* and *C. pulicaris* all of which are of veterinary importance in connection with 'sweet itch' in horses, and also with the transmission of viruses to farm livestock, e.g. the virus of AFRICAN HORSE SICKNESS; BLUETONGUE, EPIZOOTIC HAEMORRHAGIC DISEASE of deer and cattle and SCHMALLENBERG VIRUS. In the North European 2006 outbreak of bluetongue, Oxford University researchers found that 38 per cent of all outbreaks could be attributed to midges.

Migram
A disease of sheep on the Romney Marsh. Signs include trembling and muscular incoordination. In an incident in 1983, MAFF reported that 150 out of 260 lambs collapsed while being driven to new pasture. The cause is unknown, but one line of investigation is into a possible association with blue-green algae in the dykes.

Milbemycin
Milbemycin is one of a family of anthelmintics that include the macrocyclic lactone group related to the avermectins. It is used in treating many farm animal and companion animal species. One form is licensed in cats for the treatment and prevention of roundworm and tapeworm infestations. Its activity in the case of heartworm (*Dirofilaria immitis*) lasts about one month. Regular dosing is required in areas where heartworm is endemic.

Miliary
Miliary is a term, expressive of size, applied to various disease lesions which are about the size of a millet seed – e.g. miliary tuberculosis, feline miliary dermatitis.

Milk

Composition Cow's milk is a very valuable food substance as it contains all the essential food constituents – proteins, carbohydrates, fats, and vitamins – in addition to a considerable percentage of mineral matter. The most important protein in milk is casein; this is present in a state of partial solution. Carbohydrates are represented by the milk-sugar (lactose) which is dissolved in the liquid portion of the milk. They, along with the fat which occurs as spherical globules, are heat- and energy-producing substances. The mineral matter consists, to a very large extent, of compounds of calcium and phosphorus. These substances are the essential constituents of bone.

The percentages of the main constituents of milk vary considerably. Fat and protein levels are affected not only by the diet of the animal, but also by its genetic make-up. However, the level of lactose is relatively constant (see table below).

In the young growing animal, muscle and bone are being formed rapidly. Hence the food of the young must be adequately provided with protein and mineral matter in particular. Since it contains considerable quantities of both of these constituents, as well as vitamins, milk is an excellent food for growing animals; it is not however a complete one – it will not provide adequate iron in the piglet (see SOWS' MILK) or adequate magnesium in the calf. Cows' milk has been fortified with OMEGA-3 fish oils to promote human 'heart health'.

Approximate Composition of Milk Products

	Water	Proteins	Fats	Sugar	Ash
Separated milk	90.0	3.7	0.2	4.9	0.8
Skimmed milk	90.0	3.6	0.8	4.6	0.8
Butter milk	91.0	3.3	0.5	3.4	0.6
Cream (thin)	64.0	2.8	30	3.5	0.5
Cream (thick)	39.0	1.6	56	2.3	0.4
Whey	93.0	0.9	0.2	4.8	0.5

Approximate Composition of Milk of Different Animals

	Water	Proteins	Fats	Sugar	Ash
Mare	90.5	2	1.2	5.8	0.4
Cow	97.4	3.4	3.8	4.8	0.8
Ewe	81.9	5.8	6.5	4.8	0.9
Goat	84.1	4	6	5	0.8
Sow	84.6	6.3	4.8	3.4	0.9
(Human)	(87.4)	(2.1)	(3.8)	(6.3)	(0.3)

VetBooks.ir

Legal standards In Britain, under the Sale of Food and Drugs Act, milk containing less than 3 per cent of butterfat, or less than 8.5 per cent of non-fatty solids (i.e. proteins, sugar and ash), is deemed to be not genuine (until or unless the contrary is proved) by reason of either the addition of water or the abstraction of some of the fatty or non-fatty solids. (See SOLIDS-NOT-FAT.)

The specific gravity of cow's milk varies between 1.028 and 1.032. The greater the fat content, the lower the specific gravity because fat is lighter than water and solids, bulk for bulk.

The pH reaction of the milk of the herbivorous animals is generally approximately neutral, while that of the carnivorous animals is acid.

Bacteria Since 1982 the total bacterial count (TBC) has been applied once weekly to samples of milk collected from each supplier. Average results over a month, using the Plate Count Test, determined the payment for the milk. The 'cleanest' grade, with an average number of micro-organisms of 20,000 or fewer per ml attracted a price premium; milk with more than 100,000 organisms per ml was subject to a deduction from the agreed price per ml.

Since 1996, the milk marketing organisation Milk Marque has used the more sensitive Bactoscan Test to determine milk hygienic quality. Milk is divided into three bands: band A, fewer than 100,000 cells per ml; band B, 101 to 500,000 cells per ml; band C, more than 500,000 cells per ml. (See also MILK-BORNE DISEASE; PASTEURISATION OF MILK.)

Sediment in milk Milk containing sediment has been the subject of prosecutions under the Food and Drugs Act 1955. Milk and Dairy Regulations 1959 require that before milking is begun, all dirt on or around the flanks, tail, udder and teats of each cow shall be removed, and that the udder and teats shall be kept thoroughly clean during milking. Additionally, milking must be carried out in a good light (daylight or electric light); no dusty material may be moved during or within half an hour before milking.

In order to minimise contamination of milk during milking, the cow's udder should be sprayed or wiped with a disposable towel wrung out of water containing a disinfectant, and the hands of the milker should be thoroughly washed before the milking of each cow (preferably in water containing a disinfectant). (See MASTITIS IN COWS for recommended procedure.)

Lactic acid is produced by the action of bacteria on lactose – the result being sour milk – and is also present in sour cream and yoghurt. (See also LACTIC ACID.

White blood cells in milk In the EU, milk may not be sold if it contains more than 400,000 cells per ml. Most milk marketing companies impose a penalty if bulk milk has a cell count of 250,000 cells per ml or more; some have more stringent limits. High levels of white blood cells in milk are the result of subclinical mastitis due to (a) trauma, defective milking machine or technique; (b) infection; (c) both. (See MASTITIS IN COWS.)

Antibiotics in milk It is important that milk should not contain traces of antibiotics, which are frequently used in treating mastitis. Some people are allergic to antibiotics, and if they drink milk containing them they may suffer severe effects, e.g. a troublesome rash and a period off work. It has also been feared that the continual consumption of small quantities of antibiotic may result in people becoming sensitised, later undergoing a severe reaction when given that antibiotic by their doctor. A third danger is the development of organisms resistant to antibiotics, which could possibly give rise to illness not responding to antibiotic treatment. Antibiotic residues can also affect the manufacturing processes of cheese and yoghurt.

All medicines containing antibiotics are labelled with a 'withdrawal period' which must elapse after treatment is ended before the milk can be used for human food. Unless otherwise stated, the minimum standard withdrawal period for milk is seven days.

Chlorophenol taint Most strong-smelling disinfectants, such as those based on phenol or cresol, can cause a taint in milk, even in very low concentrations.

The disinfectants do not have to come into direct physical contact with the milk, but can be absorbed from the atmosphere by any exposed milk surface, particularly in the bulk tank. They should be stored well away from the milking parlour or dairy.

Similarly, neither creosote nor products containing phenols should be used where they may come into contact with teats and udders by indirect means, e.g. on woodwork of buildings, or in the disinfection of cubicle beds, cowsheds, loose-boxes, and collecting yards.

Plants affecting the milk A large number of plants affect milk or milk secretion in animals eating them, and very often the real cause of unusual tastes or odours in the milk is some common wild plant. Some plants give milk a characteristic taint or odour (such as garlics), and others alter its colour; some decrease the total secretion and others lessen the fat content; a few alter the colour and character of butter made from the milk; and one or two, whose poisonous principles are excreted by the mammary

gland, render the milk actually poisonous. (See BRACKEN POISONING.)

Dioxins in milk Unacceptably high levels of dioxin are occasionally found in milk.

The World Health Organisation has recommended a 'tolerable daily intake' for dioxins of 0.01 nanograms per kilogram of milk.

Milk, Absence of

Absence of milk in the mammary glands following parturition, is discussed under AGALACTIA and SOWS' MILK, ABSENCE OF.

Milk, Unpasteurised

(See MILK-BORNE DISEASE.)

Milk Allergy in Cows

This may develop especially in the Channel Islands breeds, in cows which have become sensitised to the alpha-casein in their own milk. If milking is delayed, they may develop clinical signs of a type 1 hypersensitivity, e.g. dyspnoea, drooling of saliva, urticaria, and swollen eyelids, in an otherwise bright animal. The withdrawal of milk results in an almost immediate remission of these signs.

Milk-Borne Disease

Various infections may be transmitted to people through unpasteurised or defectively pasteurised milk. (See BRUCELLOSIS; SALMONELLOSIS; Q FEVER; TUBERCULOSIS.)

Over a period of 30 years, 77 per cent of 233 reported outbreaks of communicable disease attributed to milk and dairy products in England and Wales were associated with unpasteurised milk.

After compulsory pasteurisation was introduced in Scotland, outbreaks of milk-borne salmonellosis fell to 8, affecting 46 people as compared with 14 outbreaks affecting 1,090 people in the previous three years.

Campylobacter jejuni, present in unpasteurised or incompletely unpasteurised milk, has caused outbreaks of human enteritis.

Corynebacterium ulcerans has been implicated as the cause of sore throat in a patient from a community that drank raw milk and has been found in the udder of cattle.

Goat's milk, if unpasteurised, may be a source of various infections transmissible to people. (See BRUCELLOSIS; Q FEVER; TOXOPLASMOSIS; TUBERCULOSIS.)

Milk Development Council (MDC)

A government-backed body set up in 1995 to fund, by means of a levy on milk, research and development into milk and milk products. It became part of DAIRYCO and this is now one part of the AGRICULTURE AND HORTICULTURE DEVELOPMENT BOARD.

Milk-Drop Syndrome

A sudden drop in milk yield in individual cows with a flaccid udder (flabby bag); the usual cause is *Leptospira hardjo*.

Milker's Nodule

A benign viral disease (PARAVACCINIA VIRUS) transmitted to the fingers of milkers by contact with the teats of infected ruminants (see CAT POX). It is also known as PSEUDO-COWPOX (see VIRAL INFECTIONS OF COWS' TEATS).

Milk Fever

Also called hypocalcaemia and parturient paresis. Milk fever is a metabolic condition – mainly resulting from hypocalcaemia (low circulating calcium levels) in milk cows, milk goats, and sometimes of ewes, bitches and cats in which there is a partial or complete loss of consciousness, paralysis of the hindquarters, and sometimes paralysis of other parts.

In the hill ewe, the condition is colloquially known as 'MOSS-ILL'. Hypocalcaemia also occurs in lowland ewes.

Milk fever would appear to be one of the diseases that is to some extent traceable to artificial methods of management of farmstock. It is most frequently, though not exclusively, encountered in heavy-milking cows, of the specialist dairy breeds. A few cases occur some hours before calving, but the majority take place within three days subsequent to parturition.

Some cases occur up to four weeks after calving, but, as a rule, delayed cases are mild – though they take longer to recover.

Research has suggested that the calcium-controlling 'mechanism' is a very complex one, involving all the endocrine glands and both the sympathetic and the parasympathetic nervous systems.

Blood samples have shown that in cows as well as a shortage of calcium in the blood, there may also be too little phosphorus and either too much or too little magnesium. This accounts for the differing signs in what is collectively called milk fever.

The level of CORTISOL in the plasma of cows during milk fever is significantly higher than in normal cows.

Signs The affected cow at first shows a certain amount of excitement. She paddles with her hind-feet, stares around in a somewhat fearful manner, may bellow, and if tied attempts to break loose. The pupils are dilated. After a time she staggers on her feet, loses balance and falls to the ground. She may make efforts to rise, but after struggling for a

VetBooks.ir

VetBooks.ir

time she gives up and remains quiet. In many cases a characteristic position is assumed: the cow lies on her brisket, head turned round over one shoulder (often the left), and the muzzle pointing to the stifle.

The breathing becomes deep and slow, pulse is fast but weak, the extremities of the body grow cold, the temperature falls to 2° C to 2.7° C (4° F to 5° F) below normal, and death may follow coma.

Whereas formerly the mortality was 90 per cent or so, it has been reduced to less than 5 per cent in cases that are treated.

Differential diagnosis In countries where rabies is present, this disease may be mistaken for milk fever – especially as the position in the recumbent animal, with the head turned to one side, resembles the milk-fever posture.

In Britain, some cases treated as milk fever but unresponsive to treatment with calcium borogluconate are due to NUTRITIONAL MYOPATHY associated with low VITAMIN E and SELENIUM intakes. Reluctance to move, stiffness and recumbency are the signs, and deaths may occur.

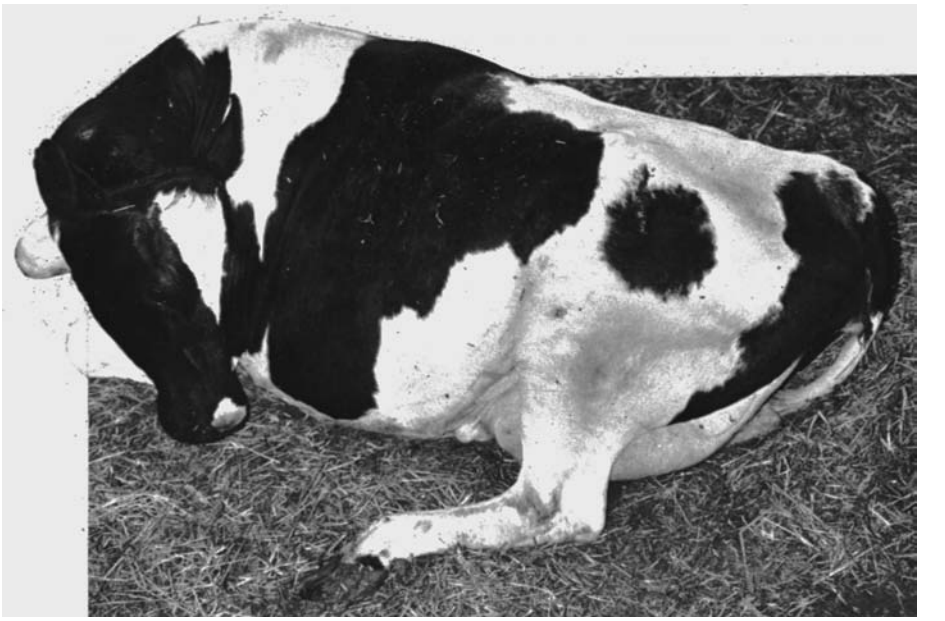
Treatment The intravenous or subcutaneous injection of CALCIUM BOROGLUCONATE solution with or without added MAGNESIUM.

When a deficiency of blood PHOSPHORUS complicates milk fever, and there is no response to calcium treatment, phosphorus in the form of 85 g (3 oz) of sodium acid phosphate may be given by mouth twice daily.

Prevention Milk fever has proved difficult to prevent. Reducing calcium intake in the later stages of pregnancy, followed by a boost in in-feed calcium two to three days before calving, has been suggested.

Acidic diets (DCAB, DCAD) can help control milk fever. VITAMIN D and its derivatives have been used to prevent hypocalcaemia.

Milking



(see also under MASTITIS; MILKING MACHINES). At milking time, the 'milk let-down' mechanism begins to operate; it is actuated by the hormone oxytocin which is secreted in the posterior pituitary gland and which is released into the bloodstream following a nervous stimulus. This stimulus may be caused by the rattling of milk pails, the placing of food in the manger, the washing of the udder, etc.

Milking Machines

Their action simulates that of the sucking calf. The teat-orifice is opened and milk withdrawn by means of a partial vacuum applied to the outside of the teat. As continuous vacuum would restrict circulation of the blood in the teat, cause pain, and inhibit milk ejection, the vacuum is applied intermittently by means of a pulsator.

The basic principles of machine milking are, in fact, vacuum and pulsation, and the way in which these are applied to the teat in the teat-cup assembly.

For maintenance of a healthy udder, what is first required is a strong stimulus to 'let-down', followed by rapid milking. As soon as the machine ceases to milk, the udder should be stripped and the

Milk fever: the characteristic posture.

machine removed. In practice, attention to this involves the herdsman not having too many units to cope with, not other tasks to perform. Automatic cluster-removal is useful here.

To maintain udder health a strong stimulus to 'let down' is required, followed by rapid milking. This is achieved by the herdsman not having too many units to cope with, nor other tasks to perform. Milking machines can be made to milk faster by increasing the degree of vacuum, increasing the pulsator rate, or by widening the pulsator ratio. If, however, the herdsman already has more to do than he can manage, a faster milking can result only in prolonged attachment after the udder is empty. The milking routine must be reorganised to avoid this, or mastitis will follow.

A liner with a hard mouthpiece is likely to cause trouble; changing from slack, wide-bore liners to the narrow-bore stretched type may make an improvement.

Investigation has shown that the slow milker is almost invariably the cow with a small teat-orifice. If it is not practicable to cull such an animal, the milking machine pulsation ratio may, with advantage, be altered. At 60 pulsations per minute, and at 38 cm of mercury, a ratio of 4:1 (i.e. the liner being opened for 4 times as long as it is closed) will reduce milking time – especially with slow milkers – without hurting the cow, or adversely affecting the stripping yield.

Common faults in milking machines are incorrect vacuum level, or vacuum fluctuations, blocked air bleeds, unsuitable pulsation rate, and faulty liners. Such faults can lead to MASTITIS. Regular, skilled maintenance of milking machines is therefore all-important. Milking machines should be checked at least twice a year and any faults repaired at once.

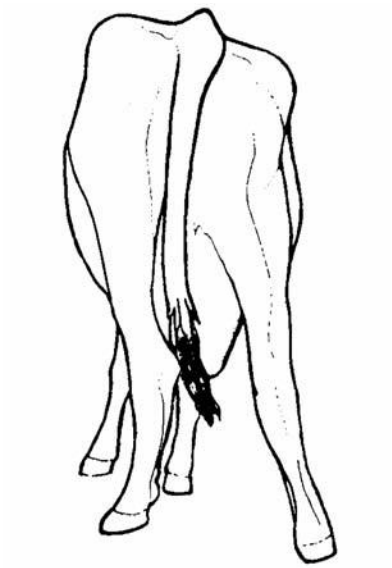
Milking Parlours

(See under DAIRY HERD MANAGEMENT.)

Milking Shorthorn Cattle

The name usually used in Canada, New Zealand and the USA for DAIRY SHORTHORN CATTLE.

'Milk Lameness'



This is a translation of the Swedish name for a condition encountered in high-yielding dairy cattle, and characterised by hip lameness. During 1 stage they assume a characteristic posture.

Some unthriftiness and sluggishness of movement may be observed in the herd. Animals stop frequently to rest.

The cause of 'milk lameness' is a deficiency of phosphorus in the bloodstream, and – since hip lameness may have several causes – blood tests are necessary in order to confirm a diagnosis.

In an outbreak in Scotland, recovery soon followed the feeding of sterilised bone-flour in small amounts. It seemed that the cows had been unable to acquire sufficient phosphorus from unsupplemented grazing.

Lameness associated with a blood-phosphorus deficiency is, of course, well known in many parts of the world – subjected either to drought or to high rainfall – where the soil or herbage is deficient in phosphorus.

'Milk lameness': the characteristic posture.

Milk Ring Test

A test that has been used to determine the presence of BRUCELLOSIS in dairy herds. It has largely been replaced by an ELISA test for antibodies to the disease.

'Milk Scald'

An alopecia around the muzzles of calves fed poorly mixed, or cool, milk substitute.

Milk Sinus

(See MAMMARY GLAND.)

'Milk-spot Liver'

'Milk-spot liver' is a name given to pigs' livers showing whitish spots or streaks of fibrous tissue – the result of chronic inflammation caused by the larvae of the roundworm, *Ascaris suum* and *Toxocara canis*. A similar condition may occur in lambs which have been grazing fields or fodder crops to which pig slurry has been applied. On a Scottish lowland farm this led to the condemnation of 70 per cent of lambs' livers at the local abattoir in two successive years. (See LAMB CARCASE REJECTION.)

Migrating larvae of *Toxocara canis* may also cause 'milk-spot liver' in pigs.

Milk-Spot Liver in Sheep
A lesion seen in the livers of young sheep caused by the migrating stages (metacestodes) of tapeworms.

Milk Teeth
(See DENTITION.)

Milk Testing
This is usually done by the milk companies on farms weekly and is used to determine the content of milk (butterfat, extraneous water, lactose, pH, protein, specific gravity), and quality (See BACTOSCAN, SOMATIC CELL COUNT). Investigation tests can also be made on bulk milk to test for bacteria which cause MASTITIS. Milk can be used as a non-invasive way of testing for ANTIBODIES to detect infections in individual animals or herds e.g. BOVINE VIRAL DIARRHOEA, INFECTIOUS BOVINE RHINOTRACHEITIS, JOHNE'S DISEASE, LEPTOSPIRA HARDJO, NEOSPORA CANINUM.

Milk Tetany
Another name for hypomagnesaemia in the calf. It occurs at about 2 months old in suckler or veal calves and is usually caused by a predominantly milk diet.

Milk Yield
Milk yield varies according to the breed of cow. Average annual yields are: British Holstein, 7,000 kg; Friesian, 6,150 kg; Guernsey, 4,510 kg; and Jersey, 4,325 kg. (For other figures see under LACTATION; see also STRESS.)

Milling Mistakes
The inadvertent inclusion of a medicinal compound intended for one species in feed mixed for another has caused problems. For example, LINCOMYCIN in feed for dairy cows produced severe diarrhoea, reduced milk yield, and ACETONAEMIA. (See also MONENSIN SODIUM.

Millipedes
Non-poisonous, many-segmented arthropods with two legs per segment; they may be kept as 'pets'. Those wishing to keep them should be informed about their care and nutrition, as millipedes will refuse to eat unsuitable food and may die of starvation as a result. Lesions to the integument (skin) are usually associated with problems in, shedding (dysecdysis); the condition usually clears up at the next moult. Millipedes are prone to disease caused by bacteria, fungi or viruses. Loss of haemolymph (equivalent to blood in a mammal) due to injury may be stopped by icing sugar, Plasticine, glue, etc. In the USA *Narceus annularis* is the intermediate host of a large, 'thorn-headed' worm *Macracanthohyncus ingens*, which can cause diarrhoea (and sometimes dysentery) in dogs. Hosts of the adult worm are raccoons, black bears, skunks, foxes and moles.

Mineral Blocks
These are commonly used, particularly for cattle and sheep, to supplement mineral intake particularly at pasture. They can be used for providing minerals, energy, anthelmintics and antiprotozoals. It has been shown animals tend to use them variably with some ignoring them and others over-using them. If it is important that all animals receive the minerals or medicines, it is better to provide all animals with the correct dose by other methods.

Mineralocorticoids
A group of hormones produced from the adrenal cortex that affect the metabolism of sodium, chloride and potassium. (See ADRENAL GLANDS.)

Minerals
(See under CALCIUM; COBALT; FLUOROSIS; IRON; MANGANESE; PHOSPHORUS; TRACE ELEMENTS; METABOLIC PROFILE TESTS; SELENIUM; SODIUM DEFICIENCY.)

Miniature Bull Terrier
A small breed with similar characteristics to the BULL TERRIER. Lens luxation may be found in individual dogs.

Miniature Chickens
(See BANTAM CHICKENS.)

Miniature Dogs
This usually refers to the size of dogs that are smaller than the STANDARD-size and larger that the TOY-size.

Miniature Pinschers
These were developed in the late 19th century by crossing the DOBERMANN PINSCHER probably with the ITALIAN GREYHOUND and the DACHSHUND. They are small, about 28 cm (11 in) at the shoulder and weigh 3.5 kg to 4.5 kg (7½ lb to 10 lb). It suffers from MUCOPOLYSACCHARIDOSIS VI for which there is a DNA test.

Miniature Poodle Dogs
A considerably smaller version of the standard POODLE, resulting from DWARFISM. There are DNA tests for PROGRESSIVE RETINAL ATROPHY, VON WILLEBRAND'S DISEASE. (See POODLE.)

Miniature Schnauzer
A small breed developed in Germany from the SCHNAUZER. With miniaturisation, certain defects

have appeared. CATARACT and PROGRESSIVE RETINAL ATROPHY are recessive traits. VON WILLEBRAND'S DISEASE is an autosomal dominant trait. There are DNA tests for MYOTONIA CONGENITA, MUCOPOLYSACCHARIDOSIS VI and LEGG-CALVÉ-PERTHES DISEASE may also be seen.

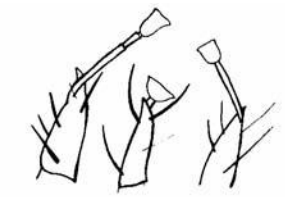
Minimal-Disease Pigs
Those reared free from certain infections. (See also SPF.)

Minimum Inhibitory Concentration
The lowest concentration of an antibiotic that inhibits the growth of a particular bacterial species under laboratory conditions.

Mink, Diseases of
These include mastitis, metritis, paragonimiasis, and transmissible mink encephalopathy. (See ALEUTIAN DISEASE.) A vaccine against botulism is available. (NB: The keeping of mink in the UK is no longer lawful, except under special conditions – e.g. in zoos). Under the Wildlife and Countryside Act 1981, injured wild mink that are treated must not be released into the wild.

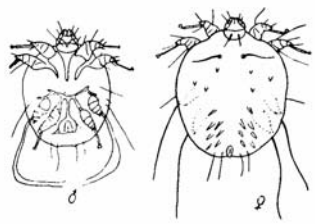
Miosis
The contraction of the pupil. It usually refers to excessive contraction.

Miotics
This is pertaining to or resulting in miosis. Myotics are also the name given to drugs which contract the pupil of the eye, such as eserine and opium.



Misalliance
Mismating, an unintended or undesirable mating of two animals. Pregnancy can usually be prevented by timely intervention with STILBENES. (Synonym: MESALLIANCE)

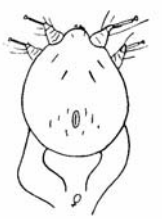
Mistletoe
Mistletoe (*Viscum album*) is toxic. Clinical signs include incoordination with continuous nodding of the head, followed by dilation of the pupils, excessive salivation, polyuria, hypersensitivity and dyspnoea. The condition is difficult to treat. Mistletoe is found in a herbal remedy for the symptomatic relief of anxiety, nervousness, excitability and travel sickness in dogs and cats and it is used as an adjunct in treatment of epilepsy in these animals. Mistletoe has been used in human medicine as a vasodilator and for its cytotoxic effect in cancer treatment.



Mites, Parasitic
Parasitic mites, including mange mites (see also MANGE).

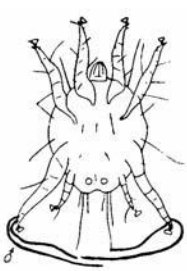
Types of mite The following genera are important. All are minute and, under favourable circumstances, are just visible to the naked eye.

Sarcoptes, with one species, *S. scabiei*, and numerous varieties. These mites live in the skin of mammals.



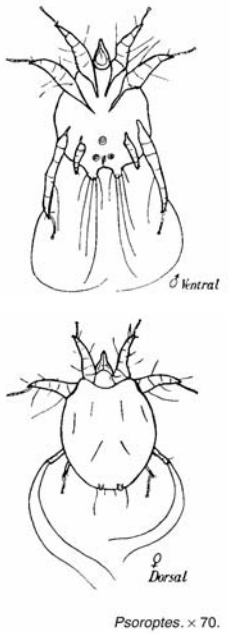
Legs of mange mites. (*Psoroptes, Chorioptes, Sarcoptes.*)

Sarcoptes. × 70.



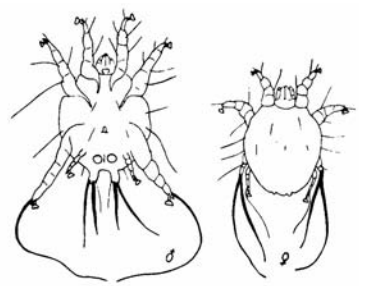
Cnemidocoptes, found in birds. They resemble *Sarcoptes*. *Cn. mutans* causes scalyleg. *Cn, Gallinae* is the depluming mite and *Cn. pilae* infests the cere and legs of budgerigars.

Notoedres is a genus closely allied to *Sarcoptes*, found on carnivores.



Notoedres. × 70.

Otodectes is found in the external ear, notably in dogs, cats and ferrets.



Otodectes. × 70.

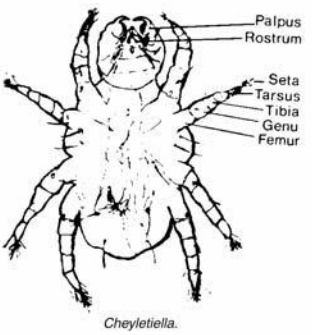
Psoroptes is found in the external ear and on the body of rabbits; it is the cause of SHEEP SCAB.

Psoroptes. × 70.

Chorioptes (Symbiotes). One species is known – *C. equi* – with numerous varieties.

Chorioptes. × 70.

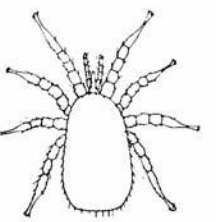
Drugs to kill them (Acaricides) A wide range of products is available, in a variety of formulations, depending on the animal to be treated and the mite causing the problem. Many are based on AVERMECTINS, PYRETHROIDS or ORGANOPHOSPHORUS COMPOUNDS (see under MANGE).



Other mites

Air sac mite (*Cytodites nudus*) is found in air sacs and may cause little harm as they have been found in healthy birds. However, in a heavy infestation some birds show emaciation, peritonitis and obstruction of the airways. They are said to exacerbate any respiratory condition occurring concurrently in poultry. They may be seen as white specks 0.6 to 0.4mm in size. Cage birds especially Gouldian finches (*Chloebia gouldine*) are particularly susceptible to their effects.

Budgerigar Mite (*Cnemidocoptes pilae*) affects the cere and/or the legs of the bird and results in overgrowth. This may be serious, resulting in partial closure of the nostrils and impairment in breathing.



Cat fur mite (*Lynxacarus radooskyi*) This has a pair of flap-like appendages which enable it to cling to a hair-shaft. It causes scurfiness, especially along the cat's back, and is present in the USA, Australia, Fiji and Hawaii.

Cheyletiella Two members of this genus are of some veterinary importance in Britain, viz. *C. parasitivorax* and *C. yasguri*. These mites infest dogs, cats, foxes, rabbits and hares. In the dog they are most frequently found on the nape of the neck, and down the back. Redness of the skin and intense itching may be caused – the latter symptom occurring in man also. Three dressings, at five-day intervals, with derris or pyrethrum are recommended; for cats, selenium sulphide.

Cheyletiella.

Depluming Mite (*Cnemidocoptes gallinae*) burrows into the shafts of feathers and causes irritation with the result that the bird may pull them out, thus interfering with the control of body heat. Several treatments have been used including malathion dipping but this is not without risk. Application of a lotion of soap (0.67 per cent) and sulphur (1.25 per cent) in warm water after the birds are fully wet is probably the safest treatment.

Dermanyssus gallinae. × 35.

Flour mites These can cause loss of nutrients in stored animal feeds (see DIET AND DIETETICS - DETERIORATION WITH STORAGE), and can also be parasitic on animals, causing dermatitis. For such a case in horses, see FLOUR-MITE INFESTATION.

Forage mites are occasionally parasites of the horse which live normally in the forage. They may cause considerable damage to the skin, but are usually easily killed.

Harvest mites The so-called 'harvest mite' or 'chigger' is the larva of a species of *Trombidium*, currently called *Neotrombicula autumnalis* (formerly *Trombicula autumnalis*). It is microscopic in size, blood-red in colour, and in shape resembles a tick. The nymph and adults are free-living in the soil, only the larvae being parasitic. The unfed larvae is red in colour and about 2 mm in length. When engorged it measures about 4.5 mm in length and is pale yellow in colour. The mites resemble small ticks and have six legs, ending in hooks to catch onto grazing animals. The larvae suck tissue fluids through a feeding tube introduced into the skin of animals and birds and can cause irritation. They are active in the warmer months in temperate climates. Larvae feed for two or three days and fall to the ground to complete their life cycle in the course of one year. (See HYPERSENSITIVITY.)

House-dust mite *Dermatophagoides pteronyssinus* can cause allergies in people and pets.

Linguatula serrata This parasite has a flat body shaped somewhat like a tongue, but grooved. It is without appendages, apart from two pairs of hooks at its anterior end. The adult lives in the nasal passages of dogs, cats and foxes, and is up to 2 cm in length.

The eggs are expelled from the nose by sneezing; they may also be swallowed and excreted in the faeces. Sheep, cattle and rabbits swallow the eggs and become intermediate hosts.

After the eggs hatch in the stomach, larvae migrate to the mesenteric lymph nodes, and encyst either there or in organs such as the liver, lungs, or kidneys.

The life-cycle is completed when the final host eats viscera containing the infective nymphs.

Northern Fowl Mite (*Ornithonyssus sylviarum*) also causes anaemia but can usually be found on birds, and has been seen on rats and also man. Treatment with tetrachlorvinphos is usually effective as is permethrin. The mite is found in temperate regions. In the Tropics it is replaced by the Tropical Fowl Mite (*Ornithonyssus bursa*).

Parasitus consanguineus A mite which normally feeds on small arthropods, roundworms and their eggs. It is found in dung, compost, spilt grain, etc. Opportunist infestation of a recumbent cow has been reported.

Poultry Cyst Mite (*Laminosioptes cysticola*) has been found in subcutaneous tissue and muscle, resulting in carcase condemnation, although it is doubtful if it would cause harm. They are seen as yellowish nodules in the tissues and are often numerous. It is seen in free-range poultry, turkeys, pheasants, pigeons and geese. The mite does no harm to poultry but an affected carcase is rejected for human consumption on aesthetic grounds.

Poultry Skin Mite (*Laminiosioptes bilobatus*) causes a fine scaly dermatitis followed by thick brownish, sharply-edged scabs. Treatment is as for depluming mite but on mainland Europe a mixture of equal parts of alcohol and balsam of Peru is also applied to affected parts.

Red mite of poultry (*Dermanyssus gallinae*) is a serious parasite in poultry. They live in cracks and crevices in the poultry house and travel out of their havens at night to suck blood from birds. They return to their havens in the morning and so are not commonly seen on birds. The birds become anaemic. It can be a problem on organic farms and here control is by painting perches with nicotine sulphate.

Scaly-Leg Mite (*Cnemidocoptes mutans*) is usually found on older birds and lives under the scales of the legs. Treatment is by dipping the legs in 0.5 per cent malathion.

Other species affected

Lagomorphs In rabbits the earmite is *Psoroptes canicui*.

Rodents Mites include *Myobia musculi* (mouse), *Mycoptes musculinus* (mouse), *Sarcoptes scabiei* (mouse, rat), *Notoedres muris* (rat).

Snakes (*Ophionyssus natricis*) can survive 20 days off the host and may cause dermatitis in man. Affected snakes show tan or black specks under the scales which appear dull around the eyes and in skin folds. They may rub against vivarium furniture or spend more time in water if available. The mites may interfere with moulting. Avermectins may be used, but not in chelonians, where fipronil may be applied as a topical application.

Mitochondria

Small membrane-bound cytoplasmic structures in cells; they are the main site of adenosine triphosphate (ATP) synthesis in the body (see CELLS).

VetBooks.ir

VetBooks.ir

Mitosis
The usual process of cell reproduction. Mitosis gives each of the new cells the same number of chromosomes as are possessed by the dividing cell, i.e. the diploid number. (Compare MEIOSIS.)

Mitral Regurgitation (MR)
An occurrence in cardiac disease, seen in dogs, where there is a defect in the MITRAL VALVE allowing the blood to flow back into the atrium against the normal flow.

Mitral Valve
Mitral valve is the left atrioventricular valve of the heart, which is so-called because of its supposed likeness to a bishop's mitre. Disease of the mitral valve is a common condition in the dog. (See HEART DISEASES.)

MJ
(See MEGAJOULES.)

ML
(See MACROCYCLIC LACTONES.)

Ml (ml)
Millilitre, equal to 1 cubic millimetre of fluid.

MLC
(See MEAT AND LIVESTOCK COMMISSION.)

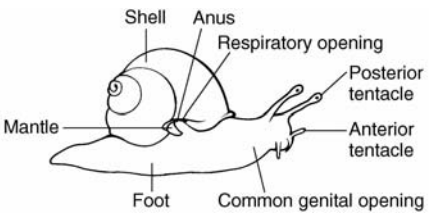
Modified Ziehl-Neelsen Stain
It is used to stain various micro-organisms, such as *Cryptosporidium* spp. (See CRYPTOSPORIDIOSIS; ZIEHL-NEELSEN STAIN.)

Moist Grain Storage
Moist grain storage, using propionic acid as a preservative. (See MUSCLES, DISEASES OF - NUTRITIONAL MUSCULAR DYSTROPHY.)

Moist Sounds
(See RALES.)

Mokola Virus
A rhabdovirus with some similarities to rabies virus. It was first isolated from shrews in Nigeria, and has caused the deaths of cats in Zimbabwe, where rabies vaccine has been found to be ineffective. Mokola virus has also proved fatal in humans.

Molar Teeth
(See DENTITION.)



Molasses
A liquid by product of sugar refining and containing about 50 per cent sugars and acts as a very palatable feed for farm animals and horses. It can be used to act as a vehicle for administering medicines, minerals etc.

Molecular Biology
The study of the structure and function of biological molecules; especially nucleic acids and proteins.

Mollities Ossium
(See OSTEOMALACIA.)

Molluscicide
A product used to destroy snails and slugs. (See under LIVER-FLUKES.)

Molluscs
Formerly, veterinary interest in snails was confined to their role in the transmission of disease. Nowadays, there is a trend to keep these creatures in captivity – for food, for study and 'as companion animals'.

External features of the snail species *Helix pomatia*.

Molybdenum
This trace element is commonly present in soil and pasture grasses, and is beneficial except when it occurs in excessive amounts – such as in the 'teart soils' of central Somerset, and of small areas of Gloucestershire and Warwickshire. Here 'molybdenosis' causes scouring in ruminants, especially cattle. The scouring is worse from May until October when the grass contains most water-soluble molybdenum. Staring coats, marked loss of condition and evil-smelling faeces are observed in affected cattle. A daily dose of copper sulphate (2 g for adults and half this for young stock) obviates or remedies the trouble.

Molybdenosis may occur also as the result of aerial contamination of pasture in the vicinity of aluminium-alloy and other factories, and of oil refineries. In an outbreak near the Esso Refinery at Fawley, younger cattle showed a marked stiffness of back and legs, with great difficulty in getting to their feet and reluctance to move – in addition to diarrhoea.

If an animal is receiving extra molybdenum in its diet, it is likely to need extra copper. Levels of molybdenum which interfere with copper metabolism also inhibit the synthesis of B_{12}, the cobalt-containing vitamin, by the rumen microflora. Similar problems occur in other parts of the world including New Zealand. (See 'PEAT SCOURS'.)

'Monday Morning Disease'

(See EQUINE MYOGLOBINURIA; EQUINE RHABDOMYOLYSIS.)

Monensin Sodium

Monensin sodium was licensed in the UK as a growth promoter for cattle but such use is now banned in the EU, although it is used elsewhere (see ADDITIVES) and as a coccidiostat for poultry. It is contained in an INTRARUMINAL device administered about a month before calving to produce a continuous release of monensin for about 95 days to reduce the incidence of ACETONAEMIA in dairy cattle. Monensin is produced by fermentation of a strain of *Streptomyces cinnamonensis*.

Overdosage of monensin can kill cattle. Autopsy findings include multiple haemorrhages and oedema of the right side of the heart.

Monensin toxicity has also been recorded in horses, sheep, chickens and turkeys.

Poisoning has been reported in dogs given a proprietary dog food contaminated with monensin still present in a storage bin not properly cleaned. (See also IONOPHORES.)

Monepantel

An AMINO ACETONITRITE DERIVATIVE used as an oral anthelmintic in sheep.

Mongee, Mongree

A dog produced by the planned mating of two different breeds of pedigree dog. The aim is that this F1 generation is less likely to suffer any of the inherited abnormalities present in either breed and to be more resistant to disease and so more healthy. There are numerous crosses used, including LABRADOODLES (labrador cross poodle); SPROCKERS (springer spaniel cross cocker spaniel).

Mongooses

Mongooses are vectors of rabies in South Africa, Central America, West Indies, and India. In India, the snake-killing mongoose possesses IMMUNITY to cobra venom. (See also MEERKATS.)

Monilia

A group of yeast-like organisms.

Moniliasis

Moniliasis is a disease due to the yeast-like fungus *Candida albicans*. In humans it follows, in some cases, the use of certain antibiotics.

The disease occurs in turkeys and fowls, and in other domestic animals. It including dogs and cattle must be borne in mind when using antibiotics. A high temperature, loss of weight, and oedema of the lungs may result.

Nystatin has been used – successfully, it is claimed – in the treatment of turkeys with moniliasis.

Monkeys

Monkeys (also referred to as SUB-HUMAN PRIMATES) belong to the order Primata which includes about 200 species, ranging in size from the tree shrew, weighing about 100 g, to the gorilla, weighing up to 275 kg.

Two sub-orders are recognised: New World monkeys (catarrhines); and Old World monkeys (platyrrhines), which include apes.

Monkeys, Anaesthetising

Ketamine is recommended as premedication before using closed circuit anaesthesia.

Monkeys, Diseases of

These include:

1. Infection with herpes simian B virus. This is easily transmitted to people bitten by monkeys (or perhaps to people merely handling monkeys with B virus lesions); it is of the greatest importance, as an ENCEPHALITIS or ENCEPHALOMYELITIS is produced in man, with death as the usual outcome. This infection should be suspected in monkeys showing vesicles on the lips, tongue, inside of the cheeks, or on the body. The vesicles burst and give rise to ulcers and scab formation. Occasionally, affected monkeys have conjunctivitis and a thick discharge from the nose.
2. TUBERCULOSIS. This is generally the miliary form, due to the human type of tubercle bacillus. Signs include: loss of weight, of appetite, dullness; sometimes cough and rapid breathing. Monkeys may be tuberculin-tested by injecting mammalian tuberculin into an eyelid. The result is noted by the presence or absence of swelling after 72 hours.
3. Pneumonia (unconnected with tuberculosis). A monkey that is coughing and sneezing can be assumed to be seriously ill. Death from pneumonia can occur within 24 hours, and affect a high proportion of any group of monkeys. A wide range of pathogens cause pneumonia in monkeys; they include paramyxovirus, *Streptococcus* spp., *E. coli*, *Pasteurella* spp., *Bordetella* spp., and *Klebsiella* spp. and a range of fungal pathogens. They are also susceptible to parainfluenza, measles and tuberculosis.
4. Dysentery due to *Shigella* organisms. This is a common cause of death among laboratory monkeys.
5. Phycomycosis. (See separate entry PHYCOMYCOSIS.)
6. Marburg disease, which can be fatal in both monkeys and man, is caused by a virus related

VetBooks.ir

VetBooks.ir

to Ebola virus and has been seen in laboratory workers in contact with blood and tissues of Vervet monkeys. Signs: headache, fever, muscular pain, prostration, diarrhoea and vomiting, with epistaxis and vomiting of blood.

7. Rabies.
8. Monkey pox. This is an apparently rare disease of monkeys. The virus was first isolated in 1958 in a monkey colony in the Statens Seruminstitut, Copenhagen. Cases of presumed monkey pox (resembling human smallpox) in man occurred in Africa in 1970. Since the worldwide eradication of smallpox, monkey pox has become the most important orthopox virus infection of man. Yet, despite a recent increase in the number of cases reported, human monkey pox remains 'a rare sporadic disease'.
9. YELLOW FEVER.
10. Measles. This was reported in 1975 in 11 colobus monkeys imported into the UK. No rash was seen; signs comprised a nasal discharge, conjunctivitis, cough, facial oedema and pneumonia. All died. Diagnosis was by laboratory tests.
11. Malaria. Fulciparum malaria has occurred in owl monkeys.
12. *Yersinia enterocolitica* infection. (See also KYASANUR FOREST FEVER.)
13. Leptospirosis.
14. Simian sarcoma virus.
15. Toxoplasmosis.
16. Infectious hepatitis.
17. Jaundice and blindness (temporary) have been caused by lead poisoning in monkeys. Sources of lead are many and varied and the animals have a tendency of 'exploring' everyday items (that could include lead) and old paint on enclosures must be considered. Treatment includes the use of CHELATING AGENTS and supportive therapy.
18. Cases have occurred of laboratory workers contracting viral haemorrhagic disease caused by an Ebola-related filovirus and by simian haemorrhagic fever in monkeys imported from the Philippines. (See also PETS, CHILDREN'S AND EXOTIC.)

Monkshood Poisoning
(See ACONITE.)

Monobasic
A compound containing one replaceable hydrogen ion.

Monochloroacetate Poisoning
Monochloroacetate poisoning has occurred in cattle, sheep, and other animals. Sodium monochloroacetate is a contact herbicide.

Monoclonal Antibodies
Identical immunoglobulin molecules produced by a single clone of plasma cells. (See GENETIC ENGINEERING.)

Monocyte
A type of white blood cell. (See under BLOOD.)

Monocytosis
(See 'PULLET DISEASE'.)

Monogenetic Flukes
Parasites that infest the gills of freshwater fish; they belong to the groups Gyrodactylus and Dactylogyrus. In the EU *Gyrodactylus solaris* infestation is a NOTIFIABLE DISEASE and there are restrictions on the movement of fish out of areas where this parasite has been detected.

Monomorphic
A term used to describe species of birds that show no external sign of their gender; e.g. many parrots and birds of prey.

Monoplegia
Monoplegia means PARALYSIS of a single limb, or part.

Monorchid
This term is commonly used by dog-breeders to mean an animal in which only one testicle has descended into the scrotum. Such an animal is correctly called a unilateral cryptorchid, the term 'monorchid' being reserved for the animal with a single testicle (a far rarer condition).

Under Kennel Club rules, a dog which does not have both testicles in the scrotum cannot be entered for show; but there is as yet no ban on the registration of dogs sired by a cryptorchid.

Cryptorchidism is an inherited condition (though it has been claimed that feeding rats on a biotin-deficient diet caused their testicles to return to the abdomen after two or three weeks), but the precise mechanisms of inheritance has not yet been determined.

Monosaccharide
Monosaccharide, or simple sugar, is a sugar having no more than six carbon atoms in the molecule. Among monosaccharides are fructose, glucose, galactose, levulose, etc. Monosaccharides have been termed the 'building blocks' of carbohydrates.

Monotocous
Normally producing only one offspring at birth, like cattle and horses, as compared with a litter of, for example, puppies.

VetBooks.ir

Monster, Teras

Severely malformed young are occasionally born to all species (teratogenesis). The cause may be genetic, or disease; or it may follow consumption of toxic substances. Haemolytic disease, for example, is responsible for abnormal piglets. (See also under TERATOMA; BULL-DOG CALVES; GENETICS, HEREDITY AND BREEDING - GENETIC DEFECTS).

Montbéliarde Cattle, Montbeliard Cattle

A breed of red and white cattle from Montbéliard, France used for milk and cheese production. A breed book started in 1872. In the 1970s red HOLSTEIN and FLECKVIEH were introduced to the breed but with little success. They have a white head and short horns with cows weighing 600 to 700 kg (1320 lb to 1540 lb) with a withers height of 145 cm (58 in) and bulls 900 kg to 1200 kg (1980 lb to 2640 lb). The milk yield is about 7500 l with 3.9 per cent fat and 3.45 per cent protein; the males can be used for meat.

'Moon Blindness'

(See PERIODIC OPHTHALMIA.)

Moorland Pony Breeds

These are described under various breed names. They are hardy animals and their height should not exceed 14.2 HANDS, which is the defined height of a pony. They are often grouped with MOUNTAIN PONIES to be Mountain and Moorland Ponies.

Morantel

An anthelmintic related to levamisole used to treat sheep with worm infestations.

Moraxella

Small rod-shaped bacteria found in pairs. Outbreaks of conjunctivitis and keratitis are often associated with *M. Bovis* (formerly *Haemophilus bovis*) infection. (See under EYE, DISEASES AND INJURIES OF.)

Morbidity

Morbidity is the condition of having a disease. Proportional morbidity is the incidence of disease in a flock or herd, e.g. 'morbidity is 60 per cent' in a given group of animals with reference to a particular disease.

Morbilliviruses

These include the viruses of canine distemper, rinderpest, *peste de petits ruminants*, and human measles. (See also SEALS.)

Morbillivirus in Horses

Morbillivirus in horses caused a severe disease outbreak, with transmission to man, in Queensland. Deaths occurred in both species. The clinical signs were severe respiratory distress, panting, high temperature, stiffness and frothy nasal discharge. If the horse survived for two days, there were cyanosis and oedema.

The virus is believed to have come from fruit bats; a bat miscarriage was found on the pasture grazed by the horses and the virus isolated from it. A survey found the virus in the reproductive tract of three species of fruit bat and 12 to 15 per cent had antibodies to the virus.

Morel's Disease

This affects sheep and is caused by the Gram-positive micrococcus *Staphylococcus aureus anaerobius*. The disease bears some resemblance to caseous lymphadenitis, with abscesses in subcutaneous tissue and intramuscular fascia, and has been reported in Central and North Africa, Europe and parts of Asia.

Morgan Horses

These are good trotting horses, all descended from a single stallion born in Massachusetts in 1789 and belonging to a Mr Morgan. They make good cavalry mounts. They are normally bay or chestnut.

Morlam

A strain of sheep bred at Beltsville, USA. The best ewes have given six lambs in two years, lambs being born in September, May and January – an eight-month breeding cycle.

Morning Glory

Plants of the *Ipomoea* spp. are common in most warm climates. They are grown for their attractive flowers and spread as a weed in some areas. Some varieties produce seeds containing the hallucinogen, lysergic acid. The pink or reddish flowered *Ipomoea muelleri* is said to have caused losses of up to 7000 sheep on some sheep stations in Western Australia. There is a loss of condition and, after a time, forced exercise gives rise to a swaying, uncoordinated gait and knuckling of the hind-feet, with panting when the animal is driven a few yards.

Morphine

Morphine is the chief alkaloid of opium. Widely used in human medicine, it is the standard against which other analgesics are measured. In animals, it is used mainly for the relief of severe pain in dogs. In the horse and cat, morphine may produce great excitement and is normally contra-indicated, although in horses it is an effective drug when combined with alpha 2 agonists (e.g. XYLAZINE, MEDETOMIDINE).

VetBooks.ir

Morphology
Literally, the 'science and study of form and structure'. Generally the term is used to describe the form and structure of organs, organisms and tissues.

Mortality
The use of death as a statistic.

Mortality Rate
This is the death rate, and is often used as a measure of disease severity or to give assessment indications of welfare, husbandry, transport, etc.

Mortar Eating
Mortar eating by cattle is a form of PICA and may be regarded as an indication of a mineral-deficient diet. The animals are probably seeking calcium and magnesium.

Mortierella
A genus of fungi. *M. wolfii* is the most frequent cause of mycotic abortion in cattle in New Zealand. It has been isolated in the UK from cases of abortion; rarely, from mastitis; and from the diseased liver of a calf.

Morula
In the cow, some five days after fertilisation of the egg, the embryo comprises a minute spherical group of 30 to 60 cells, inside a transparent shell. This is known as the morula because of its mulberry-like appearance.

Mosaic
An animal having one or more cell populations with different KARYOTYPES which have originated from a single zygote as a result of mutation or mitotic loss, etc. (See CYTOGENETICS.)

Mosaicism
(See under ERYTHROCYTE MOSAICISM.)

Mosquitoes
(See under FLIES.)

'Moss-Ill'
A colloquial name for hypocalcaemia (see under MILK FEVER) in hill ewes. It is seen mainly in the mature ewe, and during the weeks preceding, but rarely following, lambing. It often follows within 12 to 48 hours of a move to fresh pasture.

Signs Stilted gait, abnormally high carriage of the head, muscular tremors (particularly of the lips in the early stages), recumbency and coma.

Treatment Calcium borogluconate by subcutaneous or intravenous injection.

Moth Balls
(See NAPHTHALENE POISONING.)

Moths, Parasitic
In tropical Africa, Asia, and America, a small moth (*Arcyophora longivalvis)* feeds on the secretions of the eyes of cattle; its long proboscis is able to reach under the cow's 3rd eyelid (nictitating membrane). After sunset these moths fly out from their daytime woodland cover and alight on cows' faces. Several moths may be seen feeding from the same eye at the same time, and they are apparently attracted to eyes which are already inflamed. During the daytime the cattle's eyes are visited also by numerous flies, which transmit bacteria, worms, and other infective agents causing eye disease. As a result of their feeding habits, the proboscis of the moth becomes contaminated and transmits infection to other cattle.

A. patricula also frequents eyes, as do some African hawk moths. Their hosts include elephants, horses, pigs, cattle, and man.

In Malaya, Hans Banziger found blood-feeding moths. Some of these take blood from wounds already inflicted, or they take surplus blood left on the skin surface by mosquitoes. Banziger also found what one might call a vampire moth – *Colpe eustrigata* – which can, with its proboscis, penetrate human or animal skin in order to obtain blood.

Motor
Motor is a term applied to those nerves and tracts in the brain and spinal cord that have to do with the impulses which pass from the higher nerve-centres to the muscles causing movement. (See NERVES.)

Mouldy Food
(See DIET AND DIETETICS - PALATABILITY; also MYCOTOXICOSIS.) Mouldy hay or straw can lead to 'FARMER'S LUNG', and to abortion in cattle. (See ASPERGILLOSIS; also SWEET VERNAL GRASS.)

Moulting
Many mammals shed their hair coat at certain times of the year. This is particularly seen in the horse, and is also called 'shedding' or 'casting the coat'. It usually occurs twice a year in temperate climates. At other times moulting occurs in animals that are ill or debilitated.

In hens, moulting involves a complicated physiological process including neuroendocrine release of corticosteroid and thyroid hormones along with activation of the visceral forebrain system. Traditionally, forced moulting at the end of egg production has involved withdrawal of feed and supplementary lighting. Under EU welfare rules, withdrawal of feed is not permitted, but the provision of wheat

middlings alone or with maize is a practical alternative. Other methods have included supplying feed with high levels of lucerne, deletion of sodium or supplementation with zinc or manipulating the zinc and calcium levels in the feed. Birds in their second production period will lay about 75 per cent of the eggs laid in the first production.

Mountain Ponies

These are small horses or ponies that are adapted to living under rugged conditions. Often they are considered as Mountain and Moorland Ponies. WELSH MOUNTAIN PONIES are typical of this type of equine animal.

'Mountain Sickness'

A disease of cattle kept at high altitudes in North and South America. Local cattle are affected to an extent of only 1 per cent or so; recovery is unusual. Death occurs from congestive heart failure, after signs of depression, oedema of the brisket, and distressed breathing on light exertion. There may also be pulsation of the jugular vein.

Mouse

1. (See MICE; RODENTS.)
2. A small loose body. (See JOINT MOUSE.)

Mouse Viral Hepatitis

The virus can become present in mice breeding colonies. The method of eradication is to remove ova from an infected female, wash the ova in a suitable cleansing agent and then implant into uninfected receptive females. This procedure is used because the virus is present on the outer part of the ovum (zona pellucida). The process is repeated until a virus-free population is produced.

Mouth

Also known as the ORAL cavity.

Mouth, Diseases of

The mouth is one of the few internal cavities which can be examined by direct vision, so that its examination affords valuable evidence in some cases of disease (e.g. in ANAEMIA, JAUNDICE, cyanosis, and see TONGUE).

Inflammation of the mouth is known as stomatitis, and that of the gums as gingivitis.

Conditions of the mouth As a rule the signs that lead one to suspect that the mouth is diseased are as follows: salivation and difficulty in feeding in all animals; 'quidding' in the horse; smacking of the lips, in cattle particularly; rubbing the mouth along the edge of the trough, floor, etc., or pawing at it with the front feet, and much working of the jaws. Dogs may occasionally hold their mouths open, especially when a piece of bone or other substance becomes fixed between the teeth, and this sign is also present in rabies. (See also FELINE CALICIVIRUS; FELINE STOMATITIS; RANULA.)

Deformities of the mouth occasionally occur in all animals. (See CLEFT PALATE. Jaw deformities are referred to under TEETH, DISEASES OF and, in the case of cattle, under ACTINOMYCOSIS.)

Ulceration The presence of ulcers in the mouth may be associated with FOOT-AND-MOUTH DISEASE, SWINE VESICULAR DISEASE, MUCOSAL DISEASE of cattle, CATTLE PLAGUE (RINDERPEST) and BLUETONGUE; and sometimes with ORF in sheep, feline enteritis, and kidney failure/LEPTOSPIROSIS in dogs.

In CALF DIPHTHERIA, a whitish false membrane may cover part of the inside of the mouth. 'BROWN MOUTH' may be accompanied by necrosis. A bluish discoloration may be seen after asphyxia or in BLUETONGUE.

Gingivitis The gums may become inflamed (and often ulcerated) as a result of injury or disease, become red and slightly swollen, and often bleed easily. The condition may be acute, i.e. rapid in onset – and often rapidly resolved – (as with injury, burns and some viral infections), or it may be chronic (i.e. persistent). Chronic gingivitis is very common in people and most animal species, being caused by bacteria that grow on the teeth, forming dental plaque. This form of gingivitis can be treated by cleaning the teeth to remove the film of plaque. Tooth brushing is very effective, provided there is minimal calculus formation. However, appropriate diet can be very helpful in reducing problems. (See also FELINE GINGIVITIS.)

Glossitis Inflammation of the tongue, which is commonly due to injury (including teething) or exposure to irritants. In cats, both CALICIVIRUS and FELINE HERPESVIRUS can cause inflammation and ulceration of the tongue in addition to signs of 'cat flu'. (See FELINE INFLUENZA.)

Periodontitis The body reacts to an accumulation of certain types of bacteria accumulating on the teeth in DENTAL PLAQUE and around the teeth within the gingival sulcus, or groove. Initially gingivitis is caused and, if the process is not arrested, inflammation of the deeper tooth support tissues: periodontitis (perio = around, odont = tooth). One effect of the inflammation is local tissue damage. Left untreated the disease progresses to the point where teeth become loose and fall out. Significant levels of periodontal disease predispose to problems elsewhere in the body. Control of periodontitis requires a combination of profes-

VetBooks.ir

VetBooks.ir

sional dental hygiene treatment and ongoing oral home care, ideally including twice daily tooth brushing. In farm animals periodontitis of the back teeth is often complicated by impaction of fibrous plant material between the teeth and progressing to jaw abscesses (actinobacillus/lumpy jaw). Hill sheep are also prone to looseness and loss of incisor teeth from periodontitis, which is called 'BROKEN MOUTH'. Affected sheep usually also have significant problems further back in the mouth affecting molars and premolars.

Stomatitis Unlike gingivitis and periodontitis, inflammation of the lining of the mouth (stomatitis) is painful. Acute periodontitis, like gingivitis, is typically caused by viruses, burns and injuries. Chronic stomatitis is often at least in part a reaction to bacterial plaque on the teeth although there are other causes such as internal disease (e.g. kidney failure) and autoimmune disease.

Stomatitis in cats: Chronic caudal stomatitis is a commonly recognised condition in cats that may be difficult to treat. If it occurs largely in areas close to teeth there is usually a good response to tooth removal. In caudal stomatitis, tooth removal helps by reducing stimulation by the vast numbers of bacteria that accumulate in dental plaque, but there is an underlying immune system dysfunction that maintains the problem of significant levels in 10 to 20 per cent of severe caudal stomatitis.

Stomatitis in reptiles: 'MOUTH ROT' is commonly seen in reptiles such as tortoises and snakes. Their immune systems do not function efficiently at lower than ideal body temperatures making them prone to overgrowth with bacteria and fungi in their mouths.

Tumours in the mouth are sometimes seen. Warty growths, scattered over the mucous membrane of the whole of the cavity of the mouth, are not uncommon in young dogs. In addition to papillomas, fibromas, squamous cell carcinomas and malignant melanomas may occur. (See also EPULIS, a non-malignant gum tumour often difficult to remove.)

In one series of cases, oral tumours were removed from 100 dogs by mandibulectomy or maxillectomy. For basal cell carcinomas and squamous cell carcinomas, these techniques gave one-year survival rates of 100 per cent and 84 per cent, respectively. However, the prognosis for sarcomas was not so good: the tumours recurred in 32 per cent of cases and metastases developed in 27 per cent of cases; the one-year survival rates for fibrosarcomas, osteosarcomas and malignant melanomas were 50 per cent, 42 per cent and 0 per cent, respectively.

High-energy ionizing radiation gives good penetration of bone, and may be used for tumours of the mouth which are not practicable to treat by surgical excision.

Wounds and injuries In the majority of cases, mouth wounds do not prove serious after any foreign bodies have been removed, for the whole cavity is so well supplied with blood vessels that healing is always rapid. Haemorrhage may be alarming at first, but, unless a larger artery has been severed, it soon ceases. Large tears in the mucous membrane, or in the skin of the lips or cheeks, should be sutured. Antiseptic mouth washes should be applied afterwards. When the wounding has been severe, an animal will often refuse to eat solid food, and may require to be fed on liquids for a few days. Plenty of water should always be provided for drinking purposes. (See also under TONGUE; SALIVATION; TEETH.)

Mouth Rot

A severe problem of the mouth particularly in reptiles. (See INFECTIOUS ULCERATIVE STOMATITIS; MOUTH ROT - STOMATITIS.)

Movement of Cattle

(See IDENTIFICATION OF CATTLE.)

Movement of Goats

(See MOVEMENT OF SHEEP AND GOATS.)

Movement of Pigs

In Britain movement of pigs is controlled by the Pig (Records, Identification and Movement) Order 1995. All owners of pigs must inform the Divisional Veterinary Manager, DEFRA, of their holding. Records of pig movement, including identification marks, must be kept for three years. Pigs moved to slaughter need have only a temporary mark ('slap mark') but those moved between holdings or exported must have permanent markings, including the herd identification number. Pigs must not be moved between markets or collecting centres. When pigs are moved to another farm, none may be moved off those premises for 20 days following, except for slaughter. If pigs are fed waste food, they can only be moved to other premises under the same ownership, or to a slaughterhouse. A licence to move pigs is filled in by the owner and a copy must be kept for inspection by a local authority officer.

Movement of Sheep and Goats

Records must be kept of all sheep and goat movements to or from the premises on which they are kept; the destination of the animals must be noted. Each flock or herd is allocated an identification number under the Sheep and Goats Identification Order 2007. In addition, all sheep and goats born on a holding must be individually identified with an ear tag or tattoo within one year of birth, or before they are moved, whichever is earlier. The Sheep and Goats (Records, Identification and Movement)

Order 2008, as amended, gives details of the requirements initially.

Moxidectin
Moxidectin is effective both as an anthelmintic and against ectoparasites in sheep and cattle. It can be administered orally, by injection, or as a 'pour-on'.

MP
(See METABOLISABLE PROTEIN.)

MR
(See MITRAL REGURGITATION.)

MRD (Multifocal Retinal Dysplasia)
An inherited condition in some breeds of dogs that can cause serious eye problems. The retinal development is abnormal in a number of focal areas across the fundus. It is seen in a number of popular dog breeds including ENGLISH SPRINGER SPANIEL, GOLDEN RETRIEVER and CAVALIER KING CHARLES SPANIEL. While each individual area of retinal pathology may cause little visual impairment, the possibility of complete retinal detachment render this condition a serious inherited ocular abnormality.

MRI
1. Magnetic resonance imaging (see NUCLEAR MAGNETIC RESONANCE; DIAGNOSTIC IMAGING).
2. Meuse Rhine I(j)ssel breed of cattle.

MRL (Maximim Residue Level)
The maximum permitted level of a medicine in a food animal's body at slaughter. The MRLs are set by EU regulation. (See also WITHDRAWAL PERIOD.)

MRSA
The abbreviation of Met(h)icillin Resistant *Staphylococcus aureus*. It was seen first in humans and involves all *S. aureus* which have any resistance to met(h)icillin; some strains have multiple antibiotic resistance and this has caused concern. Diagnosis involves a microbiological investigation. The organism may be present in an infection or lesion but not the cause of it, although its presence must always be considered serious. The organism results in bacteraemia in humans as well as local infections. In animals, infection signs can be a mild, superficial, self-limiting disease, to spreading superficial infections, or a life-threatening disease. The infection was found in companion animals initially associated with those involved with human infections. Now it occurs more commonly and is often looked for before operating on small animals, especially dogs. A UK survey showed 1.5 per cent of clinical skin samples were infected with MRSA. Strains (including ST398) have been found in pigs in Denmark and seen in those working with them. MRSA strains also occur in other species including horses and less frequently in cattle. Livestock-associated strain CC398 has been isolated from bulk milk samples on British farms but would be destroyed by PASTEURISATION OF MILK.

Infection is increasingly being diagnosed in horses where it can involve skin and underlying soft tissues, the respiratory system, bones, implants and catheter sites.

MRSP
The abbreviation of Met(h)icillin Resistant *Staphylococcus pseudointermedius*. It has been seen in dogs in the USA and European countries, but currently it is uncommon in the UK.

MS
(See METABOLIC SYNDROME.)

Mucilage
Mucilage is an aqueous solution of a gum such as acacia or tragacanth. It is used as a demulcent and to suspend insoluble ingredients in oral medicines.

Mucin
(See MUCUS.)

Mucolipidosis II
A LYSOSOMAL STORAGE DISEASE caused by a deficiency of the enzyme, N-acetylglucosamine-1-phospotransferase. It has an autosomal recessive mode of inheritance. Cats fail to thrive, have facial deformities, dullness and ATAXIA. There is a DNA test for cats.

Mucolytic
Destroys or dissolves mucus. It also refers to agents that have this action.

Mucometra, Hydrometra
An uncommon condition in cats in which the uterus becomes filled with mucin-containing fluid. It is usually discovered at hysterectomy, but can be diagnosed in advanced cases by an ultrasound scan.

Mucophilosis
Another name for EPITHELIOCYSTIS in fish.

Mucopolysaccharidosis II
A LYSOSOMAL STORAGE DISEASE caused by a deficit or absence of the enzyme iduronate-2-sulphatase. It is called Hunter syndrome in humans. There are development delays, facial deformities and nervous signs. There is a DNA test in cats.

VetBooks.ir

Mucopolysaccharidosis VI

A rare genetic defect and LYSOSOMAL STORAGE DISEASE, which causes facial deformity, skin nodules and clouding of the cornea. It is caused by lack of an enzyme which breaks down mucopolysaccharides. It is caused by lack of an enzyme which breaks down mucopolysaccharides. It is seen in GERMAN SHEPHERD DOGS, MINIATURE PINSCHERS, MINIATURE SCHNAUZERS, SCHIPPERKES (DNA tests available) and also DOMESTIC SHORT-HAIRED CATS, RAGDOLL CATS, SIAMESE CATS and some other cat breeds (DNA test available).

Feline cases have been treated, using bone marrow from healthy cats with the same parents.

Mucopolysaccharidosis VII

A condition due to deficiency of beta-glucuronidase in cells. It is recorded in humans, dogs, cats and mice. There can be facial deformities and enlarged feet. There is a DNA test in cats.

Mucopurulent

Containing a mixture of mucus and pus.

Mucor

A genus of usually saprophytic fungi which is highly pathogenic to frogs and toads. The disease is characterised by the appearance of hyperaemic nodules on the underside of the body and also often granulomata throughout the body. It is usually fatal.

Mucoraceous

Related to or within the *Mucoracaea* Family.

Mucormycosis

Infection with *Rhizopus microsporus* is a cause of death of piglets under a fortnight old. The organism has been isolated from stomach ulcers in piglets which, before death, showed signs of vomiting and scouring. In many cases moniliasis was also present. Abortion in cattle has been attributed to mucormycosis. Two mucoraceous fungi have been found in bovine JEJUNAL HAEMORRHAGIC SYNDROME.

Mucosa

(adjective, Mucosal)

(See MUCOUS MEMBRANE.)

Mucosal Disease

(See BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE.)

Mucosal Oedema

Swelling of one or more MUCOUS MEMBRANES with fluid (OEDEMA). The area may pit with a finger.

Mucositis

Inflammation of the MUCOSA.

Mucous Membrane

The mucous membrane is a layer of cells that lines many hollow organs; the air passages; the whole of the alimentary canal and the ducts of the glands which open into it; the urinary passages; and the genital passages. (See MUCUS; BRUSH BORDER; IMMUNE RESPONSE.)

Mucus

Mucus is the slimy secretion derived from mucous membranes, such as those lining the nose, air passages, stomach, intestines, etc. Mucus is composed of a substance called mucin, water and cells cast off from the surface of the membrane, white blood cells, and often contains particles of dust, etc.

Under normal circumstances the surface of a mucous membrane is lubricated by only a small quantity of mucus. Excessive mucus secretion is the familiar accompaniment of nasal catarrh.

Mucus Agglutination Test

This is used in the diagnosis of *Campylobacter (Vibrio)* fetus infection in cattle. (See under *Campylobacter* SPP. INFECTIONS.)

Mud, Muddy Gateways

(See 'POACHING'.)

Mud Fever

Common name for a syndrome, rather than a specific condition. It is better called PASTERN DERMATITIS. The cause is multifactorial but can be an infection with *Dermatophilus congolensis*. It is particularly found in the featherings of the legs, of horses and goats.

'Mulberry Heart'

A disease caused by vitamin E and selenium deficiency which is usually fatal in pigs. Such deficient diets for the pregnant sow can lead to mulberry heart disease in the newborn piglets. After weaning, the cause is usually lack of vitamin E and selenium supplements in the weaner/grower ration. The disease is mainly one of pigs between three and four months old.

The disease is preventable.

Signs include lack of appetite and shivering – especially of shoulders and hindquarters. The forelegs may be splayed in an effort to maintain balance and the snout may be rested on the ground. A sitting-dog posture may be assumed. Black spots on buttocks, ears, etc., may be seen on many pigs in the herd. Temperature is subnormal. Distressed breathing may be observed. Death usually follows within 12 hours of the onset of signs. Occasional survivors are usually blind and unsteady on their legs. (See also under HEART DISEASES.)

Post-mortem findings include OEDEMA of the PERICARDIUM and EPICARDIAL HAEMORRHAGES,

which give rise to the characteristic 'mulberry' appearance.

Mule

The common definition of a mule is the sterile offspring of a jack donkey and a mare. However, scientifically authenticated reports from both China and the USA have supported ancient folklore – to the effect that a female mule is sometimes fertile.

In the context of sheep, 'mule' is a most imprecise term; indeed, it is a colloquial expression varying according to period, locality, and changes in breeding policy.

The following crosses have all been referred to as a 'mule': BORDER LEICESTER ram × BLACKFACE ewe; Border Leicester or Hexham/LEICESTER ram × SWALEDALE or SWALEDALE/BLACKFACE ewe; BLUE-FACED LEICESTER ram × SWALEDALE or BLACKFACE ewe (though this cross is now known as the North Country mule).

Mule is also the term used for a cross between a British finch (bullfinch, greenfinch and goldfinch) and the domestic canary: e.g., a bullfinch-canary mule.

Mulesing

A synonym for the MULE'S OPERATION.

Mule's Operation

This involves the removal of a fold of skin from the crutch of MERINO SHEEP and other breeds to produce a hairless area. It is carried out by Australian shepherds for the control of BLOW-FLY STRIKE. Mulesing is a synonym. It is considered an unacceptable mutilation in many countries, including the UK.

Multicentric Leukaemia, Aleukaemic leukaemia

A malignant disease of the lymph glands and liver of dogs in which there is cancerous proliferation of lymphocytes in the affected organs. Treatment includes chemotherapy and radiation but the disease is inevitably fatal. (See LEUKAEMIA (LYMPHOSARCOMA.))

Multicoloured

A coat colour usually used when referring to horses where there are three or more colours present. (See also PIEBALD; SKEWBALD.)

Multifactorial

1. A disease, problem of infection resulting from a number of factors which occur at the same time or in sequence to cause the problem (for example CALF PNEUMONIA).
2. It can be used to indicate several different organisms or factors which on their own may produce a clinical or pathological entity.
3. In genetics it relates to a problem or entity which is the result of the interaction of several or many genes.

Multifocal Retinal Dysplasia

(See MRD.)

Multilocular

Consists of many small parts or cavities.

Multiparous

A female animal which has produced more than one viable set of offspring. (Synonym PLURIPAROUS).

Multiple Suckling

(See under NURSE COWS.)

Multiple Vaccines

(See under VACCINATION.)

Mummification of Fetus

Mummification of the fetus sometimes occurs after resorption of fluid from the placenta and fetus following the death of the latter. It is not uncommon in dairy cattle. In sows, it has been reported following AUJESZKY'S DISEASE and SWINE ERYSIPELAS. In ewes, it may be associated with TOXOPLASMOSIS and, very occasionally, ENZOOTIC OVINE ABORTION. A mummified fetus, remaining in the uterus for longer than the normal gestation period, will lower a cow's productivity. (CLOPROSTENOL and other prostaglandins can be used to abort the mummified fetus in many instances.) Fetal mummification is a sequel to the relatively common phenomenon of extrauterine pregnancy in rabbits; it may also occur in the bitch and cat.

Mumps

Mumps is another name for parotiditis or inflammation of the parotid glands at the base of the ears and at the back of the angle of the lower jaw.

Antibodies against the human mumps virus have been detected in the blood serum of dogs.

A survey revealed that 38 out of 209 apparently healthy country dogs in the UK had the virus, with about 18 per cent in one USA study being affected. Clinically, mumps has been confirmed only rarely in dogs in the UK. Signs include loss of appetite, depression and greatly enlarged and painful submaxillary lymph nodes.

Munchhausen By-Proxy Syndrome

A psychiatric condition of humans in which a person injures a member of the family (usually a child) in order to gain attention. Harm may also be inflicted on the family pet to achieve the same ends. Pets are presented with unusual injuries or

VetBooks.ir

following the administration of sub-lethal doses of poison. A guide to suspecting this condition as it affects pets was published in *Journal of Small Animal Practice* (2001) **42** 218–226.

Munchkin
A dwarf breed of cat originating from the USA. DWARFISM has been bred into munchkins, which have very short legs. They find it difficult to climb and jump, rendering them vulnerable to attack by dogs and other cats. It has fewer spinal problems than are seen in similarly-shaped dogs.

'Munga'
The African name for the grain of the bulrush millet, *Pennisetum typhoides*. The grain, when parasiticised with ergot, has caused agalactia in sows without other signs. A heavy piglet mortality resulted.

Muriellopsis
Blue-green algae. Some are grown commercially for the extraction of LUTEIN.

Murine
Relating to, or pertaining to mice.

Murine Typhus
A disease of rodents caused by a RICKETTSIA, which is transmissible to people, in whom it has been known to cause death in some cases.

Murmur
A sound detected on AUSCULTATION indicating heart or vascular problems (see HEART).

Murrain
An obsolete name formerly applied to a number of diseases affecting domestic animals such as anthrax, foot-and-mouth disease, etc.

Murray Grey
An Australian beef breed, originating from a roan Shorthorn cow and an Angus bull. A first consignment of 50 reached the UK in 1973. The breed is noted for its size, docility, and easy calving.

Murray Valley Encephalitis
Caused by a mosquito-borne flavivirus, this disease occurs in Australia and New Guinea. It affects wild birds. In children it may cause fever, vomiting and encephalitis, sometimes with a high mortality.

Musca Autumnalis
(See AUTUMN FLY.)

Muscle
Muscular tissue is divided into three great classes: *voluntary muscle, involuntary muscle* and *cardiac muscle*. Of these, the first only is consciously (i.e. voluntarily) controlled, the two latter working automatically (involuntarily). Voluntary muscle is often called 'striped' or 'striated', because under the microscope each muscle fibre shows very distinct cross-striping, while involuntary muscle does not, and is consequently often called 'unstriped', 'non-striated' or 'plain', or smooth, muscle. Cardiac muscle is striated in an imperfect manner, is not under the conscious control of the brain, and has a specialised arrangement of its fibres.

Structure of muscle Voluntary muscle forms the chief clothing of the skeleton, and is the red flesh forming beef, mutton, pork, etc., of the food animals. The voluntary muscles are arranged over the body, the majority of them being attached to some part of the bony or cartilaginous skeleton, and are called 'skeletal muscles'. The individual muscle is attached at each end by muscle fibres or tendons to the skeleton, which it operates, in effect, as a system of levers.

Each muscle is enclosed in a sheath of fibrous tissue, known as the 'fascia' or 'epimysium', and from this, partitions of fibrous tissue, known as 'perimysium', run into the substance of the muscle, dividing it into small bundles of 'fibres'. A muscle fibre is about 0.05 mm (1/500 in) thick, and of varying length. Each is enclosed in an elastic sheath known as the sarcolemma. If the fibre is cut across and examined by the microscope, it is seen to be further divided into 'fibrils'. Within the sarcolemma lie numerous nuclei belonging to the muscle fibre, which was originally developed from a single cell. To the sarcolemma, at either end, is attached a minute bundle of fibrous tissue fibres, which unite the muscle fibre to its neighbour or to one of the connective tissue partitions in the muscle; by means of these connections the fibre produces its effect upon contracting. The sarcolemma is penetrated by a nerve fibre, which breaks up upon the surface of the muscle fibre into a complicated 'end-plate', and by this means each muscle fibre is brought under the control of the central nervous system, from which energy is discharged and produces muscular contraction.

Between the pillar-like muscle fibres run many capillary blood vessels. They are so placed that the contractions of the muscle fibres empty them of blood, and thus the active muscle is ensured of a continually changing blood supply. None of these capillaries, however, enters the sarcolemma surrounding the fibres, so that the blood does not come into direct contact with the fibrils themselves. These are nourished by the lymph which exudes from the capillaries and bathes the outside of the sarcolemma, passing into the fibrils by a process of osmosis. The lymph circulation is

VetBooks.ir

also automatically varied by the muscular contractions. Between the muscle fibres, and enveloped in a sheath of connective tissue there is sporadic distribution of special structures known as 'muscle spindles'.

Involuntary muscle forms the greater part of the walls of the hollow organs of the body, such as stomach, intestines, bladder, etc., and the walls of the blood vessels, ducts from glands, the uterus and Fallopian tubes, the urethra, ureters, the iris and ciliary muscle of the eye, the 'dartos' tunic of the scrotum, and is associated with the skin and hair follicles. The fibres are smaller than those of voluntary muscle. Each is pointed at the ends, has usually one oval nucleus in the centre, and a delicate sheath of sarcolemma enveloping it. The fibres are grouped in bundles, much as are the striped fibres, but they adhere to one another by a cementing material, not by tendon bundles found in voluntary muscle.

Cardiac muscle is a specialised form of involuntary muscle in which the fibres are provided with numbers of projections, each of which is united to a similar projection from an adjacent cell, so that the whole forms an intricate network or mesh of fibres instead of an arrangement of bundles. Each fibre possesses a large nucleus which is more or less central in position.

Development of muscle All the muscles of the developing animal arise from the central layer (mesoblast) of the embryo, each fibre taking origin from a single cell. From birth or hatching muscles have the power both of increasing in size – as the result of use, e.g. in racehorses and greyhounds and other animals that are trained to be fit – and of healing themselves after parts of them have been destroyed by injury or removed surgically. This occurs by development of cells called myoblasts in the same way as muscle is formed in the growing embryo. Unstriped muscle as well as striped muscle can take part in this increase in size, as witness the development of the muscular wall of the uterus during pregnancy. In this case not only do the numbers of muscle fibres increase, but each becomes three or four times its previous size. The fully pregnant uterus increases its weight about 20 times what it is when empty, and in the course of a month to six weeks after parturition decreases again in weight and size.

Action of muscle A nerve impulse originates in some part of the brain or spinal cord, either consciously or as a reflex, and passes down the fibres of the motor nerve to the muscle, where a series of complex chemical reactions occur. The source of energy for muscular contraction is adenosine triphosphate (ATP). When this is split into adenosine diphosphate (ADP) and phosphoric acid, energy becomes available. For subsequent resynthesis of ATP from ADP, creatine phosphate (CP) is converted to creatine plus phosphoric acid – oxygen from the bloodstream being required. (These are but two of many complex reactions, involving several enzymes.) (See also LACTIC ACID.)

During strenuous exercise, more oxygen may be needed than is readily available, leading to the so-called 'oxygen debt', which results in panting in mammals and GULAR FLUTTERING in birds and some reptiles. This 'oxygen debt' can be partly offset as the muscle makes use of another chemical reaction, involving the conversion of glycogen to lactic acid.

Fatigue The accumulation of lactic acid in the muscles causes the stiffness of fatigue, which has been defined as 'a decrease in capacity for work caused by work itself'. In large quantities, lactic acid in the muscles can lead to CRAMP.

After exercise, lactic acid is either eliminated as carbon dioxide and water, or converted in the liver back to glycogen.

The importance of a sufficient period of rest for animals which have been called upon for great exertion, such as in hunting or racing, is obvious.

Muscle tonus is the state of partial contraction of a muscle by virtue of which it is ready for work at all times. Tonus is specially evident in the plain muscle fibres present in the walls of the arteries, and it is owing to tonus that such striking and rapid changes in the amount of the blood in a part can occur. If the inhibitory fibres (called 'vasodilators') in the arteries are activated, an immediate increase of blood takes place; while if the stimulating fibres (called 'vasoconstrictors') are acted upon, the muscle fibres in the walls contract, the calibre of the vessels is decreased, and the blood supply is lessened.

Condition is that remarkable state into which horses and other animals can be brought by care in feeding, general management, and carefully regulated work, which is the highest pitch of perfection to which muscles can attain. It is a potential quality not possessed by all animals, and, even when attained, does not last for long periods. In the process of training it is possible by excessive enthusiasm to produce a condition of 'staleness', in which speed or staying-power diminishes, but recovery from which follows a period of rest. Condition consists in a gradual education of the muscles of the skeleton, of the heart and respiratory organs particularly, as well as of the body generally, so that they will sustain fatigue with greater and greater facility.

All superfluous fat is removed from the body; the volume of the muscles is increased, and their elasticity, tone, responsiveness to stimuli, power of

VetBooks.ir

contraction, and blood supply are heightened; the respiratory system is made to accommodate itself to the oxygenation of vastly greater amounts of blood in a shorter space of time than normally; the heart muscle – the main pump of the circulation – hypertrophies, and the walls of the smaller arteries – the secondary pumps of the circulatory system – are keyed up to the highest state of responsiveness to local requirements. In the production of all this lies the art of the trainer.

Equine and canine athletes The speed and stamina of the thoroughbred and the greyhound are due to the fact that both animal species can increase, during exercise, their packed cell volumes to between 60 and 70 per cent. Together with large increases in the heart's output, the result is much larger increases in effective blood flow to the muscles than occurs in humans. In the fit thoroughbred, resting heart rates of 25 to 30 beats per minute can be increased to between 240 and 250; and in the greyhound, heart rates below 100 can be increased to 300 beats per minute. Both species also have large hearts for their bodyweight. Approximately 57 per cent of the greyhound's liveweight is due to muscle, as compared with 40 per cent for most other mammals.

M

Muscle Relaxants

Muscle relaxants are drugs which produce relaxation or paralysis in voluntary muscle, such as does curare. They are used to facilitate such procedures as inserting a breathing tube into the trachea (endotracheal intubation). They may be used in conjunction with a general anaesthetic, thereby enabling a lower dose of anaesthetic to be used and reducing side-effects. The use of muscle relaxants, however, requires special skills and equipment. As they prevent animals from reacting to painful stimulation, they must never be used without adequate analgesia and never as immobilisation agents.

Muscles

Muscles, which are collectively and popularly known as the 'flesh' of an animal, comprise the voluntary muscles, and amount to over one-third the weight of the whole body in an average animal of ordinary condition. The total number of voluntary muscles is over 700 in the horse, and more than this in some of the other domesticated animals, so that they cannot all be described here. Each voluntary muscle is named, its blood and nerve supplies are mentioned, and its shape, relations, and actions are considered in works on comparative anatomy, to which reference must be made for further details.

Generally speaking, muscles which cause a joint to bend are called 'flexors'; those which straighten a bent joint are 'extensors'; one which carries a limb further away from the middle line of the body than previously is an 'abductor'; one which has the opposite action is an 'adductor'; and one which causes a segment of a limb to revolve is a 'rotator', or 'supinator', or a 'pronator', according to its position. A sphincter is usually involuntary, but a few are voluntary; they cause a contraction of the ring-like opening which they circumscribe. Many muscles have an insertion distant from their fleshy part (called the 'fleshy belly') by means of a tendon which is composed of fibrous tissue strands.

Muscles, Diseases of

Atrophy, or wasting, of muscles may occur as the result of inaction, diminished blood supply, or nerve injuries, as well as from malnutrition.

Inflammation of muscle, or MYOSITIS, may arise as the result of injury through kicks, blows, falls, etc. It also frequently arises as the result of a sprain or strain in the limbs. Occasionally it may be associated with partial or complete rupture.

Signs The part affected usually becomes swollen and is painful on manipulation. The muscles affected are held relaxed, and if in a limb, the foot is rested. When handled, they contract and become hard to the touch, and upon occasion they may crackle or be oedematous. When resulting from external injury there is usually some sign of this on the covering skin, but when due to strain no external lesions may be seen. Occasionally, after injury, an abscess may develop in the affected muscle, but much more frequently there is HAEMATOMA.

Atrophic myositis This has been described in the dog. The cause is unknown, but possibly damage to the fifth nerve due to over-extension of the temporo-mandibular joint.

Signs Inability to eat solid food or to lap, ATROPHY of the jaw muscles, very little voluntary movement of the jaws, and resistance to any attempt to force the jaws apart. With careful nursing, recovery takes place naturally in a high proportion of cases after three to six months. (See also 'STIFF-LIMBED LAMBS'.)

Eosinophilic myositis A disease of dogs, especially GERMAN SHEPHERD DOGS, in which there is hardening of the muscles of mastication and of the temporal muscles. The dog assumes a foxy appearance. The nictitating membrane is in evidence. There may be TONSILLITIS. The cause is unknown; the outlook grave. Diagnosis may be confirmed by haematological examination.

Ischaemic contracture A disease of muscles due to failure of their arterial supply. There is necrosis and the muscle is replaced by fibrous tissue which contracts or shortens. The condition has been reported in the dog.

Nutritional muscular dystrophy This is most common in beef cattle, but is occasionally seen in dairy cattle also. In calves and lambs it is often called 'white muscle disease'. Muscular dystrophy also occurs in foals and pigs. It may prove fatal.

Cause Animal feeds deficient in selenium (a trace element) or vitamin E, between which there is a complex relationship. Crops grown on selenium-deficient land may give rise to nutritional muscular dystrophy unless concentrates are fed as well or unless the diet is supplemented with vitamin E. This vitamin is sometimes adversely affected by the use of propionic acid as a preservative in the storage of moist barley.

A vitamin E deficiency may also be brought about by giving cod-liver oil in conjunction with rations low in vitamin E, such as dried skim milk powder, for research has shown that the inclusion of cod-liver oil in the diet leads to a striking increase in the animals' requirements of vitamin E. The disease may also be associated with poor-quality food, such as the mainly turnip and oat straw diet fed to pregnant cows during the winter in Scotland. Deterioration of food in storage, and especially of those containing unsaturated fatty acids, may be associated with the condition.

High rates of application of fertilisers containing sulphates may inhibit absorption of selenium from the soil by plants, which in turn can lead to a deficiency in grazing animals. Lucerne, clover and beans all contain an unidentified antagonist to vitamin E: another point to bear in mind when considering supplementing the diet.

Signs Muscular dystrophy takes three forms, as far as signs are concerned. The most dramatic form occurs when the heart muscle is involved – causing a heart attack which is usually followed by death within minutes or hours.

When the muscles of the back and legs are affected, the animal prefers to remain lying down, rises with difficulty, and walks slowly and stiffly. The third form is seen when the chest muscles are affected. Exaggerated compensatory movements are then made by unaffected muscles in order to maintain breathing.

The more severely affected cattle may pass dark reddish-brown urine, resulting from the presence in it of myoglobin. This sign accounts for another name for the condition – 'paralytic myoglobinuria'.

Prevention Give the cow and calf vitamin E, or alternatively plenty of good-quality silage.

Selenium supplements are useful; but care must be taken not to add them excessively to feed. There have been many cases of poisoning due to overdosage in farmers' home-mixes. (See CONCENTRATES.)

Back muscle necrosis (See under this heading for a disease of pigs.)

Muscular rheumatism is a form of myositis which attacks dogs and pigs especially, although horses and cattle are also affected. Certain animals seem to have a susceptibility to this trouble.

Causes include exposure to cold, draughts and dampness, insufficient protection against changes in the weather, standing for long periods in rainy weather, and insufficiency of bedding (especially in piggeries and kennels).

The affected muscles are found tense and quivering, and manipulation of them causes such excruciating agony that the smaller animals often scream with the pain when the parts are handled, and the larger animals may grunt or moan. Sometimes voluntary movements in the part of the animal itself excite the same distress. The muscles of the neck, shoulders, and abdominal wall are those most often affected in all animals; the muscles of the lower jaw are frequently affected in dogs; and the condition may attack almost any of the muscles of the body. When the loins are affected the condition is called 'lumbago', and when the croup and thigh are involved it is known as 'sciatica'.

Massage of the affected muscles with some mild liniment, such as soap liniment, hot applications, exercise and warmth are necessary outwardly, and internally salicylates or phenylbutazone may be given.

Cramp of the muscles is common in animals that are not in a fit condition when they are worked or exercised. (See under CRAMP; also 'SCOTTIE CRAMP'.) PARASITES are sometimes encountered in the muscles. (See TRICHINOSIS; GIARDIASIS.)

Tumours are occasionally found.

Shivering, stringhalt For these two muscular diseases of horses, see under those headings. (See also MYASTHENIA GRAVIS; MYOTONIA; MYOGLOBINURIA.)

Muscovy Duck Parvovirus

This has been reported from Pennsylvania where affected birds showed locomotor dysfunction, recumbency and weakness. Morbidity was 40 to 60 per cent and mortality 10 per cent. One of the viruses isolated appeared to represent a new group of avian parvoviruses.

VetBooks.ir

VetBooks.ir

Muscovy Ducks
(*Cairina moschata*) This is a large duck native to Mexico, Central and South America. In Britain they have been domesticated since the 16th century and were sold as Barbary ducks. They are bluish black with large flat feet and long claws; the nude head is black-and-red or red and in the drake pronounced caruncles are at the base of the bill, and there is a low erectile crest of feathers. Both sexes have white on the wings. The drake weighs 4.6 kg to 6.8 kg (10 lb to 15 lb) and is up to 86 cm (35 in) high; the female weighs 2.7 kg to 3.6 kg (6 lb to 8 lb) and height up to 64 cm (26 in). Drakes have a low breathy call and females a quiet trilling call. They have a nest of 8 to 16 white eggs and incubation is 35 days.

Muscular Dystrophy
(See MUSCLES, DISEASES OF.)

Muscular tone
The tension within a muscle or muscle fibre.

Musculoskeletal System
The muscles and skeleton that together allow movement of an animal. It is also called the LOCOMOTOR SYSTEM.

Mushroom Poisoning
This occurs following the eating of mushrooms containing the alkaloid muscarine. It occasionally happens in dogs; the signs include vomiting, diarrhoea and collapse.

'Mushy Chick' Disease
(See OMPHALITIS OF BIRDS.)

Mussel, Freshwater
The larvae (glochidia) of the mussel are parasites of fish gills and may be seen as white specks (cysts) on the gill. Unless present in large numbers they do little harm. There is a symbiosis with the freshwater fish, bitterling (*Rhodeus amarus*), which may become parasitised in this way because the female lays her eggs in the respiratory chambers of freshwater mussels, where they develop away from the threat of potential predators. In turn the glochidia attach themselves to the developing bitterling and so are dispersed to new areas.

Mustard Poisoning
English mustard consists of the dried ripe seeds of *Brassica nigra* and *B. alba* ground together. The seeds contain toxic compounds (isothiocyanates) in non-toxic form. However, they also contain the enzyme myrosinase which, in the presence of cold or lukewarm water, converts the glycosides into the volatile oil to which the action of the mustard is due. Cattle have died as a result of white mustard seed being swept off the floor of a barn on to pasture, where they are ingested after becoming moistened. Signs include walking backwards and in circles, profuse salivation and curvature of the spine. Acute gastroenteritis also occurs.

Musth, Rut
A period of great sexual excitement in male Asian and African elephants, which become very aggressive during the autumn breeding season.

Musty Food
Musty food should not be used for animals' food. It is very unpalatable, and a small quantity can spoil a large amount of food. It is not easily digested, and may lead to serious digestive upsets. There is also a risk of ASPERGILLOSIS. (See MOULDY FOOD.)

Mutation
A permanent change in the characteristics of bacteria or viruses. This is the usually implied, though not exact, meaning. (See also GENETICS, HEREDITY AND BREEDING.)

Mutilation
This term is used in a veterinary sense as meaning any operation affecting the sensitive tissue or bone structure of an animal. Under the Animal Welfare Act 2006 and the Animal Health and Welfare (Scotland) Act 2006 Part II subsidiary legislation, there is a list of the mutilations that may be performed on animals. If a mutilation is not on the list it is illegal unless performed for therapeutic purposes. The subsidiary legislation is passed separately for Scotland, England and Wales. These include DOCKING of tails, EAR CROPPING of dogs, MULESING of sheep, debarking of dogs, DE-BEAKING of poultry. (See FARM ANIMAL WELFARE COUNCIL.)

Mutilations (Permitted Procedures) Regulations
The main Regulations for England and Wales are dated 2007 with amendments. The Scottish legislation is Prohibited Procedures on Protected Animals (Exemptions) (Scotland) Regulations 2009, 2010. There is a list of permitted procedures involving identification, control of reproduction and other procedures. Schedules for various species indicate the requirements for undertaking the procedure, such as anaesthesia, etc.

Muting Of Dogs
This involves a surgical operation under general anaesthesia, when the vocal cords are completely excised. It was performed during the 1939–45 war on army dogs. It is not a permitted procedure under the subsidiary legislation of the Animal

VetBooks.ir

Welfare Act 2006. If a dog is making a nuisance of itself by excessive barking or howling, the owners should seek help from a canine behaviourist or attend dog-training classes.

Mutter-Pea Poisoning
(See LATHYRISM.)

Mutualism
Mutualism is the association of two species as a mutually beneficial partnership. See also SYNERGISM.

Muzzle, Tape
(See under RESTRAINT - DOGS AND CATS.)

Myalgia
Pain in a muscle.

Myasthenia Gravis
A disease of muscles seen in dogs and cats, and occurring in both a congenital (an inherited disorder affecting NEUROMUSCULAR transmission) and an acquired form.

The former, less common, has been diagnosed in puppies from six to eight weeks old and showing muscular weakness exacerbated by exercise but improving with rest. In cats it is common in the ABYSSINIAN breed.

The acquired form is regarded as an immune-mediated disease in which there is an impairment of neuromuscular transmission.

Apart from the muscular weakness, there may be difficulty in swallowing, vomiting, urinary incontinence and depression. (See also MEGAOESOPHAGUS.) Diagnosis can be made with the aid of neostigmine, given orally, which often gives relief within the hour. Neostigmine is also used for treatment, which may need to be prolonged. Other medications include pyridostigmine bromide; occasionally, corticosteroids are used.

Mycobacterium
(plural, Mycobacteria)
A genus of acid-fast, Gram-positive, non-motile bacteria in the form of slender rods. Species include: *M. tuberculosis, M. johnei, M. leprae* (the cause of leprosy); and *M. intracellular* and *M. xenopi*, both of which may cause a tuberculoid infection, resembling avian TB in pigs, chickens, mice. *M. phlei* is the timothy-grass bacillus.

M. chelonae-abscessus is found in reptiles, causing abscesses. In the USA it has caused sinusitis or pulmonary disease in humans. *M. xenopi* can cause generalised disease especially in stressed animals. It has caused human respiratory disease. *M. marinum* can cause generalised tuberculosis in fish. At one time in the USA feeding fish-meal containing infected fish caused wide infection on some fish farms. It can cause human skin infections.

In dogs, infections occur commonly from contact with tuberculous humans and infected meat and milk. The causative bacterium is usually *M. bovis*. Whilst respiratory and gastrointestinal signs are seen, there may be single and multiple granulomas or abscesses, especially on the head, neck and limbs. Systemic illness with fever, loss of appetite, weight loss and LYMPHADENOPATHY should arouse suspicion of tuberculous infection and possibly to human contacts. (See CAT LEPROSY.)

In cats, *M. bovis* has been reported to have caused respiratory, alimentary and joint involvement. Other infections are not uncommon and include *M. avium*, *M. tuberculosis* and *M. microti* (the vole bacillus). Clinical conditions include FELINE LEPROSY SYNDROME and other skin conditions that are usually due to contamination of skin wounds obtained either from fighting or physical injury) e.g. from barbed wire or a sharp object. In these cases, *M. avium* appears to be more pathogenic than other mycobacteria.

Mycoplasma
An infective agent that used to be considered distinct from bacteria as well as from viruses. They are now regarded as bacteria without cell walls. In size they resemble a large virus and they are filterable, but they can be cultured on artificial media. *Mycoplasma dispar* is a major component in the disease of cuffing pneumonia in calves and *M. hyopneumoniae* is responsible for enzootic pneumonia in pigs. Polyserositis in piglets occurs with *M. hyorhinis* and multiple joint arthritis in pigs over 10 weeks old is due to *M. hyosynoviae*.

M. mycoides was isolated from cattle with pleuropneumonia in 1898; *M. agalactiae* from goats in 1923. Since then, other species have been isolated from humans and dogs but so far no strain has been found in rabbits. This makes them ideal for raising hyper-immune sera for diagnostic purposes since there are no antibodies to 'native' mycoplasmas to interfere with the resultant use of the serum.

In avian species, *M gallisepticum* is a serious complicating infection in chickens; it is a primary pathogen in turkeys and pheasants. Clinically, some birds will have a swelling on one or both sides of the head; more commonly, air sacculitis is present. Infection is transmitted vertically via the eggs. The number of infected eggs in a batch is small but the disease spreads rapidly among young chicks and poults in the hatcher and during the initial weeks of life. Treatment is by antibiotics such as the tetracyclines, spiramycin, tylosin or spectinomycin. Eradication programmes in both chickens and turkeys have been successful but birds free from infection must be kept away from infected birds. *M. meleagridis* is a pathogen of the turkey and is transmitted venereally. It causes a transient respiratory condition before settling in

VetBooks.ir

the genital tract, especially that of the male (stag); it can cause leg problems in commercial turkeys. *M. meleagridis* is more difficult to eradicate than other species. It is resistant to antibiotics and, as most turkeys are now produced by artificial insemination, an infected male used for artificial insemination can quickly wreck an eradication programme; the percentage of infected eggs is very high compared with *M. gallisepticum. M. iowae* is also present in turkeys and causes decreased hatchability. *M. iowae* infection is usually detectable only in flocks that have been freed from the other mycoplasmas. Eradication is difficult but not impossible. *M. synoviae* affects chickens and turkeys, causing tenosynovitis. It may be treated by high doses of tetracyclines. The method of spread is unclear; even biting insects have been suggested as possible vectors.

In goats *M. mycoides* causes contagious caprine pleuropneumonia, as well as septicaemia and mastitis.

M. bovis, first isolated in the USA in 1962, has caused severe respiratory disease in the UK. It also causes mastitis.

M. canadense was first reported in the UK in 1978, and causes abortion in cattle; and *M. californicum* causes mastitis.

In many parts of the world, even where contagious bovine pleuropneumonia has been eradicated, mycoplasmal diseases are of considerable economic importance. They include mastitis, arthritis, bone disease, and keratitis. In cattle, *M. bovigenitalium* is a cause of abortion and mastitis.

M. hyosynoviae has caused lameness in pigs. The pigs frequently adopted adopt a 'dog-sitting' posture; and develop areas of hyperaemia on the hams.

M. wenyonii can typically result in pyrexia, swelling of the hind legs and/or udder, and enlarged prefemoral lymph modes in cattle. Other signs can occur. Arthropods and using the same hypodermic needle may assist transmission. Antibiotic treatment is often unsuccessful, but TYLOSIN may be more effective than OXYTETRACYCLINE, CORTICOSTEROIDS may assist in OEDEMA reduction.

M. pulmonis, a mouse and rat mycoplasmosis, is a pneumonia-like slow progressive disease.

Mycoplasmas are also important as contaminants of cell cultures used for vaccine production. (See also under KENNEL COUGH.)

Mycoplasma hyopneumoniae This bacterium is responsible for ENZOOTIC PNEUMONIA OF PIGS. It is seen in growing pigs and usually results in few signs except a cough. However it causes production losses from reduced weight gain and poor feed conversion efficiency. It is also part of the PORCINE RESPIRATORY DISEASE COMPLEX.

Mycoplasmosis

A mycoplasma infection. (See MYCOPLASMA; CONTAGIOUS BOVINE PLEURO-PNEUMONIA; VULVOVAGINITIS; ENZOOTIC PNEUMONIA OF PIGS; SINUSITIS; INFECTIOUS BRONCHITIS OF CHICKENS; MASTITIS.)

Mycoses

(See FUNGAL DISEASES.)

Mycosis, Mycotic Infections

Mycosis (mycotic infections) are diseases due to the growth of fungi in the body. Among the commonest are ringworm, sporotrichosis, aspergillosis. Mycotic mastitis is important in dairy cattle and 26 or more species of fungi are involved. Mycoses are particularly common in cage birds and some raptors, usually due to poor husbandry or the expectation that the birds will be able to thrive in unsuitable climatic conditions. (See also RHINOSPORIDIOSIS; FUNGAL DISEASES; SPORIDESMIN.)

Mycotoxicosis

Poisoning by toxins produced by fungi. (For examples of such toxins, see ERGOT OF RYE; AFLATOXINS; OCHRATOXIN A; ZEARALENONE; SPORIDESMIN; T_2 TOXIN; *Fusarium*; PENITREM A; and under FESCUE, RYE-GRASS.)

When, in farm animals, a change of feed leads to depressed output, or to signs of illness, poisoning by fungal toxins may be suspected. However, when analysed most suspect rations are found to contain fungal toxins in amounts too small for chemical detection.

Nevertheless, there is no doubt that occasional outbreaks of aflatoxicosis, ergotism, and zearalenone (F_2) intoxication do occur in the UK.

In one outbreak, two cows became dull and feverish, with bleeding from mouth and eyelids, and died within 48 hours. Other cows became ill, some with diarrhoea. Animals may die or have to be slaughtered. Similar haemorrhages and deaths from this cause have been reported in the USA.

Mycotoxins

Toxins produced by fungi or moulds. Some can produce relatively specific signs (for example ERGOT OF RYE). However many produce non-specific signs which can include poor fertility, poor growth or milk yield, increased susceptibility to infections due to IMMUNOSUPPRESSION. (See also AFLATOXINS; ASPERGILLOSIS; MOULDY FOOD; MYCOTOXICOSIS; ZEARALENONE.)

Mydriasis

An excessive dilation of the pupil of the eye. Drugs which are given when dilation is required for diagnostic purposes are called 'mydriatics'. (See also ATROPINE.)

VetBooks.ir

Myelin
Myelin is the white fat-like substance forming a sheath round myelinated (myelin-covered) nerve fibres.

Myelitis
Myelitis is a condition in which destructive changes occur in the spinal cord. It usually follows upon viral infections. Paralysis of a muscle or of groups of muscles may occur; there may be twitchings or spasms of muscles; the penis may hang from the prepuce, the bladder and rectum become unable to retain their contents, and finally a form of paraplegia often occurs. The paralysis may gradually pass forwards (craniad); the sensation being lost in the skin of the loins, then of the back, and later the fore-legs become unable to support the weight of the body. Occasionally the condition disappears spontaneously, but the majority of cases end fatally. (See also OSTEOMYELITIS.)

Myelocyte
A bone-marrow cell, from which white cells (basophils, neutrophils and eosinophils) of the blood are produced. They are found in the blood in certain forms of leukaemia.

Myelography
Radiography of the spinal cord, using a contrast medium. (See SPINE AND SPINAL CORD, DISEASES AND INJURIES OF.)

Myeloid
Cells relating to or pertaining to or similar to those found in bone marrow. It can also mean pertaining to the spinal cord. Thirdly, it can refer to the appearance of myelocytes not necessarily in or arising from the bone marrow. (See LEUKOSIS COMPLEX.)

Myeloma
A tumour of the bone-marrow cells. (See under GENETIC ENGINEERING.)

Myelopathy
The pathology of the SPINAL CORD.

Myeloproliperative Diseases
These develop as the result of the abnormal proliferation of bone-marrow cells, both within and outside the medullary cavity of bones.

Signs Fever, weight loss, anaemia. A clinical examination will reveal enlargement of both spleen and liver.

In cats the feline leukaemia virus (FeLV) is often a complicating factor.

Myeloschisis
A cleft spinal cord. Also called DIASTEMATOMYELIA.

Myiasis
Also known as fly strike, as in sheep blowfly myiasis, it is the presence of larvae of dipterous flies in tissues and organs of the living animal, and the tissue destruction and disorders resulting therefrom. The condition may occur in cats, dogs and rabbits, especially long-haired breeds. They often are affected when faecal soiling occurs, from diarrhoea, or following road accidents. Cyromazine, administered as a 'pour-on' treatment, is used to protect sheep against the blowfly.

(See BLOW-FLY STRIKE; FLIES - DIPTEROUS LARVAE OR MAGGOTS - MYIASIS; STRIKE; MAGGOTS IN SHEEP; also UITPEULOOG.)

Myocarditis
Myocarditis, or inflammation of the heart muscle, is referred to under HEART DISEASES - MYOCARDITIS, but it should be added that epidemics of myocarditis have been seen in puppies 5 to 16 weeks old in Britain, Australia and the USA. Spaniels, boxer crosses, Alsatians, Scottish terriers and poodles are breeds in which sudden death has occurred – puppies dropping dead a moment after eating or playing, no premonitory signs having been noticed. (See CANINE PARVOVIRUS.)

In LISTERIOSIS in poultry it can cause sudden death with the heart muscle having a striped appearance, which is almost diagnostic.

Myocardium
The heart muscle. Disease of this can lead to congestive heart failure, which is characterised by congestion of the veins, with a tendency towards liver enlargement and ascites. It results from pathological changes in the heart muscle rather than from disease of the coronary artery or heart valves, and is seen in the giant breeds of dogs, e.g. GREAT DANE, IRISH WOLFHOUND. Signs include loss of appetite, lethargy, accelerated heartbeat, irregular pulse and, in the later stages, ascites. Death occurs within days or weeks. Dilation of auricles and ventricles is seen at autopsy.

In cattle, for the effect of nutritional muscular dystrophy, see under MUSCLES, DISEASES OF.

Myoclonia Congenita
Congenital muscle tremors in pigs, also occurring in dogs such as LABRADOR RETRIEVERS, and cats.

Myoclonus
Repetitive contractions of a group of skeletal muscles, which usually occurs quite rhythmically. It may occur in sleep as a normal physiological phenomenon, but it is also a clinical sign of EPILEPSY or the DISTEMPER syndrome. (See CANINE DISTEMPER; EPILEPSY.)

Myodystrophia
Muscle dystrophy. (See MUSCLES, DISEASES OF.)

Myodystrophia of Lambs
(See 'STIFF-LIMBED LAMBS'.)

Myoglobin
A pigment found in muscle; it transports oxygen in muscle.

Myoglobinuria
The presence of muscle pigment in urine. It occurs in AZOTURIA. In cattle, for example, it occurs during muscular dystrophy. (See EQUINE RHABDOMYOLYSIS; MUSCLES, DISEASES OF.)

Myoma
Myoma is a tumour which consists almost totally of muscular tissue. They are rare in animals, and when encountered are generally found in the wall of the uterus.

Myopathy
A term commonly used to describe non-inflammatory degeneration of muscles, although it should really include all muscular conditions. A typical myopathy is muscular dystrophy.

M

Myopathy, Congenital
A congenital condition mainly seen in some dog breeds. In GOLDEN RETRIEVERS and LABRADOR RETRIEVERS it is seen in the male dog from a young age and it tends to become worse with age. The animals show a stiff gait, abduction of the front legs, bunny-hopping with the hind limbs and a swollen tongue. The condition becomes worse with exercise.

Myosin
A contractile protein present in muscle, along with actin. Their interaction is controlled by calcium.

Myosis
Myosis means an unusual narrowing of the pupil.

Myositis
Myositis means inflammation of a muscle. (See MUSCLES, DISEASES OF.)

Myotics
Myotics are drugs which contract the pupil of the eye, such as eserine and opium.

Myotonia
A tonic spasm of the muscle whereby there is difficulty or delay in muscle relaxation after muscular effort. It is seen in some forms of MUSCULAR DYSTROPHY, but also a non-dystrophic congenital myotonia and is described in several species including dogs, cats and goats ('fainting goats'). Myotonia was the diagnosis in a case involving a nine-month-old cavalier King Charles spaniel, which could not withdraw its tongue into its mouth. The tongue protruded from the left side of its mouth. Eating and drinking were rendered difficult. It was considered that the condition was not inherited in this case. Replacement of muscle fibres by fat was the main finding. The condition is quite common in some breeds, such as CHOW CHOWS, where it may be inherited.

Myotonia Congenita
An inherited condition which commences at a young age and shows stiffness and a stilted gait. It is seen in CHOW CHOWS, IRISH SETTERS, LABRADOR RETRIEVERS and MINIATURE SCHNAUZERS.

Mysoline
Mysoline is the trade name for the anti-convulsant drug, PRIMIDONE which is used in the treatment of EPILEPSY. A side-effect of this drug may be thirst, polyuria resulting in urinary incontinence, in the dog.

Myxobolus species
This is a parasite of the *Myxosporidia* genus that mainly affects fish. There is some evidence that some species may infest mammals that spend some time in water (otters, water voles, etc.) and might infect humans. *M. dermatobia ishii* has been found in the stomach, intestine and gills of eels in England. The most common species is *Myxobolus cerebralis*, the cause of 'whirling disease' in freshwater fish. (See WHIRLING DISEASE.)

Myxoedema
A thickening and degradation of the skin that occurs in hypothyroidism; seen mainly in pigs and dogs (see THYROID GLAND, DISEASES OF - HYPOTHYROIDISM).

Myxoma
Myxoma is a tumour consisting of imperfect connective tissue, set in a mucoid ground substance. (See TUMOURS.)

Myxomatosis, Infectious
A disease of rabbits caused by a virus. The disease has a very high mortality rate when introduced into a country, but later the virus may become less potent or the survivors more resistant. Myxomatosis appeared in wild rabbits in Kent and Sussex in October 1953, and spread rapidly throughout most of Britain. Signs include swelling (oedema) of the eyelids, nose and muzzle, and of the mucous membrane of the vulva and anus. Secondary bacterial infection occurs leading to conjunctivitis, 'gummed' eyelids and pneumonia. Orchitis is

caused in the male. Emaciation, fever and death follow. The disease is transmitted by mosquitos, the rabbit flea and also by contagion. A heterologous vaccine, and a combined vaccine for both myxomatosis and RABBIT HAEMORRHAGIC DISEASE, are available. It is now an offence to deliberately spread myxomatosis as a means of rabbit control.

Myxomatous Valvular Disease

Also known as ENDOCARDIOSIS, condition of the heart valves in which they are misshapen due to fibrous defects. (See HEART DISEASES.)

Myxosporidia

A group of protozoan parasites of marine and freshwater fish with 744 species known up to 2011. In most cases the lifecycles are unknown, but they would appear to involve more than one host or to spend some time in a non-animal environment. They may be spread by cannibalism of dead fish.

Myxovirus

A synonym for influenza virus. (See VIRUSES – ORTHOMYXOVIRUS, PARAMYXOVIRUS.)

VetBooks.ir

N

N-acetylglucosamine-1-phosphotransferase
A transferase enzyme which is deficient in some cats, resulting in MUCOLIPIDOSIS II.

Nagana
Nagana is an unscientific but convenient name for trypanosomiasis transmitted by tsetse flies (*Glossina* spp.) in Africa. The TRYPANOSOMES involved are *Trypanosoma vivax*, *T. uniforme*, *T. congolense*, *T. brucei*, *T. simiae*, and *T. suis*. The signs of nagana include ANAEMIA, intermittent fever and (except in pigs, in which the disease may be very acute) a slow, progressive emaciation. In both horses and dogs the eyes may be affected, as shown by corneal opacity. Horses often have oedema affecting the limbs and abdomen. Cattle may abort.

The drug QUINAPYRAMINE is used (among others) in treatment.

The kudu, hyena and bush-buck, as well as other wild animals, act as reservoirs of the infection.

Nail Binding
(See INJURIES FROM SHOEING.)

Nails, Claws
A claw contains a matrix with blood vessels, nerves, etc., from which it grows and is nourished. Lying within the matrix is the bone of the terminal phalanx of the digit, which gives the nail its characteristic form in the different animals. When not in use in the carnivora, nails are retracted by ligaments in an upwards direction; this is more marked in cats, where the nail may almost disappear, than in dogs. Dew claws in dogs are non-weight-bearing claws on the inner aspect of the legs. In some countries they may be removed at birth. They commonly become torn through catching on soft furnishing or clothing.

Nails, Diseases of
The nails of cats and dogs sometimes become torn or broken through fighting or accidents. Sometimes only the tip is injured, and the matrix higher up is undamaged; in such cases a fine pellicle of horn covers the tip until such time as the horn has grown down from above, and the whole nail is not shed. In other cases infection occurs, causing great tenderness of the part. (See ONYCHOMYCOSIS; PARONYCHIA.)

Ingrowing nails particularly occur in the 'dew claws', on the insides of the paws of dogs. These more or less rudimentary digits do not touch the ground, and are consequently not subjected to wear from friction. The nails grow, and owing to their curve eventually penetrate the soft pad behind them. Where actual penetration has occurred, the nail should be cut short and an antiseptic dressing applied. It is customary for owners of sporting and other dogs to have the dew claws removed during puppyhood to avoid future trouble of this nature. Amputation of dew claws can be carried out in the adult under anaesthesia. Ingrowing nails occur in other claws where there is not sufficient wear such as following arthritis.

Onychomycosis, or a fungal infection of the claws, is a not uncommon condition in cats, and is of public-health importance as a reservoir of ringworm transmissible to children. (See RINGWORM.)

Nairobi Sheep Disease
Nairobi sheep disease is an acute infectious fever of sheep and goats, caused by a bunyavirus, and occurring in eastern and southern Africa. The virus is transmitted by the tick *Rhipicephalus appendiculatus*.

Signs Imported sheep usually show an acute febrile disturbance within five or six days after being infected by the ticks. This lasts for up to nine days and then a fall in temperature occurs and other clinical signs appear. Death may take place a day or two later, or a further rise in temperature may be shown, death or recovery following. There is rapidity and difficulty in breathing, a mucopurulent nasal discharge and green watery diarrhoea, which may contain mucus or blood. The genital organs of ewes are swollen and congested, and abortion may occur in pregnant ewes.

Immunity In the great majority of cases, recovery confers a strong and lasting immunity. This is also possessed by sheep in areas where the infection is endemic.

Naloxone hydrochloride
An antagonist to narcotics; it is structurally related to oxymorphine. It reverses the effects of previously administered narcotics.

Nanny
Popular name for an adult female goat (DOE).

Nanocephalus
An abnormally small head.

Nanogram (ng)
A unit of weight equivalent to 10^{-9} g; 1000 micrograms 1 microgram (μg) is 10^{-6} g; 1000 micrograms equal 1 milligram (mg).

VetBooks.ir

Nanomelus
A congenital problem where there are undersized extremities.

Nanometre (nm)
A unit of linear measurement used in e.g. virology. One nm equals one billionth (1×10^{-9}) of a metre.

Nanoparticles
These are extremely small particles which are 1 to 100 nanometres ($1x10^{-7}$ to $1 x10^{-9}$ m) in size. Each particle is able to act as a whole unit or entity in terms of its transport and properties.

Naphthalene Poisoning
Naphthalene poisoning might arise from the ingestion of mothballs. In the dog, it has been shown experimentally to give rise to haemolytic anaemia. (In children, poisoning from mothballs gives rise to 'port-wine coloured' urine.) Another sign is cataract. Chlorinated naphthalenes have been identified as one cause of HYPERKERATOSIS in cattle; and tear stains may be a sign of this type of poisoning.

Narasin
An anticoccidial medicine used on its own or together with nicarbacin.

Narcolepsy
Narcolepsy is a sudden collapse into deep sleep. It has been recorded in dogs, and may be partly genetic in origin and has been seen in horses. A case was recorded in the UK in a three-year-old Corgi which sometimes collapsed when taken for his first walk of the day, or offered food. Often yawning and a vacant expression would precede a sudden drop from a standing position to a sitting one or a lying one. No excitement, salivation, or convulsions were seen, and at other times the dog was active and mentally alert; he was easily aroused after he had collapsed. The condition has also been recorded in DACHSHUNDS, DOBERMANNS, LABRADOR RETRIEVERS and poodles.

Nares
Nares is the Latin word for the nostrils.

Nasal
Relating to the nose.

Nasal Bot Fly Larvae, *Oestrus ovis* Larvae
These are serious parasites of sheep. (See under FLIES - ORDER DIPTERA - BOT AND WARBLE FLIES.)

Nasal Disorders
(See NOSE AND NASAL PASSAGES, DISEASES OF.)

Nasal Passages
(See NOSE AND NASAL PASSAGES.)

Naso-Gastric Tube
These flexible tubes are used routinely to give fluids in horses. Cuffed tubes can be used to clear choke.

Nasolacrimal Duct, Nasolacrymal Duct
A duct at the inner CANTHUS of the eye, which drains tears after their passage across the eye's surface. The duct passes into the nasal passage. When blocked or constricted, EPIPHORA or tear overflow occurs, and tear staining (CHROMODACTYORRHOEA) may be seen.

Naso-Oesophageal Tubes
Narrow tubes inserted through the nose into the stomach. They are tolerated by many, if not most, cats, and can be used to provide nutritional support via liquid foods for a week or two. The use of small-diameter tubes does not prevent voluntary intake of food.

Naso-Pharynx
The upper part of the throat lying posterior to the nasal cavity.

Nasturtium officinale
(See WATERCRESS.)

Natamycin
An antibiotic used for the treatment of ringworm in cattle and horses. Application can be made with a knapsack sprayer. (See RINGWORM.)

National Farmers Union (NFU)
The main association for farmers in England and Wales. Address: Agricultural House, Stonleigh Park, Stoneleigh, Warwickshire CV8 2TZ; telephone: 024 7685 8500; website: www.nfuonline.com.

National Milk Records (NMR)
A British organisation producing milk recording services, including individual and herd records for milk yields, butterfat, protein, lactose, somatic cell counts. It can also produce individual cow lactations, pedigree records and other information.

National Office of Animal Health (NOAH)
Founded in 1986, to represent those UK companies which manufacture animal-health products licensed under the Medicines Act. Address: 3 Crossfield Chambers, Gladbeck Way, Enfield, Middlesex EN2 7HF. Telephone: 0208 367 3131; email: noah@noah.co.uk: website: www.noah.co.uk. Publications include: Compendium of Data

Sheets for Animal Medicines (annually and online at www.noahcompendium.co.uk); *The Safe Storage & Handling of Animal Medicines; Poisoning in Veterinary Practice*.

National Pet Register
This provides a service for reuniting lost pets with their owners, and also for third-party liability. Address: Thorpe Underwood Hall, Great Ouseburn, York, North Yorkshire YO26 9SZ. Telephone: 0870 4023800.

National Scrapie Plan
A long-term UK plan which aims to reduce and, eventually, eradicate the number of sheep not genetically resistant to scrapie and other transmissible spongiform encephalopathies. Under the scheme, sheep are individually identified by electronic tag, and blood-tested to establish whether they are susceptible or resistant to scrapie. Sheep identified as susceptible must not be bred from. Under DEFRA proposals in 2003, farmers with confirmed scrapie cases on their farms will have their flocks genotyped so that the more susceptible sheep can be identified and removed, or the whole flock disposed of.

Natural England
A non-departmental public body responsible to the Secretary of State for DEFRA. Its remit is the protection and improvement of England's natural environment and to encourage people to enjoy and become involved in their surroundings. Head Office: Natural England, 1 East Parade, Sheffield, S1 2ET. Telephone: 0300 060 6000; 0845 600 3078; email: enquiries@naturalengland.org.uk.

Natural Rubber
(See LATEX.)

Nature
An informal name for OEDEMA of the udder.

Navel
Another name for the UMBILICUS.

Navel-Ill
(See JOINT-ILL.)

Navicular Bone
Navicular bone is the popular name for the sesamoid of the third phalanx of the horse. It is a little boat-shaped bone, developed just above the deep flexor tendon, and serves, as do all sesamoid bones, to minimise friction where the tendon passes round a corner of another bone. It enters into the formation of the 'coffin-joint', between the second and third phalanges of the digit. It is of great importance in deep punctured wounds of the foot when these are situated towards the heels, for, when damaged, its surface becomes inflamed, the inflammation spreads to the coffin-joint and may produce incurable lameness. (See NAVICULAR DISEASE.)

Fractures of the navicular bone can result in a hind-limb from a violent kick against a solid object. There is sudden onset of acute lameness.

Navicular Disease
Navicular disease is a chronic condition of inflammation affecting the horse's navicular bone and its associated structures. The fore-feet are usually both affected, though the condition may arise in only one of these, or in the hind-feet (rarely). Ulceration of the cartilage first, and later of the bone on the surface over which the deep flexor tendon plays, may sometimes be seen at autopsy.

Causes These are still a matter of hypothesis rather than certainty, and controversy persists. Some authors have referred to increased VASCULARISATION of the NAVICULAR BONE; others suggest that ISCHAEMIA may be responsible, leading to pain and, if at least two of the distal arteries are occluded, to chronic lameness. In horses lame as a result of navicular disease, occlusion of the main artery and progressive arterial thrombosis are frequent, with a resulting area of ischaemic necrosis and CAVITATION of the navicular bone.

Another view is that the disease is not caused primarily by ischaemia and subsequent necrosis, but is a consequence of bone remodelling due to altered pressure from the deep flexor tendon and increased load on the caudal part of the foot – the condition not being irreversible unless secondary lesions such as adhesions and bony spurs have developed. Special shoeing to alter the load on the navicular bone is recommended.

Signs Navicular disease usually develops so slowly that the owner has considerable difficulty in remembering exactly when the first signs were noticed. In fact, little or no importance may be attached to the almost characteristic 'pointing' of one or both fore-feet, because 'he has always done that'. 'Pointing' consists of resting the affected foot (or feet) by placing it a short distance in advance of the other when standing in harness or in the stable. When both feet are affected, each is alternately pointed. Later, the horse may go lame or be tender on his feet at times, but with a rest he generally becomes sound again. As the disease advances, he may either start off in the mornings stiff and become better with exercise as he warms to his work, or may become lame as the day goes on. Sooner or later, however, there comes a time when he will go permanently 'pottery' or 'groggy'. The length of the stride decreases and there is difficulty in advancing the feet, so it looks as if the shoulder

is the seat of the lesion. When made to turn, the horse pivots round on the fore-feet instead of lifting them, and when made to back, drags the toes. If the shoe of such a horse is examined it is usually found to be more worn at the toes than at the heels. In fact a 'groggy' horse may wear his shoes quite thin at the toes before the heels show much sign of wear at all. In the final stages the horse becomes distinctly lame and unfit for work. When observed in the stable he is noticed to be continually shifting from one foot on to the other, and the resting foot is placed well out in front.

Treatment must aim at the relief of pain and improvement of the local blood circulation. The vasodilator ISOXSUPRINE or a formulation of WARFARIN may be added to the feed of horses; the dosage of warfarin requires great care – with overdosage there is a danger of haemorrhage. Warfarin treatment has been reported effective in about 75 per cent of cases of navicular disease.

Before the advent of drug therapy it was customary to perform the operation of neurectomy, which consists of removal of a section of the plantar or median nerve of the limb. In a favourable case, following operation, the horse becomes apparently sound, although the diseased condition is still at work in the bone. No pain is felt, and the horse is fit for light work at slow paces. The feet require constant attention to ensure that no stones, nails, etc. lodge in the hoof, for even when these inflict serious damage the horse still goes sound, not feeling the pain.

Navy Beans
Navy beans may cause death if fed raw. (See LEGUME POISONING.)

NE
(See NECROTISING ENTERITIS.)

Near East Encephalitis
An alphavirus infection of horses and donkeys; less frequently of cattle and sheep. Convulsions/paralysis may follow fever and precede death. (See EQUINE ENCEPHALITIS; BORNA DISEASE.)

Nebulisation
The conversion of a liquid to a mist or fine spray. A nebuliser is used.

Neck
In animals, the neck is that part of the body connecting the head with the trunk. It contains the trachea, oesophagus, blood vessels, the spinal cord and cervical vertebrae. Both the mouse and giraffe have seven cervical vertebrae, as do most mammals.

The weight of the head is supported by the powerful *ligamentum nuchae*, which takes the strain off the muscles, thereby avoiding fatigue. In the horse the ligament extends from the spines of the withers to the posterior of the occipital bone of the SKULL.

Necrobacillosis
Damage of an organ, or tissue, caused by *Fusobacterium necrophorum*. The necrotic area has a characteristic rotting odour.

Necrolytic Migratory Erythema
(Synonym: HEPATOCUTANEOUS SYNDROME)

Necropsy
Examination of a dead body. (See AUTOPSY; POST-MORTEM EXAMINATION.)

Necrosis
Death of cells or of a limited portion of tissue. The resultant dead tissue may remain firm (COAGULATION NECROSIS) or liquefy (LIQUEFACTION NECROSIS).

Necrosis (Bacillary), Necrobacillosis
(See CALF DIPHTHERIA.)

Necrotic Enteritis
A subacute or chronic enteritis which follows a more severe episode caused by infection with *Salmonella* spp. or *Campylobacter sputorum* var. *mucosalis*. A condition of unweaned and older pigs, characterised by scouring and loss of condition.

The lesions are in the caecum and ileum. (See also under ILEUM.)

Cold, damp, dirty surroundings appear to predispose to necrotic enteritis. (See PORCINE INTESTINAL ADENOMATOSIS.)

Necrotic Enteritis in Chickens
A disease of chickens characterised by unthriftiness and diarrhoea caused by *Clostridium perfringens* (*welchii*) type C. There is usually a concurrent defect in nutrition. The disease has been reported in most European and North American countries, and in Australia. In the USA when disease occurs, raising the ambient temperature and reducing light levels has a beneficial effect. The condition became more common following the EU ban on using antimicrobial growth promoters in diets.

Necrotic Migratory Erythema
(See HEPATOCUTANEOUS SYNDROME.)

Necrotic Stomatitis
A serious infection of the inside of the mouth and the tongue, seen in calves; it may also be found in reptiles. (See CALF DIPHTHERIA.

Necrotising Enteritis (NE)
This is seen in several species. In pigs it occur in young piglets and is caused by *Clostridium* SPP.

VetBooks.ir

VetBooks.ir

perfringens type C. It can be prevented by vaccinating the sows. Infection can persist on farms for several years after an outbreak.

Necrotising Mycotic Dermatitis
Seen in reptiles including crocodiles and various lizard species, it is caused by the fungus *Chrysosporium* anamorph of *Nannizziopsis vriesii*.

Needle-Stick Injury
(See ACCIDENTAL SELF-INJECTION.)

Negative Pressure Wound Therapy
An airtight area over the wound subjected to a continuous vacuum of 75-125mm (Hg) mercury depending on the severity of the tissue damage will facilitate closure.

Negri Bodies
Negri bodies are comparatively large, rounded bodies in the brain cells of animals infected with rabies. Their presence can be demonstrated by staining with Seller's stain, among others. The cerebral cortex, Ammon's horn, and the Purkinje cells of the cerebellum are the main sites to examine. The diagnosis of rabies once depended upon the demonstration of Negri bodies in the affected animal. (See RABIES.)

Neisseria
Spherical, Gram-negative bacteria, some of which are associated with eye infections.

Nematocide
A drug that destroys nematodes.

Nematode
Nematode is a general term applied to the parasitic *Nemathelminthes*, which include the roundworms, as distinct from the *Platyhelminthes*, or flatworms. (See ROUNDWORMS; WORMS.)

'Nematode Poisoning'
In the USA, larvae of *Anguina agrostis* on Chewing's fescue in immature hay caused an outbreak of poisoning in cattle. Signs included knuckling of the fetlocks, head tucked between the fore-legs, recumbency, convulsions, and death.

Nematodiriosis, formerly, Nematodiriasis
Infection with *Nematodirus* species.

Nematodirus
Parasitic worms of, particularly, lambs; also sheep and calves. *N. battus* infection is transferred from one season's lambs to the next as large numbers of eggs are deposited on pasture. Development of the eggs occurs only after exposure to cold and moisture. However, there is a summer form of nematodiriasis which usually involves the sudden onset of thick black diarrhoea in lambs, with dehydration and death. The eggs in the faeces are twice as large as most other helminths. Deaths can also occur before eggs are produced. The infection risk is lessened by rearing young lambs on different pastures each year. In recent years, a summer/autumn type of infection has also occurred. It is thought to be due to spring shed eggs hatching without previous chilling in the south of England, or in Scotland due to prolonged survival of spring hatched larvae or a different *Nematodirus* strain. (See WORMS.)

Nembutal
(See PENTOBARBITONE SODIUM.)

Neoarsphenamine
A drug effective against BLACKHEAD OF TURKEYS. It has been largely superseded by dimetridazole and nifursol.

Neomycin
An aminoglycoside antibiotic obtained from *Streptomyces fradiae*. It is administered as an injection for horses, pigs, sheep, dogs and cats but should be used with care, especially in the young animal, as it can result in kidney damage. Its action closely resembles that of streptomycin. It is used, sometimes in combination with other medicaments, in a number of veterinary formulations, particularly ophthalmic and otic topical preparations. NB: A topical spray of this antibiotic has caused profound deafness in children. (See DEAFNESS.)

Neonatal
Referring to the newborn.

Neonate
A neonate is a newborn animal.

Neonicotinoids
A group of pesticides which may have an effect on BEES.

Neophilic Effect
This describes the ready early acceptance of certain dietary ingredients following exposure to some of their chemical constituents or metabolites in the amniotic fluid during pregnancy. (See NEOPHOBIC EFFECT.)

Neophobic Effect, Neophobia
This describes rejection of some dietary ingredients in young animals due to unfamiliarity, caused by their absence from the diet of the gestating mother. (See NEOPHILIC EFFECT.)

VetBooks.ir

Neoplasia
A tumour which develops persistent, purposeless, proliferative new growth.

Neoplasm
Neoplasm means literally 'a new growth', and is applied to tumours in general.

Neopolitan Mastiff Dogs
A breed relatively new to the UK. It is possible that an eye condition, EURYBLEPHARON, is inherited by an unknown mechanism.

Neospora Caninum
This parasite was discovered in Norway in 1984, and later recognised in Sweden, the USA, Australia and the UK in 1990. It is now found worldwide.

Cause A protozoan resembling *Toxoplasma gondii*. Congenital infection occurs in cattle, dogs and cats. The life cycle involves the definitive host, the dog, and the secondary host, mainly cattle infected by oral ingestion. There is transplacental infection in cattle; the calves are usually born healthy but persistently infected and thus infection continues within the herd. Concurrent infections such as with pestivirus increases the incidence of abortion.

Signs Infected animals (puppies, calves) may develop ataxia, a fleeting paralysis and NYSTAGMUS. Meningitis appears in some cases. The parasite is a common cause of bovine abortion; it may also be found in aborted ovine fetuses. There is currently no effective vaccine in UK, although one available elsewhere does reduce herd abortion levels. The only control is to cull all infected cattle as identified by serology.

Neosporosis
A disease of dogs which is important as the causal parasite *Neospora caninum*. (See NEOSPORA CANINUM.)

Neoteny
The retention of juvenile activities and appearance into adulthood. It is the basis of popularity of some breeds of dog that remain as playful as puppies throughout their life. The extreme example is an amphibian, the axolotl or Mexican walking fish, which rarely matures to the adult stage.

Neotrombicola autumnalis
The current name for the harvest mite, which used to be called *Trombicula autumnalis*. (See MITES, PARASITIC - OTHER MITES - HARVEST MITES.)

Nephazoline
(See IMIDAZOLINE COMPOUNDS.)

Nephrectomy
Nephrectomy is the operation by which one of the kidneys is removed. (See KIDNEYS, DISEASES OF.)

Nephritis
Inflammation of the kidneys (see KIDNEYS, DISEASES OF; LEPTOSPIROSIS).

Nephrolithiasis
The presence of a stone (calculus) in the pelvis of the kidney.

Nephron
The structural unit of the KIDNEY.

Nephropathy
Any disease of the kidney. (See also FAMILIAL NEPHROPATHY.)

Nephroptosis
'Floating kidney' – abnormal positioning of the kidney (see KIDNEYS, DISEASES OF).

Nephrosclerosis, Arteriolar
A condition found in hamsters characterised by polydipsia, polyuria, proteinuria and weight loss. Diagnosis is by urine analysis. Anabolic steroids may assist in treatment.

Nephrosis
This is a disease of the kidneys, involving damage to the tubules. It leads to albuminuria and often to oedema. (See also KIDNEYS, DISEASES OF.)

Nephrosis, Infectious Avian
A disease of chickens. (See GUMBORO DISEASE; INFECTIOUS BURSAL DISEASE.)

Nephrotic Syndrome
(See NEPHROSIS.)

Nephrotomy
Surgical incision into a kidney.

Nerve Block
Anaesthesia of a nerve or nerves supplying part of the body to assist diagnosis or treatment. Often used in diagnosing the cause of lameness in the horse.

Nerve of Smell
(See OLFACTORY NERVE.)

Nerves
The nerves are fibre-like tissues that convey impulses ('messages') between the central nervous system and other parts of the body. The basic unit of the nervous system is the neuron, a cell with at least one projection. Bipolar neurons have one

long projection, the axon, and one short branching projection, the dendrite. A typical neuron (multipolar) has several dendrites but usually only one axon (nerve fibre).

Dendrites conduct nerve impulses towards the nerve cell; axons conduct away from it.

A synapse is a point or area where one neuron is able to make contact with another; the contact being between the axon of one neuron and a dendrite of another neuron, or between the axon of one neuron and the cell of another neuron. Any neuron may connect with axons or dendrites of several other neurons.

Nerve fibres may be myelinated (enclosed in a sheath) or unmyelinated (see MYELIN). Some nerve fibres (axons) convey impulses to brain or spinal cord from skin or sense organ, and are termed sensory or afferent. Their impulses are passed, through connecting links or interneurons, to motor or efferent nerves from brain or spinal cord (*but see* spinal reflex under SPINAL CORD Functions).

Nerve impulses are dependent upon the permeability of cell membranes. There is a potential difference of about 70 to 80 millivolts between the inside and the outside of an axon – the inside being the negative. This is owing to the fact that in a resting state the cell membrane is permeable to K(+) and Cl(–) ions, but not to Na(+) ions. Stimulation of the nerve results in the membrane becoming permeable to the sodium ions, which flow in causing the inside of the axon to carry a positive electrical charge instead of a negative one. A so-called depolarisation wave is set up, 'self-perpetuating', along one neuron after another. A single nerve fibre can send about 1,000 separate impulses per second.

ACETYLCHOLINE is released by somatic (muscle) nerve fibres at synapses between neurons on either side of ganglia, and also at the junction of motor nerve endings and voluntary (striated) muscle. Acetylcholine is released also at synapses by parasympathetic nerve fibres. NORADRENALIN is released at synapses of sympathetic nerve fibres, and at their junction with smooth (unstriated) involuntary muscle fibres.

Nerves, Injuries to

Continued or repeated severe pressure upon a nerve trunk may be sufficient to damage it and result in paralysis; severe bruising in which a nerve is driven against a bone with considerable force may produce paralysis or inflammation of the nerve; a nerve may be severed along with other tissues in a deep wound; fracture of a bone, such as the 1st rib, may produce rupture of any nerves that lie upon or near to it; and other accidents may also involve the nerves of the part. A nerve may sometimes be injured at its origin before it leaves the brain or spinal cord by haemorrhage. (See also under IMMUNISATION.)

Signs Sometimes, it is not until after a wound has healed that the injury to the nerve becomes obvious. In 'radial paralysis', or in other cases where large and important motor nerves have been damaged, the resulting paralysis of the muscles they supply is seen at once. (See RADIAL PARALYSIS.) Atrophy of muscles results.

(See FACIAL PARALYSIS for another example of a nerve injury.)

A tumour, such as a neurofibrosarcoma or (in the cat) a lymphosarcoma, may press upon or infiltrate the brachial plexus causing progressive lameness and pain. (See BRACHIAL.) Another tumour is a NEUROMA.

If a nerve is cut, the distal part degenerates. This is called Wallerian degeneration.

Neuritis (See under NEURITIS.)

Nervousness

A state of excitability which results in physical and mental unrest. It is often seen in wild animals, and is a defence or protective mechanism against danger. It often occurs in domestic animals following a fright or unusual occurrence such as noise (fireworks, aircraft) or injury. It is also seen when an animal is exposed to a new situation or unfamiliar people, or where an animal is badly treated by a person. Pathological nervousness can be treated by mild SEDATION or DELMADINONE ACETATE.

Nervous System

(See CENTRAL NERVOUS SYSTEM.)

Nervous System, Diseases of

(See BRAIN DISEASES; ENCEPHALITIS; BOTULISM; CHOREA; DISTEMPER; CANINE VIRAL HEPATITIS; TETANUS; RABIES; SPINAL CORD; LISTERIOSIS; etc.)

Netherland Dwarf Rabbits

A small compact rabbit weighing about 1 kg (2 lb) with short smooth hair coat of any colour, short ears and prominent eyes.

Netobimin

A broad-spectrum anthelmintic for use in cattle and sheep against intestinal roundworms, tapeworms, lungworms and liver fluke.

Nettle Rash

(See URTICARIA.)

Neurectomy

Neurectomy is an operation in which part of a nerve is excised. The operation is sometimes

performed to give relief from otherwise incurable lameness in the horse, but the response, if any, may be only temporary.

Neurilemma
Neurilemma is the thin membranous covering of nerve fibres.

Neuritis
Inflammation affecting nerves or their sheaths. It is often accompanied by pain (neuralgia), sometimes by spastic paralysis. Causes include viral infections, allergies, malnutrition, and poisoning, as well as physical injuries. (See NEUROMA; NERVES, INJURIES TO; and under IMMUNISATION.)

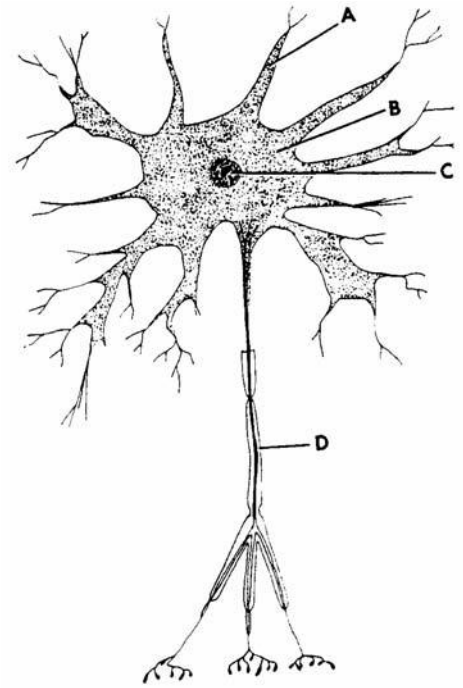
Neuro-
Prefix meaning nerve-related.

Neurogenic
Relating to, or originating from, the NERVOUS SYSTEM.

Neuroglia
A fine web of tissue and branching cells which supports the nerve fibres and cells of the nervous system.

Neuroleptanalgesia
A state of combined sedation and analgesia. It is used for carrying out minor surgical procedures where full anaesthesia is not required. A combination of a sedative, e.g. ACEPROMAZINE, and a powerful analgesic, usually an opiate, is used.

Neurological
Pertaining to the NERVOUS SYSTEM.



Neurology
The science of the study of the NERVOUS SYSTEM in health and disease.

Neuroma
A tumour connected with a nerve, and very painful.

Neuromuscular
This results in the termination of nerves within muscles.

Neuron
Neuron is a single unit of the nervous system, consisting of one nerve cell, with all its processes. (See illustration opposite and also NERVES.)

Neuronopathy
Any disease that affects the NEURON.

A typical neuron: A – dentrites, B – nerve cell body, C – nucleus, and D – axon. (After Francis, *Introduction to Human Anatomy*, courtesy of C. V. Mosby Co.)

Neuropathy
A disease of the peripheral nervous system, which may be the result of a functional disturbance or pathological disorder. The cause may be known or unknown.

Neuropeptide-V
A protective substance produced in cases of severe stress. It quells the effect of corticosteroid-releasing hormone and reduces the damage that may result from excess or long-term release of corticosteroids. It appears to be produced in the HYPOTHALAMUS. (See DEHYDROEPIANDROSTERONE.)

Neurotoxins
Substances which damage, destroy or poison nerve tissue.

Neurotransmitters
A substance which is released from the end of a nerve and travels to an organ or tissues, resulting in its stimulation or inhibition. These include ACETYLCHOLINE, ADRENALIN, and DOPAMINE.

Neurotropic Virus
Neurotropic virus is one which shows a predilection for becoming localised in, and fixing itself to, nerve tissues. The best known of these is that of RABIES. Rabies virus enters the body through torn nerve fibres at the seat of an injury, such as a bite,

VetBooks.ir

and, growing along them, eventually reaches the spinal cord and brain. Other neurotropic viruses are those of louping-ill in sheep, and BORNA DISEASE in horses and cattle.

Neutering

(See CASTRATION and SPAYING; also VASECTOMY.)

Neutrons

Elementary particles with approximately the same mass as a proton. The latter has been defined as a stable, positively charged elementary particle found in atomic nuclei in numbers equal to its atomic number.

Neutropenia

A reduced number of neutrophil granular leukocytes in the blood.

(In human medicine, most cases are attributed to the direct toxic effect of certain antibiotics, e.g. penicillin and the cephalosporins, or to immune-mediated mechanisms. With this type of blood DYSCRASIA patients are at serious risk of an overwhelming infection.) The condition is often encountered in young parrots infected with the PSITTACINE BEAK AND FEATHER DISEASE virus.

Neutrophil

A type of white blood cell which can migrate into the tissues and engulf bacteria, etc. Neutrophil activation in cattle and possibly other species requires the release of stored intracellular calcium which passes through the plasma membrane, a process called store operated calcium entry. (See under BLOOD; ABSCESS.)

Newcastle Disease

An infectious, febrile NOTIFIABLE DISEASE of chickens, turkeys, ducks, pigeons and wild birds. Globally, it is the most economically important disease of livestock. Aviary birds, particularly finches (canaries, etc.), may be infected by wind spread. Waterfowl can be infected but clinical disease is rare. In humans, conjunctivitis is the main clinical sign, but people working with infected birds may develop an influenza-like illness.

Cause Paramyxovirus.

Signs The first sign noticed in laying birds may be a drop in egg yield with the production of pale, misshapen and/or soft-shelled eggs. According to the virus strain, infected birds develop respiratory or nervous signs; it is rare to find both together. Severe breathing difficulties develop in birds affected with the respiratory strain. In the nervous form, torticollis, paralysis of the wings or legs and impaction of the intestine are features. In mild cases, the main clinical sign may be diarrhoea, usually black. Mortality varies. Egg production may recover, but not to its former level. Post mortem examination shows haemorrhages of the PROVENTRICULUS.

Control Live and inactivated vaccines are used. Vaccination regimes can vary according to local circumstances and must be established on the basis of veterinary advice; the manufacturer may need to be consulted. Live vaccines include the Hitchner B1; they are administered in the drinking water, by beak-dipping, by eye-dropper or by aerosol spray. The manufacturer's directions must be strictly followed in each case. The inactivated vaccine is used for secondary vaccination after primary immunisation with live vaccine. It is administered intramuscularly into the thigh muscle or subcutaneously into the back of the neck.

It should always be assumed that, in the vicinity of an outbreak, every flock to be vaccinated is incubating the disease. The incubation period is around 21 days and it takes 10 to 14 days to build up an immunity.

New Forest Disease, Infectious Bovine Keratitis

A painful eye condition which can lead to blindness if neglected. (See EYE, DISEASES AND INJURIES OF.)

New Forest Fly

A blood-sucking fly, found in many parts of Britain. *Hippobosca equina* attacks horses and cattle. It deposits larvae (not eggs) in the soil. When disturbed, it makes a characteristic sideways movement. (See FLIES.)

New Forest Ponies

These ponies have been bred in the New Forest of Southern England since 1066. They are not feral but are managed by their owners who have common law grazing rights in the forest. The mares and foals and a few geldings live wild for most of the year. Licensed stallions are turned out for three months starting May. The ponies may be bay, chestnut or grey, but not piebald or skewbald. They are normally over 12 HANDS high but must not exceed 14.2. They make excellent children's ponies.

Newfoundland Dogs

A large breed of dog developed in Canada to rescue people from rivers and the sea; it is a powerful swimmer. It is long-haired and usually black or brown. HIP DYSPLASIA, AORTIC STENOSIS, ununited ANCONEAL PROCESS and OSTEOCHONDRITIS may be inherited. They are susceptible to CRUCIATE LIGAMENT RUPTURE. There is a DNA test for CYSTINURIA.

New Hampshire Red Chickens
The chickens are derived from New Hampshire, USA. The adults are a rich chestnut red colour and they produce large light brown eggs. The males weigh 3.9 kg (8.5 lb) and the hens 3 kg (6.5 lb).

'Newmarket Cough'
(See EQUINE INFLUENZA; COUGHING.)

'New Wire Disease'
(See GALVANISED AVIARY WIRE; ZINC POISONING.)

New Zealand Huntaway Dogs
(See HUNTAWAY DOGS.)

New Zealand White Rabbit
A medium-sized breed of white rabbit popular as a pet and also as a laboratory animal. Glaucoma is inherited in some strains of the breed.

NFU
(See NATIONAL FARMERS UNION.)

Niacin, Nicotinic Acid
One of the vitamin B group, present in most animal feeds, and produced in the digestive system from tryptophan. With maize feeding, a niacin deficiency may occur. It has been suggested that niacin supplements benefit dairy cows, as synthesis of the vitamin in the rumen may not be sufficient, which was formerly thought to be the case. In dogs a niacin deficiency causes 'BLACK TONGUE'. (See SHEEPDOGS; VITAMINS.)

Nicarbazin
One of the first coccidiostats to be available in the UK and still in use in meat-producing birds. It is contraindicated in layers and breeders.

Nicergoline
A cerebral vasodilator, which blocks SEROTONIN and DOPAMINE receptors. It improves certain disorders in the aged dog including diminished vigour and vigilance, sleep disorders and some psychomotor disturbances.

Nicking
This is defined in the Docking and Nicking of Horses Act 1949 as 'the deliberate severing of any tendon or muscle in the tail of a horse'. The practice is illegal.

Niclosamide
A nitrosalicylanilide anthelmintic which has activity against tapeworms except for *Echinococcus granulosus* and *Dipylidium caninum* in dogs. It is effective against ruminal flukes in ruminants (paramphistomides).

Nicotine Poisoning
Nicotine poisoning has killed cattle dressed with nicotine against warbles, and may also arise from the old practice by shepherds of dosing their flocks with tobacco against parasitic worms. Poisoning has also been reported in poultry when perches have been painted with nicotine sulphate to try to control red mite (*Dermanyssus galinae*). It can also occur in dogs eating cigarettes or e-cigarettes and their refills.

Nicotinic Acid
One of the vitamin B group present naturally in the body and convertible to NIACIN.

Nictitating Membrane
The 'third eyelid', or haw, also known as the membrana nictitans, consists of a plate of cartilage covered with conjunctiva, and having lymphatic tissue and the HARDERIAN GLAND. Often pigmented, the membrane is always prominent in breeds of dogs such as the bloodhound and ST BERNARD. Occasionally distortion of the membrane occurs in GERMAN SHEPHERD DOGS and GREAT DANES. In other breeds of dog, and in the cat, its protrusion across part of the eye may indicate general debility if bilateral; causes of unilateral protrusion include the presence of a foreign body, ulceration, a nerve injury, or occasionally a tumour. (See EYE, DISEASES AND INJURIES OF; HAW; HARDERIAN GLAND.)

Nictitating Membrane Gland Prolapse
This is a common problem in dogs, and in a survey most (64 per cent) were UNILATERAL, and of those BILATERAL 41 per cent were simultaneous, otherwise usually the second occurred within three months of the first. It is seen as a reddish or bulging mass in the inner corner of the eye. The condition usually occurs before two years old and is rarely seen after three years old. It is common in AMERICAN COCKER SPANIEL, BASSET HOUND, BEAGLE, BOSTON TERRIER, ENGLISH COCKER SPANIEL, ENGLISH BULLDOG, FRENCH BULLDOG, GREAT DANE, LHASA APSO, PEKINGESE and is often bilateral in CANE CORSO, ENGLISH BULLDOG, FRENCH BULLDOG, GREAT DANE, SHAR-PEI. Surgical replacement of the prolapsed gland is usually possible.

Nidicolous
A term used for a bird or animal that remains in its nest or birthplace for a long period after birth. This applies to mammals, marsupials and many birds. Such animals are dependent on their parents for their feeding, protection and learning necessary survival skills.

VetBooks.ir

VetBooks.ir

Nidifugous
A term used of birds that are able to leave the nest soon after hatching. These include chickens, ducks, geese, turkeys, and many waterfowl, waders and game birds.

Niemann-Pick Disease
A nervous problem seen in Siamese kittens; it is caused by a sphingomyelinase deficiency. Currently there is no treatment.

Nifursol
A drug active against histomoniasis, used in the prevention of BLACKHEAD OF TURKEYS. As there is no adequate residue depletion data, the product was banned in the EU for use in food-producing animals.

'Night Blindness'
'Night blindness' is seen in VITAMIN A deficiency and early progressive retinal atrophy. However it has been shown that continuous lighting caused blindness in turkey breeding flocks. The permanent constricted state of the iris did not allow the normal contractions to occur, and so prevented the pumping out from the eye of the toxic by-products of metabolism, resulting in opacity of the vitreous humour. It is illegal to have lights on in poultry houses 24 hours a day.

(See EYE, DISEASES AND INJURIES OF; NYCTALOPIA.)

Night Lighting
Night lighting is commonly practised in poultry houses, using 40-watt lamps (or equivalent) to give a 14-hour day, or 1500-watt lamps for three 20-second exposures a night. The object is increased egg production during the winter months, and the effect is due not merely to the provision of extra feeding-time, but also to the influence of light indirectly on the ovaries. However, an investigation carried out in conjunction into eye abnormalities in turkey breeding flocks, leading to blindness, showed that the cause was continuous artificial light. Seventy per cent of poults showed signs after five weeks of exposure, and it was shown that it was the continuity and not the intensity of the light which was doing the damage.

Nightshade Poisoning
The nightshades comprise garden or black nightshade (*Solanum nigrum*), woody nightshade or bittersweet (*S. dulcamara*), and deadly nightshade or belladonna (*Atropa belladonna*). (See GARDEN NIGHTSHADE POISONING; BITTERSWEET POISONING; and ATROPINE POISONING).

Nigroid Bodies
Nigroid bodies are black or brown irregular outgrowths from the edges of the iris of the horse's eye. (See IRIS.)

Nipah Virus
Nipah virus is responsible for a disease of pigs in tropical areas. It causes fever, nervous signs, respiratory difficulties and abortions. An outbreak of encephalitis among pig farmers in Malaysia, caused by the virus, resulted in the slaughter of 1.1 million pigs (out of a total pig population of 2.4 million) on 956 farms in an effort to control the outbreak. Only 796 pig farms remained. Of 256 people who suffered from encephalitis, 105 died. The infection is thought to have originated in flying foxes.

Nipple-Drinkers
Nipple-drinkers are popular in pig and poultry enterprises as they supply water on demand without using troughs, and avoiding the possibility of drinking water being fouled. Similar drinkers are available for use by dogs in kennels. Animals may have to be taught how to use them.

Nipples
Infection and necrosis of sows' nipples are not uncommonly caused by *Fusiformis necrophorus*, and may lead to the death of piglets from starvation. (See also MAMILLA - MAMILLITIS.)

Nit
Egg of louse or other parasitic insect.

Nitenpyram
A treatment for flea infestation in dogs and cats. It is given in tablet form or mixed into a small amount of food. It is given on the day when fleas are seen. It is contraindicated in animals less than four weeks old or those weighing less than 1 kg. After administration, the animal may scratch more than usual due to the reaction of the fleas to the product.

Nitrite Poisoning
Poisoning as a result of eating plants with a high potassium nitrate content is common in some of the western parts of the USA. The nitrate is reduced to nitrite by substances within the plant under certain climatic conditions, and when such a plant is eaten the nitrite is rapidly absorbed from the digestive system and converts haemoglobin into METHAEMOGLOBIN. This is incapable of giving up its oxygen to the tissues and as a result the animal dies.

Sodium nitrite is used for curing meat and has found its way into swill, causing fatal poisoning in pigs. The main signs observed were vomiting,

VetBooks.ir

squealing and distressed breathing. Nitrite poisoning has also occurred, in piggeries with poor ventilation, from condensation dripping down. It may arise, too, in grazing animals where nitrogenous fertilisers have been spread during dry weather, or before rain has washed it away. Feed or bedding contaminated by fertiliser from broken bags can be a source of nitrate poisoning. The nitrate itself has a fairly low toxicity, before being converted into the poisonous nitrite.

Treatment consists of 4 per cent methylene blue intravenously, and ascorbic acid. (See NITROSAMINES.)

Signs include abdominal pain, head pressing, sometimes diarrhoea, weakness and ATAXIA, DYSPNOEA, rapid heart action and, especially, CYANOSIS. The mucous membranes appear brown, due to the presence of methaemoglobin, as does the blood. Convulsions, coma and death may follow. A change in temperament may occur with normally quiet cows becoming wild and also abortion is recorded.

Fatal nitrite poisoning of pigs has occurred following the use, for drinking purposes, of rainwater containing decaying organic matter.

Nitrites

Nitrites are salts which, in excess, convert haemoglobin into METHAEMOGLOBIN, and may cause death from lack of oxygen. They are used on meat to provide flavour and colour and as a MEAT PATHOGEN INHIBITOR for pathogens including BOTULISM. (See NITRITE POISONING; NITROSAMINES.)

Nitrofurans

A group of drugs developed in the USA during the 1940s, and including nitrofurazone, furazolidone, and nitrofurantoin (for urinary tract infections). They are effective against a wide range of bacteria, including Gram-negative; some against protozoa and fungi. It is thought that they interfere with the carbohydrate metabolism of micro-organisms. The use of furazolidone and nitrofurantoin for medicines in food-producing animals is prohibited in the EU.

Nitrogen

(See AIR). For liquid nitrogen see CRYOSURGERY; ARTIFICIAL INSEMINATION.

Nitrogen dioxide A reddish-brown heavy gas with an offensive odour. This is formed by oxidation, on exposure to air, from the colourless nitric oxide. The latter appears to be the chief oxide of nitrogen produced in the early stages of silage-making.

Emissions of this gas from silage clamps have caused human illness and the death of farm animals.

Signs Dyspnoea, cyanosis, muscular weakness and, in piglets, vomiting.

Nitrophenide

A coccidiostat for poultry, especially caecal coccidiosis (*Eimeria tenella*), and to a lesser extent intestinal coccidiosis (*Eimeria necatrix*).

Nitrophenide Poisoning

Nitrophenide poisoning, characterised by paralysis, has occurred in pigs fed medicated meal intended for poultry and containing nitrophenide as a treatment for coccidiosis.

Nitrosamines

They are very powerful chemical carcinogens. They cause cancer of specific organs irrespective of the route of administration. Some nitrosamines can be formed from nitrite and secondary amine or amide in the acid stomach contents of animals. Nitrites used as food preservatives, and high levels of nitrates in drinking water, can be carcinogens.

Nitroscanate

A general anthelmintic for use in dogs. It acts against both tapeworms and roundworms.

Nitrothiazole

The drug 2-amino-5-nitrothiazole was mainly used in controlling blackhead in turkeys (by preventive medication).

Nitrous Oxide

This anaesthetic is not much used in veterinary practice but, where it is, there is a need for good ventilation, as it interferes with vitamin B metabolism and, in a pregnant anaesthetist, may bring about a miscarriage.

Nitroxynil

Nitroxynil, a fasciolicide, is used by SUBCUTANEOUS injection for the treatment of fluke in cattle and sheep and, given by mouth, against gapeworm in birds. Animals must not be slaughtered for meat until 30 days after administration. In heifers it should not be used during the last trimester of pregnancy; in sheep and goats it should not be used within one year of first lambing or kidding.

nm

(See NANOMETRE.)

NMR

1. (See NATIONAL MILK RECORDS.)
2. (See NUCLEAR MAGNETIC RESONANCE.)

NOAH
(See NATIONAL OFFICE OF ANIMAL HEALTH.)

Nocardiosis
Infection with *Nocardia asteroides* in cattle, dogs, cats and man. It is a saprophytic inhabitant of the soil and belongs to the genus *Actinomycetes*. It was formerly classified as a fungus but is now regarded as a bacterium. It has occasionally been isolated from the udders of cows affected with mastitis, and has been reported as the cause of 'incurable mastitis' in an outbreak on a Texas farm. Involvement of the liver and mesentery, with marked loss of condition, thirst, and some diarrhoea – calling for euthanasia – has been recorded in the dog in Britain. PLEURO-PNEUMONIA, occasionally also a skin infection, may result from *Nocardia* in dogs and cats.

Nocturnal
Active in or of the night (compare with DIURNAL).

Node
(See LYMPH NODES.)

Nodular Panniculitis
An inflammatory reaction involving subcutaneous fat, and characterised by nodules which burst. Abscesses and sloughing may occur. (See AUTO-IMMUNE DISEASE, of which the above is an example, occurring in dogs.)

Noise
(See STRESS.)

Non-Hodgkin's Lymphoma
(See LYMPHOMA.)

Non-Parenchymatous
The adjective used for the cells or tissues (e.g. non-parenchymatous cells, tissues) that form the support structure for the cells active within a tissue or organ.

Non-Starch Polysaccharides
These are present in cereals and contribute to the viscosity of the intestinal contents. Wheat and barley have a greater impact on intestinal viscosity than other cereals.

Non-Steroidal Anti-Inflammation Drugs (NSAID)
NSAID is an acronym for Non-Steroidal, Anti-Inflammatory Drugs. They are very widely used in the control of postoperative pain, arthritis and other inflammatory conditions; also as anti-inflammatory agents where pain may not be an issue and steroids are best avoided. They are also anti-pyretic. FLUNIXIN MEGLUMINE, PHENYLBUTAZONE, CARPROFEN, MELOXICAM, FIROCOXIB, KETOPROFEN, TEPOXALIN, ROBENACOXIB and ASPIRIN are examples of NSAIDs. Diclofenac is licensed in some EU countries. PARACETAMOL is generally included in the group although it does not have anti-inflammatory effects and should not be used in cats. Duration of activity in cats of many NSAIDs is usually longer than in dogs, but suitable compounds include meloxicam and robenacoxib. They may be administered orally or by injection according to type and formulation. There are restrictions on the use of most NSAIDs in horses competing under Jockey Club, etc. rules.

Side effects are uncommon, but in most species can include gastric or intestinal ulceration or bleeding, renal toxicity, growth plate defects, HYPOTENSION, HYPERSENSITIVITY and CNS signs such as seizures, ataxia, depression and coma.

(See ANALGESICS.)

Non-Structural Carbohydrates (NSC)
A term used to cover simple SUGARS, STARCHES and FRUCTANS. It is a term sometimes used of plants in nutrition and rationing particularly of horses. They are rapidly digested compared with FIBRE. (See also FIBRE; HORSES, FEEDING OF; RATIONS FOR LIVESTOCK.)

Noradrenalin, Noradrenaline; Norepinephrine
A hormone secreted by the adrenal gland medulla. It causes increased heart rate, and constricts the blood vessels, causing a rise in blood pressure. (See NERVES.)

Norepinephrine
American name for ADRENALIN and also used in the British Pharmacopoeia. (See NORADRENALIN.)

Norfolk Black Turkey
This black turkey is believed to be the first variety domesticated in Britain; it was previously called the BLACK TURKEY. The stags weigh 11.4 kg (25 lb) and the hen 5.9 kg to 6.8 kg (13 lb to 15 lb). Occasionally 'CURLED TONGUE' is seen in the breed.

Norgestomet
This is used, with oestradiol, to control oestrus in cattle. It suppresses oestrus and ovulation by pituitary inhibition, while the oestrogen shortens the luteal phase of the reproductive cycle. An implant containing those drugs will suppress oestrous, which recommences on removal of the implant. It is used in beef cattle and maiden heifers, which are not supplying milk for human consumption.

VetBooks.ir

Normal Saline, Physiological Saline

Normal saline (Physiological saline) is a solution of sodium chloride in sterile distilled water, which is isotonic with the strength of this salt in the bloodstream – that is, about 0.9 per cent for mammals. (See also DEHYDRATION; DEXTRAN.)

Normoblast

Normoblast is a red blood cell which still contains the remnant of a nucleus.

Norsk Skaukatt

(See NORWEGIAN FOREST CATS.)

North Country Cheviot Sheep

This breed is mainly found in Scotland and Northern England. It was developed by Sir John Sinclair in 1791 who bought some CHEVIOT SHEEP and to increase their size mated them with SCOTTISH BLACKFACE SHEEP and possibly later with English or BORDER LEICESTER SHEEP. It has a Roman nose, black nostrils and a black line around the eyes with erect ears; both sexes are polled. The rams weigh up to 102 kg and ewes up to 79 kg.

North Country Mule

This is a cross of BLUE-FACED LEICESTER ram with SWALEDALE or BLACKFACE ewe.

North Devon Cattle

Also called 'Red Ruby', 'Devon Ruby' or 'Devon'. They are a traditional breed with a herd book begun in 1850. It is now uncommon except in the south west of England. It has a dark red colour with a coat of medium thickness becoming long in winter and short and sleek in summer. The cows weigh about 430 kg to 590 kg and the bulls 770 kg to 1,000 kg. Previously dual-purpose (milk, meat), they are now used for beef.

Northern Fowl Mite

This can infect canaries as well as poultry, and has caused allergic reactions in poultry-keepers in Israel. (See MITES, PARASITIC.)

Norwegian Buhund Dogs

A breed of boxer-sized dog introduced into the UK in the 1950s. Hereditary CATARACT may be present, but the mechanism of inheritance is unknown. (See under EYE, DISEASES AND INJURIES OF.)

Norwegian Elkhound Dogs

This is a breed not often seen in the UK. GLAUCOMA and PROGRESSIVE RETINAL ATROPHY may be seen in this breed but the mode of inheritance are unknown. (See under EYE, DISEASES AND INJURIES OF). DWARFISM is seen in the breed.

Norwegian Forest Cats, Norsk Skaukatt

is a medium-hair breed of cat. The breed is prone to DEAFNESS and glycogenosis (abnormal glycogen storage in the tissues). There are DNA tests for GLYCOGEN STORAGE DISEASE and HYPERTROPHIC CARDIOMYOPATHY.

Norwegian Red Cattle

A red-brown and white dairy breed of cattle which has been used in Britain since about 2000 to cross with Holstein cattle to produce a calf which has a relatively high milk yield, with higher levels of milk solids and also longer lived. The male calves can be used for beef.

Norwegian Scabies

This is a severe form of sarcoptic mange, also known as red mange. It is often called crusted scabies and may be associated with immunosuppression. The skin becomes red, the hair falls out in patches, and there is intense pruritus.

Nose and Nasal Passages

The 'nose' of an animal, which is more often termed the 'muzzle', or 'snout', according to the species, serves three important functions. It forms the outermost end of the respiratory passage; it is the organ of smell; and it contains some of the end-organs of the sense of touch.

Horses Externally, the rims of the nostrils are built up on a basis of cartilages covered over by a fold of delicate skin possessing long tactile hairs. The cartilages are not complete laterally, thereby allowing the nostrils to become greatly distended during occasions of emergency. Situated at the upper and outer part of each nostril there is a pouch-like sac which opens into the nostril at one end, but is blind at the other. This is often called the 'false nostril'. Lying just within the entrance to the nasal passages about an inch or so inside each nostril is the lowermost opening of the LACRIMAL duct carrying tears secreted by the lacrimal gland of the eye.

Internally, each nostril, and the nasal passage to which it gives access, is completely divided from the other by the septum of the nose and its associated structures. This is composed partly by the vomer bone, and partly by a wall of cartilage which is continuous with the cartilages of the nostrils. The walls of each passage are lined by mucous membrane which is reflected on to the two turbinated scroll-like bones that are found in the passage; this membrane, being well supplied with blood, and being continually moist from the secretion of its mucin glands, serves to warm and moisten the incoming air before it passes to the lungs, and to extract the larger particles of dust,

VetBooks.ir

soot, etc., that the air picks up, by causing them to adhere to its sticky surface. The entrance to the air sinuses of the skull leads out from the posterior part of each passage, the mucous membrane lining the sinuses being continuous with that of the nose. (See SINUSES OF THE SKULL.) The end-organs of the sense of smell are scattered throughout the nasal mucous membrane in the upper parts particularly. The olfactory nerves from the brain, which pass out of the cranial cavity into that of the nose by way of the ethmoid bone, are distributed to these end-organs. Posteriorly, the nasal passages lead into the pharynx.

Cattle The nostrils, situated on either side of the broad expanse of moist hairless muzzle, are smaller and thicker than in the horse. No false nostril is present, and the opening of the lacrimal duct is not visible.

Nose and Nasal Passages, Diseases of

Catarrh Inflammation of the nostrils (mucous membranes of the nose) is called RHINITIS, and may accompany ordinary catarrhal inflammation of the nasal passages such as occurs in cases of DISTEMPER in the dog, of other febrile illnesses. The signs often resemble those of a human 'cold in the head', with a discharge from the nostrils which is at first clear and colourless, later becoming thick and yellowish-green. Horses and cattle often snort and shake their heads; dogs sneeze. Conjunctivitis may accompany the nasal catarrh.

In horses, the presence of ulcers in the mucous membrane with a perforated appearance may indicate GLANDERS. For a specific condition in the pig, see ATROPHIC RHINITIS.

Parasites, such as larvae of the sheep-nostril fly, *Linguatula*, or leeches in dog or cat, may cause a discharge from one or both nostrils.

A discharge from one nostril only may in the dog, for example, indicate the presence of a FOREIGN BODY such as a grass awn; or there may be a fungal infection (e.g. ASPERGILLOSIS) which may follow local injury or tumour formation. Another possible cause is an abscess at the root of a tooth, with pus collecting in the maxillary sinus and escaping through the nasomaxillary opening. (See MALAR ABSCESS.)

Treatment Nasal catarrh should be considered contagious. The animal should be isolated accordingly, and attention paid to comfort, ventilation, and suitability of food, as discussed under NURSING OF SICK ANIMALS. Signs of other diseases must be looked for, especially when the temperature is high, and a professional diagnosis should be obtained. The nostrils should be kept moist and pliable by rubbing small quantities of petroleum jelly around their rims daily, after sponging away discharges.

Diseased conditions of the turbinated bones or of the molar teeth call for surgical measures for their correction; parasites in the nasal cavities must be expelled (see MITES, PARASITIC); and if other foreign bodies are present they must be removed.

Haemorrhage from the nostrils may be due to injuries which cause tearing or laceration of the mucous membrane; it may occur during violent exertion, such as racing or hunting with horses not in maximum condition; it may be associated with ulceration, congestion, tumour formation, or other diseased condition of the nasal mucous membrane; it may be due to fracture of a horn core in cattle and sheep, the blood entering the nose from the sinuses of the skull; in horses it may be seen in GUTTURAL POUCH DISEASE; and see 'BLEEDER HORSES'.

When the haemorrhage is only slight, little more than keeping the animal quiet, and applying douches of cold water to the bridge of the nose, will be required. A thin trickle of blood coming from one nostril only can be disregarded, as it will generally cease of its own accord. When the bleeding is very profuse, and there may be danger of collapse, more drastic measures are needed. The affected nostril should be plugged with swabs of cotton-wool enclosed in gauze, and so arranged that some of the gauze is left outside the nostril to allow of removal some hours afterwards. In horses, care must be taken not to confuse nose bleeding with pulmonary bleeding. Severe bleeding from both nostrils requires veterinary intervention; both nostrils may need to be plugged after first having performed a tracheotomy.

In rabbits, haemorrhage from the nostrils is the main PATHOGNOMONIC sign of VIRAL HAEMORRHAGIC DISEASE OF RABBITS.

Tumours include polyps, especially in the cat; and adenocarcinoma in dogs and other animals.

Among other conditions in which the nose or the nasal passages are affected may be mentioned: fungal infections, TUMOURS, mucosal disease, malignant catarrh, GLANDERS, URTICARIA, PURPURA HAEMORRHAGICA, STRANGLES and INFLUENZA. (See also INFECTIOUS NASAL GRANULOMATA IN CATTLE; RHINOSPORIDIOSIS; RHINOTRACHEITIS, INFECTIOUS BOVINE.)

'Gerbil Nose' is a DERMATITIS of the nose in gerbils associated with the secretion of the HARDERIAN GLANDS under stress.

Nosocomial

Hospital-acquired, human nosocomial infections, usually associated with medical or surgical

interventions, affect some 6 per cent of hospital patients, i.e. about 2 million people in the USA alone, resulting in some 6 million excess hospital bed-days. About 1 per cent of the victims die.

Nostril

(See NOSE AND NASAL PASSAGES.)

Nostril Flies, *Oestridae*

Nostril flies (oestridae) are members of the class of two-winged flies, whose larvae are parasitic in the nasal cavities, and in the air sinuses of the skull, of sheep. (See under FLIES.)

Notencephalocele

Protrusion of the brain substance at the back of the head.

Notifiable Diseases

Notifiable diseases are those which, when they occur upon farm premises, must be notified to the Divisional Veterinary Office of the State Veterinary Service of the Department for Environment, Food and Rural Affairs (DEFRA). The list of notifiable diseases is amended from time to time and usually applies to all member states of the European Union. Those which are notifiable in the UK but not in all other member states are identified by an asterisk in the list below.

African horse sickness
African swine fever
American foul brood (bees)
Anthrax
Aujeszky's disease*
Avian influenza
Bluetongue
Bonamiasis (in shellfish)*
Bovine spongiform encephalopathy (BSE)
Brucella melitensis
Brucellosis (bovine)
Cattle plague (rinderpest)
Classical swine fever
Contagious agalactia
Contagious bovine pleuropneumonia
Contagious epididymitis
Contagious equine metritis
Dourine
Enzootic bovine leukosis
Epizootic haemorrhagic virus disease (deer)
Epizootic lymphangitis
Equine infectious anaemia
Equine viral arteritis
Equine viral encephalomyelitis (Eastern, Western and Venezuelan)
European foul brood (bees)
Foot-and-mouth disease
Furunculosis (fish)
Glanders and farcy
Goat pox
Gyrodactylosis caused by *Gyrodactylus solaris**
Haplosporidiosis (in fish)
Infectious haematopoetic necrosis (in fish)
Infectious salmon anaemia*
Iridovirosis (in fish)
Koi Herpesvirus Disease
Lumpy skin disease
Lyassa virus in bats (if rabies)
Marteiliosis (in shellfish)*
Mikrocytosis (in fish)
Newcastle disease
Paramyxovirus in pigeons
Perkinosis
Peste des petits ruminants
Rabies
Rift Valley fever
Scrapie
Sheep pox
Sheep scab (Scotland only)
Spring viraemia of carp*
Swine vesicular disease (SVD)
Teschen disease
Tuberculosis (bovine)
Tuberculosis (deer)
Varroasis (in bees)
Vesicular stomatitis
Viral haemorrhagic septicaemia (in fish)*
Warble fly (bovine)*
West Nile fever

The following are notifiable diseases in the whole of Ireland (north and south):

Brucellosis, in ruminating animals and swine
Caprine viral arthritis-encephalitis
Caseous lymphadenitis
Enzootic abortion of ewes
Fowl typhoid
Infectious bovine rhinotracheitis
Johne's disease
Maedi/visna
Mycoplasmal (infectious) synovitis
Mycoplasmosis (*M. gallisepticum* or *M, melea gridis*)
Parasitic mange of horses
Porcine epidemic diarrhoea (coronavirus)
Pullorum disease
Pulmonary adenomatosis
Psittacosis
Salmonellosis
Transmissible gastroenteritis of pigs
Tuberculosis in ruminating animals
Turkey rhinotracheitis

In Northern Ireland only:
Duck plague
Fowl pox
Infectious laryngotracheitis

VetBooks.ir

Trichinosis
Vesicular exanthema
In the Republic of Ireland only:
Avian yersiniosis
Campylobacteriosis

(See under DISEASES OF ANIMALS ACTS – Diseases of Fish Act 1937 (as amended 1983), Diseases of Fish (Control) Regulations 1994 and the Fish Health Regulations 1997 for duties and responsibilities of animal-owners.)

Notoedric Mange
(See under MITES, PARASITIC.)

Nova Scotia Duck Tolling Retriever
A breed uncommon in UK. In this breed PROGRESSIVE RETINAL ATROPHY is inherited as a recessive trait and COLLIE EYE ANOMALY (DNA test available) is also present. (See under EYE, DISEASES AND INJURIES OF.)

Novobiocin
An antibiotic used in mastitis treatment. It is usually formulated with other antibiotics and in this form has also been used in treating otitis externa in dogs and cats.

NSAID
(See NON-STEROIDAL ANTI-INFLAMMATION DRUGS.)

NSC
(See NON-STRUCTURAL CARBOHYDRATES.)

Nubian Goats
(See ANGLO-NUBIAN GOATS.)

Nuclear Magnetic Resonance (NMR)
Also known as MAGNETIC RESONANCE IMAGING (MRI), this is a minimal or hazard-free, non-invasive technique for generating images of internal sections of the body. The system works by utilising the differing absorption of radio waves by atoms in the body when exposed to a magnetic field. The amount of absorption is measured and the data used to generate a computer image. This allows lesions to be visualised within tissues and organs. It is very useful in the detection and diagnosis of brain diseases.

Nuclear Medicine
Involves the use of radio-isotopes for diagnosis and therapy. (See RADIOISOTOPES.)

Nuclear Weapons
(See under RADIOACTIVE FALL-OUT.)

Nucleic Acids
(See DNA and RIBONUCLEIC ACID.)

Nuclein
Nuclein is a protein substance containing phosphorus derived from the nuclei of cells.

Nucleotides
These subunits of DNA are used as dietary supplements for e.g. young pigs where they increase blood flow to the intestinal walls, accelerating mucosal development. Both humoral and cellular immunity are stimulated and the incidence of diarrhoea is reduced. (See RADIOISOTOPES.)

Nucleus
The central body in a cell which controls its activities. (See CELLS.)

Nuisance Flies
Under the Clean Neighbourhoods and Environment Act 2005, local authorities have the power to enter premises and issue abatement orders. Deep pit free range poultry houses, indoor pig units, dairy units, calf pens and slurry storage areas provide idea conditions for multiplication of such flies, and up to 15 generations can be produced a year. In cattle they include the face fly, head fly, horn fly and stable fly. (See also FLIES - ORDER DIPTERA.)

Nulliparous
Relating to a female animal that has not produced viable offspring.

Nurse Cells
These are located in the female bird's reproductive tract at the junction of the oviduct and the isthmus. Spermatozoa migrating up the tract come to rest with their heads within these cells. They are then released gradually over a period to ascend the oviduct and fertilise eggs.

Nurse Cows
These are often cows from the dairy herd which, for some reason, are no longer milked. This may be because they have had mastitis and no longer produce milk in one or more quarters. They can be used to allow calves to suck from them and, if good milkers, then several batches of calves can be reared. They can also be used to increase the growth rates of calves; they are also bought by suckler herds, particularly pedigree beef herds, where the calf's natural dam is not producing sufficient milk.

Nursing of Sick Animals
The advent of qualified professional VETERINARY NURSES has been of great benefit to practising

VetBooks.ir

VetBooks.ir

veterinary surgeons, especially those engaged in small-animal practice, and to their patients; and has facilitated measures for intensive care.

Nursing of small animals at home If your dog or cat has an infectious disease, nursing may have to be undertaken at home, since only veterinary clinics with quarantine facilities can accept such cases owing to the risk to other patients.

In other cases, after initial veterinary treatment, it is often preferable to have the animal at home for nursing. There is likely to be less stress for your pet when it is not sent or kept away from its familiar surroundings.

A dog or cat which is ill, or recovering from an operation or accident, tends to seek solitude and require peace. Continual fussing and interference, however well-meant, are to be avoided; this has to be impressed on children.

Fresh air, warmth, and an absence of bright lights and noise (such as those emanating from a TV set) are desirable. A patient with eye inflammation, tetanus, or some other nervous system disorder needs protection from bright light.

Newspapers should be laid on the floor to protect the surface for contamination by urine, defecation, bleeding, etc. and destroyed after use. If a dog cannot go outside, a box of earth or ashes, or the material sold for cat trays, may be useful too. An extra sanitary tray will be needed for an ill cat.

Constipation may be a problem. A little of the oil from a tin of sardines may be taken voluntarily as a laxative. (NB a cat straining ineffectually over a litter tray may be trying to pass urine and not faeces.)

Temperature-taking often forms a part of animal nursing. Ideally, an intra-aural thermometer is best for inexperienced owners. If a clinical thermometer (with a stout, stubby end) is used the end should be lubricated before passing it into the rectum; care must be taken to avoid accidents. Cooking oil will serve for lubrication.

Animals with respiratory signs should be maintained in a constant ambient temperature.

The discharges from the eyes and nose of an ill animal should be cleaned away as required.

It is sometimes difficult to keep an ill dog or cat clean. Any hair or fur which becomes soiled should be combed or clipped off, taking great care not to damage the skin, and the part washed.

Feeding Prescription diets are specially formulated for use in assisting the treatment of specific canine and feline disorders. They are available in canned and dry form, as prescribed by veterinary surgeons; see DIET AND DIETETICS. Human invalid foods are often useful if special diets are unavailable.

Do not force solid foods on a sick animal which, if suffering from a digestive upset, is usually better off without solid food for a day or two. (See also under VOMITING.) Variety is important in feeding the sick.

During convalescence the animal may be tempted to eat by offering small quantities of warmed proprietary food, flavoured or unflavoured.

Nursing of horses The affected horse should be removed from its stall in the stable and placed in isolation. It should have plenty of bedding, be provided with clean water, and if the weather is cold it should be clothed with a rug. In cases where the horse is unable to stand, a specially thick straw be should be given, and one or two bags filled with straw, or bales of hay, are useful to prop it up in an upright position on the breast. Horses that are down must be turned over on to the other side twice or thrice daily. The rectum and bladder may require evacuation artificially, if it does not occur naturally. If bed sores appear, they should be dressed twice daily with surgical spirit, and more bedding should be supplied. In respiratory diseases the most important factor in nursing is the adequate provision of fresh air. Small feeds should be offered several times daily, and when a horse refuses one type of food it should be offered another. Whenever the breathing is faster than normal drenching should be avoided.

Nursing of cattle Isolate in a loose-box. Calves should be shut alone in a pen if infective but, ideally, in sight of other calves. The same conditions as to bedding, clothing, water, ventilation, etc., apply to cattle as to horses. Patient kindly treatment, the avoidance of all unnecessary fuss and haste, and a gentle firmness are essential.

A sick cow which refuses hay from a new ley will often eat hay from old pasture. Molasses may add palatability to food otherwise rejected; so may a little salt.

Nutraceutical Agents

Products that are not drugs, but nutritional agents that exert a specific supplementary effect on a target organ, e.g. in cases of CYSTITIS. (See URINARY BLADDER, DISEASES OF.)

Nutrition, Faulty

This can lead to disease and losses of farm animals. Examples are nutritional muscular dystrophy (see under MUSCLES, DISEASES OF); blindness as a result of vitamin A deficiency (see EYE, DISEASES AND INJURIES OF); poisoning by excessive fluorides in the diet (see FLUOROSIS); and an all-muscle meat diet can lead to CANINE and FELINE JUVENILE OSTEODYSTROPHY. (See also 'CAT, ANGRY' POSTURE.)

VetBooks.ir

Nutritional problems are commonly encountered in hutch-bound rabbits, which often develop OSTEOPOROSIS as a result. Obesity is common in pet rats. Cage-birds, especially parrots, often develop NEOPHOBIA and refuse to eat a balanced diet. A common outcome of this is the development of diseases caused by calcium imbalances and deficiencies. Captive reptiles also often develop similar disorders and home-bred tortoises are especially likely to develop skeletal and carapacial abnormalities caused by dietary imbalances of proteins and minerals.

Nutritional Encephalomalacia

(See 'CRAZY CHICK' DISEASE.)

Nutritional Hyperparathyroidism

(See CANINE JUVENILE OSTEODYSTROPHY; FELINE JUVENILE OSTEODYSTROPHY.)

Nutritional Myopathy

A condition resulting from a deficiency of VITAMIN E or SELENIUM. It is a common problem in cattle, sheep and horses. (See MUSCLES, DISEASES OF; PARALYTIC MYOGLOBINURIA; SUDDEN DEATH.

Nuttallia

Nuttallia is the name given to a genus of piroplasms which cause biliary fever in horses in many parts of the world. There are two forms involved – *Babesia* (*Nuttallia*) *equi*, which is the smaller and more important, and *B. (Nuttallia) caballi*. Each is transmitted by one or more ticks. (See BABESIA – Babesiosis.)

Nux Vomica

Nux vomica is the seed of the *Strychnos nux-vomica*, an East Indian tree. It has intensely bitter taste. The medicinal properties are due to 2 alkaloids – strychnine and brucine, which the plant contains. Brucine has an action similar to, though much weaker than, strychnine. (See under STRYCHNINE.)

Nyctalopia, 'Night Blindness'

A condition that sometimes affects horses and mules in countries where the glare of the sunlight is very intense during the day. At night such animals are quite unable to see, and will stumble into objects, that are easily discernible to human beings. (See EYE, DISEASES AND INJURIES OF.)

Nymphomania

A condition in which a female animal is (or behaves as if) in constant oestrus. It is associated with pathological changes, often of a cystic nature, in the ovaries. Hormone treatment may be tried under veterinary advice; or removing the ovaries by surgical measures, as early as possible after the erotic signs have made their appearance. (See OVARIES, DISEASES OF; HORMONE THERAPY.)

Nystagmus

Nystagmus is a condition in which the eyeballs show constant fine jerky movements of an involuntary nature. It can be seen in normal animals after rapid movement or when watching a moving object, but it is often pathological, sometimes associated with neurological conditions particularly those associated with the vestibular apparatus of the inner ear. (See EAR.)

Nystatin

An antifungal antibiotic used topically to inhibit yeast and yeast-like fungi.

O

OA
(See OSTEOARTHRITIS.)

Oak Poisoning
Both the acorns and the leaves of the oak (*Quercus* spp.) may be dangerous when eaten by stock, but the leaves are usually harmless unless eaten in large quantities. It is when there is a scarcity of food in pastures towards the end of very dry summers that signs of poisoning occur. The animals most affected are young store cattle. Cattle can develop a taste for oak and acorns then can develop signs of fever and diarrhoea with blood-stained faeces, abortion and death can occur.

Horses have been poisoned through eating either oak leaves or acorns.

It is well known that both pigs and sheep can eat acorns in small quantities without ill-effects.

Rabbits that ingest acorns develop red urine that may be confused with HAEMATURIA. The condition ceases once the rabbits stop eating acorns.

Signs Ruminants that have eaten many acorns become dull, cease feeding, lie groaning, and appear to be in considerable pain. At first, there is severe constipation accompanied by straining and colicky pains, cessation of rumination, weakness of the pulse, and a temperature below normal. Later, small amounts of inky-black faeces are passed, and a blood-stained diarrhoea sets in. Great prostration is seen, and the animals die in from three to seven days when large amounts have been eaten. In chronic cases there is always great loss of flesh, and death does not take place till weeks or months after the beginning of the signs.

Horses may not show signs of pain. The poisoned animal becomes weak and dull, has a subnormal temperature, may discharge food and saliva from its nostrils, show head-pressing, have mouth ulcers, have reddish-brown urine, ataxia and convulsions.

Autopsy findings include a uraemic smell from the carcase, OEDEMA and haemorrhages, and kidney lesions.

Treatment Cattle should be given long hay. The animals should be made comfortable, with plenty of bedding provided. During convalescence, the animals require liberal feeding to make up the loss of flesh they have sustained.

Oats
They are used in animal feeds; they are lower in energy levels than barley and wheat. When fed to dogs, oats reduce the blood cholesterol levels. (See CEREALS; DIET AND DIETETICS; and HORSES, FEEDING OF.)

Obesity
(adjective, Obese)
The excessive accumulation of fat within the body. It involves an increase in weight beyond that considered desirable for height, bone structure and conformation for that type of animal. Obesity is an important condition in the dog and cat, and may arise from overfeeding, an unsuitable diet, or from a hormone imbalance. Obesity is often associated with, and may predispose an animal to, heart disease, arthritis, and some skin and respiratory disorders, as well as intolerance of heat. In a British study of cats (2008 to 2010) obesity was seen in 11.5 per cent; cases were more common when animals were neutered, male or in middle-age (around seven years old). Many cats received too many 'treats'.

In UK horses and ponies, surveys from 2008 suggested that 50 per cent were overweight. Such animals are at risk of LAMINITIS and EQUINE METABOLIC SYNDROME. Diets with restricted calories, low non-structural carbohydrates, high fibre, adequate proteins and micronutrients will reduce weight, and can be used with regular weighing. In 2013 a vaccine was patented for treating obesity in dogs and cats by enhancing SOMATOSTATIN immunity.

Overfeeding a pet can actually constitute an offence under the Protection of Animals Act 1911 by causing unnecessary suffering. Prosecution under the Animal Welfare Acts may be made for keeping pets that are seriously overweight. Prosecutions have successfully been taken against owners of obese dogs where the condition was interfering with normal life. These prosecutions were under the ANIMAL WELFARE ACT 2006 (and could be also taken under the 2011 Act in Northern Ireland). (See GHRELIN, GLUCAGON-LIKE PEPTIDE-1, LEPTIN, OREXIN, OVERFAT PETS, OVERWEIGHT ANIMALS, OXYNTOMODULIN.)

Obligate
To be essential: the term is often used of micro-organisms or parasites that must live under defined conditions. Thus, an obligate aerobe can only exist in the presence of oxygen.

Obligatory
Unavoidable, something that has to occur.

Obstetrics
(See PARTURITION, DRUG-INDUCED; CALVING.)

Obstruction of Pharynx or Oesophagus
(See 'CHOKING'.)

VetBooks.ir

Obtundation
Dullness of attitude, with depression of consciousness.

Occiput
Occiput is the uppermost posterior part of the head where it meets the neck. The occipital bone lies in the part of the skull which forms the occiput, and can be felt as a hard bony plate in most animals. Some of the neck muscles are attached to the occipital bone, and the powerful ligamentum nuchae, which is the main supporting structure of the head and neck, is inserted into the prominence that can be felt between the ears.

Occlusion
The normal dental conformation in which the upper teeth meet those of the lower jaw. (See BRACHYCEPHALIC; BRACHYGNATHISM; DOLICHOCEPHALIC SKULL; MALOCCLUSION; PROGNATHISM.)

Occupational Hazards
(See SHEPHERDS; ORF; PIGS, TRANSMISSIBLE DISEASES OF; MEAT-HANDLERS' OCCUPATIONAL HAZARDS; ZOONOSES IN UK VETERINARIANS; NITROGEN DIOXIDE; SPOROTRICHOSIS; SALMONELLOSIS; BUBONIC PLAGUE.)

OCD
(See OSTEOCHONDRITIS DISSECANS.)

O

Ochratoxin A
Ochratoxin A is a fungal toxin sometimes found in stored feeds and originating from *Penicillium viridicatum*, for example. Poisoning in pigs may result in thirst, enlarged kidneys, and polyuria. (See MYCOTOXICOSIS.)

Octomitus
A parasite of the gall bladder and intestine of rainbow trout similar in shape to *Hexamita*.

Ocular
Pertaining to the eye. (See also OPHTHALMIC.)

Odontoma
Odontoma is a tumour arising in tissues which normally produce teeth. They are encountered in horses, sheep and cattle in association with the roots (usually) of teeth, where either they may appear as rounded or irregular masses attached to an otherwise normal tooth (sometimes making extraction extremely difficult), or they may occur as large, irregular, solid masses replacing the greater part of a normal tooth and causing a swelling on the side of the jaw. They are usually extremely dense and difficult to cut.

A so-called 'temporal odontoma' is a tumour, seen rarely in horses, about the size of a bantam's egg occurring in connection with the temporal bones. These tumours generally have an opening to the surface of the skin just below, or just in front of, the base of the ear. They contain 1 or 2 large, or many (sometimes over 100) small, imperfectly formed teeth enclosed in a single fibrous capsule.

Oedema, Edema (US)
Oedema is an accumulation of fluid in one or more of the body cavities, or beneath the skin.

A normal, physiological form of oedema affecting the region of the mammary glands occurs in cows and mares shortly before parturition, and disappears within a day or two afterwards.

Otherwise, oedema is a pathological condition. When affecting tissue spaces immediately below the skin, it is usually due to a local disturbance of circulation or it may arise through weak heart action, and is not uncommon following debilitating diseases or in old age. Oedema of the lungs occurs in an animal exposed to smoke in a burning building, parasitic bronchitis and as the result of an allergy (e.g. milk allergy and POTATO POISONING). Oedema involving the brisket or under the jaw may be a sign of severe liver-fluke infestation in sheep or cattle. (See also PARAQUAT.)

Oedema affecting the abdomen is also known as ascites (fluid accumulation in the peritoneal cavity) and may give rise to a visible swelling or 'pot-bellied' appearance. It is seen in cases of disease of heart, liver or kidneys; it sometimes accompanies diabetes. It may be associated with parasites such as liver-flukes in farm animals.

Excessive fluid in the chest is also known as hydrothorax, which may be associated with e.g. chronic pleurisy.

Oedema is a sign rather than a disease, and accordingly treatment must be directed at the cause. If due to parasites, the appropriate parasiticide must be used. A heart condition may be responsible and need appropriate treatment. Drainage or aspiration of the body cavity may be indicated but will not alone effect a permanent improvement. If tuberculosis is diagnosed, immediate destruction on public-health grounds is called for. (See also BOWEL, OEDEMA OF THE.)

Oedema, Malignant
(See GAS GANGRENE.)

Oesophageal Groove
Also known as the reticular groove, it is part of the gastric groove which in the ruminant has three parts. The other two are the omasal and abomasal grooves.

VetBooks.ir

Oesophagostomiosis, Oesophagostomiasis

Infestation with *Oesophagostomum* worms. In calves, there is a reduced intake of food for several weeks, anaemia, and diarrhoea. In goats, peritonitis has been recorded in India. In pigs, these worms may be important in the causation of NECROTIC ENTERITIS. Third-stage larvae of these (and also *Ostertagia*) worms have been found clinging to psychodid flies cultured from pig faeces. Larvae have also been recovered from flies caught near a field in which pigs were grazing. It is possible that rats may also transmit larvae from farm to farm. (See also THIN SOW SYNDROME and under ROUNDWORMS.)

Oesophagotomy

A surgical operation involving incision of the oesophagus for removal of a foreign body, etc.

Oesophagus

The tubular passage from throat to stomach, also known as the gullet. Food passes down from the mouth to the stomach by the process of PERISTALSIS.

Oesophagus, diseases of Stricture of the oesophagus in dogs and cats in the tropics is caused by *Spirocerca lupi* larvae.

Stricture has also followed anaesthesia in cats; the suggested cause is a reflux of gastric fluid causing oesophagitis. Signs may appear some days after anaesthesia.

A balloon oesophageal dilator has been used to relieve some cases of stricture. (See also under 'CHOKING'.)

Choke and occasionally MEGAOESOPHAGUS occur in horses, cattle and sheep.

Oestradiol and Oestrone, Estradiol and Estrone (US)

Oestradiol and oestrone (estradiol and estrone) are hormones secreted by the ovary (interstitial cells and Graafian follicles) which bring about oestrus and, in late pregnancy, stimulate development of the mammary gland. The early conceptus synthesises oestrogens. In dairy cattle these are secreted in the whey fraction of the milk as oestrone sulphate. (See PREGNANCY DIAGNOSIS.)

Oestridae

(See NOSTRIL FLIES.)

Oestrin

Oestrogen (see HORMONES).

Oestriol, Estriol (US)

A hormone used to treat urinary incontinence in spayed bitches. It must not be used in intact bitches, nor if signs of polydipsia are present.

Oestrogens, Estrogens (US)

Hormones, either of natural origin or prepared synthetically, which have the effect of inducing oestrus. (See under HORMONES.) Pasture oestrogens may cause infertility and sometimes abortion. (See INFERTILITY and HORMONES IN MEAT PRODUCTION; also under OESTRADIOL AND OESTRONE.)

Oestrone Sulphate

A product from OESTRADIOL and ANDROSTENEDIONE. It is higher in the pregnant female and is used to determine pregnancy in milk or blood in cattle, sheep and goats.

Oestrus, Estrus (US)

'Season' or 'heat' is the period during which the female shows desire for the male, and during which oestrogens from the Graafian follicle are circulating in the bloodstream. Oestrus precedes, or may coincide with, ovulation – rupture of the follicle and release of the ovum which passes into the top of the Fallopian tube. (See OVULATION; PHEROMONE.)

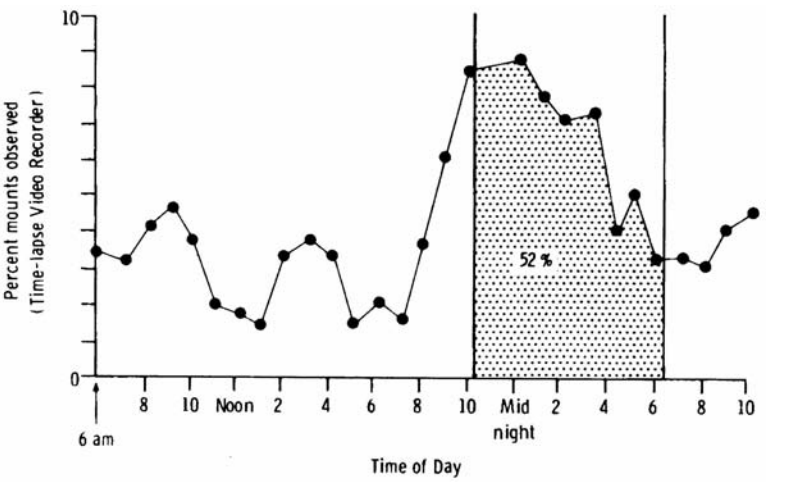
The oestrous cycles in animals vary in different species and in different breeds, and to some extent in different individuals.

Mare The mare is a polyoestrous animal with a breeding season during spring and summer. In the British Isles and in other parts of Northern Europe most mares first show normal oestrous cycles in mid-April; the frequency of ovulation is greatest in late July, and oestrous cyclical activity is at its lowest in early February.

During the oestral period the mare behaves unusually. She may become irritable or sluggish, and is easily tired. Her appetite is capricious and she may lean against the stall partition when in the stable. If her flanks are accidentally touched she may squeal or kick. The CLITORIS is frequently raised and there is usually a discharge of some amount of mucus from the vulva. Urine may be passed at frequent intervals. She shows a strong desire for the society of the male – even occasionally for that of the usually scorned gelding. Occasionally hysteria may be seen when the animal becomes quite unmanageable.

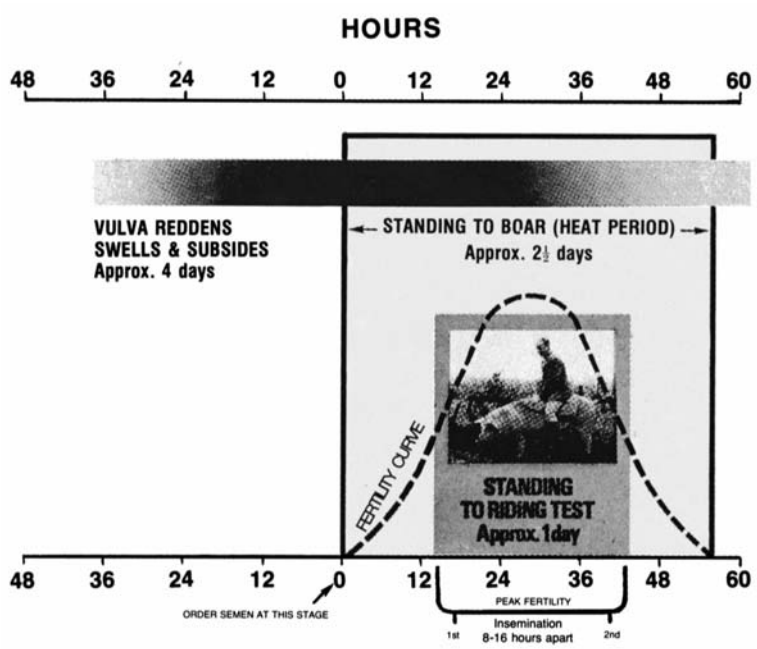
Cow The oestrous cycle is controlled by complex interactions among higher brain centres, the hypothalamus, anterior pituitary gland, ovary and uterus. Higher brain centres mediate responses to light, temperature, pheromones, and other stimuli which exert their effects through the central nervous system. The most important hormone, in regulating the oestrous cycle, is gonadotrophin-releasing hormone (GnRH).

OESTRUS



Animal	Time of year	Periodicity of Oestrus	Duration	First occurrence after parturition
Mare	Feb to July	21 days (14 to 28 days or more)	2 to 8 days	3 to 12 days; service on 9th day often successful
Cow	All year; most intense midsummer or more)	20 days (16 to 24 days	4 to 24 hours	30 to 60 days*
Ewe	End of Aug. till Jan., depending on breed and district	16 to 17 days (10 to 21 days)	1 to 2 days	†
Sow	Oct. to Nov. and Apr. to June	21 days (15 to 30 days)	1 to 3 days	8 weeks after farrowing, or 1 week after weaning of litter
Bitch	Usually Dec. to Feb., and in spring	Once only during each period	9 to 18 days	‡
Cat	Jan. onwards for 8 to 10 months (if unmated) oestrus may recur every 2 or 3 weeks		7 to 14 days	

*In the cow that is suckling a calf oestrus is usually delayed compared with a cow whose calf is removed soon after birth.
†With the exception of ewes of the Dorset Horn breed, which comes into season twice a year, and can rear two crops of lambs per year, sheep only show season in the autumn. It depends upon the breed as to how soon the rams may be put out with the flock. Generally speaking, the more low-lying the district and the milder the climate the earlier the ewes come into season; thus Suffolks are served from August till the end of September, and lamb from January till March. Mountain breeds are served from November till January, and lamb in April, May and June.
‡The bitch usually comes in season twice a year, but great variation takes places with the smaller toy breeds. Bitches of the Basenji breed (and a few individuals of other breeds) have only one heat period per year.



The cow mounts her fellows or, more importantly, stands to be mounted by them. She may bellow and race about with tail raised, or break out of a field in search of a bull. In other instances, signs are so slight as to be missed by the herdsman. (See OESTRUS, DETECTION OF, IN COWS.) Both cows and heifers in milk usually give less milk during the oestral period than in the intervals. (See CALVING EARLIER; INFERTILITY.)

Goat Rapid side-to-side and up-and-down tail movements may be seen; the animal is restless and bleats. Oestrus occurs every 19 to 21 days during the autumn, and lasts 12 to 48 hours.

Sow The sow becomes torpid and lazy, and when asked to move often grunts in a peculiar whining manner. If housed with others she behaves like the cow – mounting or being mounted. The vulva is usually distinctly swollen, and there is sometimes a blood-stained discharge. Oestrus in the sow lasts up to 60 hours and ovulation begins at 34 to 50 hours after its onset, the process taking up to five hours. The sow will accept service between

Oestrus in the cow. Mounting activity over 24 hours. Composition of 2880 cow-days. (36 adult Holsten cattle.) (With acknowledgements to Dr J. Frank Hurnik, University of Guelph, Canada, and to Dr D. B. Harker.)

A guide to insemination time in the sow. (With acknowledgements to the MLC.)

15 and 35 hours after the onset of oestrus, with the optimum at 25 to 35 hours.

Bitch She wanders away from home unless confined, and the odour of her blood-stained vaginal discharge attracts male followers. As bleeding from the vulva is slight in some bitches, especially at their first oestrus, owners should watch for swelling of the vulva. During the seven to nine days of pro-oestrus, the bitch will flirt with a dog but not accept him. Usually it is only during the last week of heat that the bitch will accept the dog, usually between the 10th and 12th days.

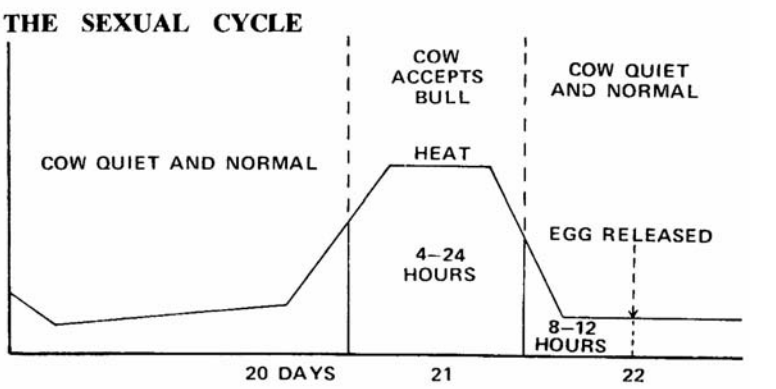
Cat The signs may suggest pain and/or a strong desire to have her back and flanks rubbed or scratched. She will roll over and over on the carpet or floor, rub herself against furniture, etc., and utter little pleased mews.

The first oestrus may be expected between the ages of six and eight months: however, it may occur as early as 14 weeks, or occasionally be delayed until the queen is about a year old.

Oestrus, Detection of, in Cows

Especially in winter, detection of oestrus is not as easy as might be thought. Studies in the USA suggest that where cows are watched four-hourly round the clock, the efficiency of heat-detection should be around 95 per cent, but in a herd where cows are seen only twice a day, the percentage is likely to drop to around 74 per cent.

The main sign of oestrus in a heifer or cow is standing still to be ridden by others ('bulling'). Part of the problem is that while 'bulling' lasts 12 hours on average, it may last only an hour; and as to the timing, 50 per cent of the displays occur at night. Moreover some cows may stand only once in 20 minutes; others will stand only for favourites; and some aggressive cows mount other cattle at a crowded trough in order to induce them to move aside to create a space.



Sometimes a cow is seen to mount another from the front. This is valuable evidence of oestrus, but it is important to remember that it is the riding cow which is bulling, not the one underneath.

The importance of pinpointing heat dates cannot be overemphasised. Only by record-keeping is it possible to identify animals that are not coming in heat at the normal time, in addition to those which are cycling (coming in heat) irregularly (see illustration on next page). Delay in seeking veterinary advice may lead to delay in conception.

As an aid to herd management, a VASECTOMY bull may be used, or a heat-detection device may be placed on a cow's back, liberating a dye when she is mounted. Applying paint to the tail which is rubbed off by mounting is also useful.

Oestrus, Suppression of

Bitches and cats may be prevented from coming 'on heat' by oral dosing with the synthetic equivalent of the naturally occurring hormone, progesterone; MEGESTROL ACETATE (Ovarid) is

(With acknowledgements to the East of Scotland College of Agriculture.)

an example. Synthetic progestogens are also used to lessen aggressive behaviour in dogs and spraying in cats.

Some progestogens can cause pathological changes in the uterus, particularly if used for prolonged periods. They may induce abnormal levels of growth hormone, suppress cortisol levels, and possibly increase the risk of mammary tumours. The use of suppressive agents can lead to PYOMETRA.

Oestrus ovis

(See NASAL BOT FLY LARVAE.)

Offal

The practice of incorporating offal – animal organs – in cattle feeds was banned in 1988 because of the risk of transmitting BOVINE SPONGIFORM ENCEPHALOPATHY.

Offals Middlings

A high-protein feed supplement for cattle (see WEATINGS).

Offensive Waste

(See HANDLING VETERINARY WASTE.)

Office International Des Epizooties (OIE)

Office International Des Epizooties (OIE) was set up in 1924 following the realisation that joint action between countries was necessary to control contagious animal diseases. It determines the animal health standards for international trade, advises the veterinary services in member countries, and aims to work towards the eradication of the most dangerous animal and zoonotic diseases. The membership comprises 192 countries and international organisations such as the UN's Food and Agriculture Organisation and the World Health Organisation. It is now often referred to as The World Organisation for Animal Health (OIE).

Official Veterinarian (OV)

The title adopted by many countries, especially in Europe, and used by veterinarians employed by government or its agencies and by other veterinary surgeons when undertaking official or government work.

OI

(See OSTEOGENESIS IMPERFECTA.)

OIE

(See OFFICE INTERNATIONAL DES EPIZOOTIES.)

Oilfield Hazards, Poisoning

In the USA about 500 cases of suspected poisoning by oilfield wastes are investigated each year at the Oklahoma animal disease diagnostic laboratory.

Hazards arise from the ingestion by cattle of petroleum hydrocarbons, salt water, heavy metals, chemicals stored on site, and rubbish such as discarded soda bags. A quantity of lead-based pipe-jointing material is used, and also chemicals to treat the mud which lubricates the drilling bit.

Signs of poisoning include weight loss and unthriftiness. A differential diagnosis has to take into account the possibility of internal parasites, faulty nutrition or other causes of debility; but standard analytical methods make it relatively easy to detect the ingested poisons.

The presence of petroleum in lung tissue and in rumen contents is frequently confirmed. Liver and kidney lesions may be found.

Oils

Oils are divided into fixed oils, which are of the nature of liquid fats, and are derived by expression from nuts, seeds, etc.; and volatile or essential oils, which are obtained by distillation. Examples are the oils of aniseed, cajaput, eucalyptus, peppermint, and turpentine. (See also PARAFFIN.)

VetBooks.ir

Oilseed Rape
Horses grazing in fields adjacent to this crop were though to be at risk of developing respiratory disease but this is now disproved. Rapeseed after oil removal by crushing or chemical extraction is used as a feed mainly in cattle but small amounts are used in pig and poultry feed.

Oldenburg
A breed of sheep native to the Hamburg Marshes, Germany. Fleece weights up to 6.35 kg (14 lb) and high lambing percentages are claimed.

Old English Sheepdog
Its very shaggy, grey and white coat is the distinguishing feature of this large dog. Wobbler syndrome (cervical spondylolithesis) and cataract may be inherited. Hip dysplasia, deafness and osteochondritis dessicans may also be found in the breed.

Olfactory
Relating to the sense of smell.

Olfactory Nerve, Nerve of Smell
Olfactory nerve (nerve of smell) is the 1st of the cranial nerves.

Oligofructose
Also called FRUCTO-OLIGOSACCHARIDE, and are naturally occurring FRUCTANS used as a sweetener; some are also considered to be PREBIOTICS.

Oligosaccharides
These are SACCHARIDE POLYMERS typically comprising a small number of simple sugars. Some are used as PREBIOTICS.

Oliguria
A diminution in the amount of URINE excreted.

Olive Pomace
A by-product of the olive-oil industry that has been used to replace wheat bran in cattle diets and barley in sheep diets. Pre-treatment with sodium hydroxide helps to delignify the product and improve palatability.

Olives
Olive powder has been used as a MEAT PATHOGEN INHIBITOR.

Ollulanus
(See CATS, WORM PARASITES IN.)

Omasum, 'Many-Plies'
Omasum ('many-plies') is the name given to the third stomach of ruminants. It is situated on the right side of the abdomen at a higher level than the fourth stomach and between this latter and the second stomach, with both of which it communicates. From its inner surface project large numbers of leaves or folia, each of which possesses roughened surfaces. In the centre of each folium is a band of muscle-fibres which produces a rasping movement of the leaf when it contracts. One leaf rubs against those on either side of it, and large particles of food material are ground down between the rough surfaces, preparatory to further digestion in the succeeding parts of the alimentary canal.

Studies at the ARC's National Institute for Research in Dairying have shown 'massive exchanges of water and solutes in the omasum of the steer. The organ appears to be the main site of magnesium absorption, and it is probably here that the cause of clinical HYPOMAGNESAEMIA should be sought'.

Omega-3 Fatty Acids
An essential component of the diet. Deficiencies result in reduced visual acuity, and can cause learning difficulties and skin problems. They have a beneficial effect on heart muscle. In the cat, there is evidence that they reduce the severity of chronic renal failure. Hens and dairy cows can be fed special diets, which increase the levels of omega-3 acids in eggs and milk.

Omentum
Omentum is a fold of peritoneum which passes from the stomach to some other organ. There are several such folds, but the most important is that which passes to the terminal part of the large colon and the beginning of the small colon, and which is called the great omentum. This does not run direct to the colon from the stomach, but forms a loose sac occupying the spaces between other organs in the abdomen. In health, there is always a considerable amount of fat deposited in the folds of the great omentum, and this, in the ox, sheep, and pig, forms part of the suet of commerce.

In the dog, the great omentum lies between the abdominal organs and the lower abdominal wall, and acts as a kind of protective bed which supports the intestines, etc.

Omeprazole
An acid pump inhibitor (gastric acid reducer) used to treat conditions in which excess gastric acid is causing problems, e.g. equine gastric ulcer syndrome. It may help control CRIB-BITING. It is not recommended for use in animals less than four weeks old or weighing less than 70 kg.

Omnivorous
An animal that feeds on a wide selection of foodstuffs including flesh, plants, insects and even

human foodstuffs is said to be omnivorous. The best examples are primates and pigs.

Omphalitis
'Navel-ill'. (See JOINT-ILL.)

Omphalitis of Birds
Infection of the yolk sack, by bacteria found in the alimentary canal and on the skin of the hen, or in the nostril of hatchery workers. It can cause high mortality of embryos and chicks. The bacteria may be relatively non-pathogenic elsewhere than in the yolk where, having a rich medium in which to grow, they cause serious disease. This can take the form of 'mushy chick disease' in birds under 10 days old, or true omphalitis. Sending birds out from a hatchery before the navels have completely closed is also a risk.

Omphalophlebitis
Omphalophlebitis means inflammation of the umbilical vein. It occurs in young animals and is commonly present in the early stages of 'navel-ill'.

Omsk Fever
The cause of this is related to the RUSSIAN SPRING-SUMMER VIRUS, but is more serious in its effects and is spread by the tick *Dermacentor pictus*.

Onchocerciasis
Infestation with worms belonging to the class Onchocerca. (See ROUNDWORMS.)

Oncogene
A gene associated with tumour formation. (See CANCER.)

The determination of the protein encoded by the *ras* oncogene has helped to explain how genes of this kind cause cancer.

The *ras* protein is part of the system on the cell surface that transmits signals from growth factors in the interior of the cell. In its mutated, oncogenetically coded form, the signal is locked in the 'on' position, so causing unrestrained growth.

Oncogenic
Giving rise to tumour formation.

Oncology
The study of tumours.

Oncornaviruses
Oncornaviruses are those which give rise to tumours, e.g. the feline leukaemia virus; the Rous sarcoma virus. (See CANCER; RETROVIRUS.)

Ondiri Disease
An infection of cattle and sheep by *Cytoecetes ondiri*; signs are fever and small haemorrhages of the mucous membranes (see BOVINE INFECTIOUS PETECHIAL FEVER).

One Eye Cold
A respiratory disease of pigeons characterised by excessive lacrimation from one or both eyes. Many different bacteria may be involved; the condition occurs usually after housing of birds in a poorly ventilated loft.

One Health
The definitions vary but that of the One Health Commission is: 'One Health is the collaborative effort of multiple health science professions, together with the related disciplines and institutions, working locally, nationally and globally – to attain optimal health for people, domestic animals, wildlife, plants and our environment.' Those involved should include human physicians, veterinary surgeons, wildlife specialists, environmentalists, anthropologists, economists and sociologists. International organisations involved include the WORLD HEALTH ORGANIZATION (WHO), the FOOD AND AGRICULTURE ORGANIZATION (FAO) and the WORLD ORGANISATION FOR ANIMAL HEALTH (OIE).

Onion Poisoning
The toxic effects of onions have been seen in cattle, sheep, horses and dogs.

The toxic principle is a pungent volatile oil, n-propyl disulphide. This gives rise to Heinz bodies, and red blood cells which contain them are removed by the reticuloendothelial system; giving rise to anaemia.

Signs Inappetence, tachycardia, staggering, jaundice, haemoglobinuria, collapse, and sometimes death.

Control Onions should not be fed at more than 25 per cent of the diet as dry matter; higher levels are poisonous to cattle. Individual animals may gorge themselves, even following proper formulation of the diet. Use in dairy cows may taint milk.

'Ontario Encephalitis'
A disease of piglets, as young as four to seven days, ending in a fatal encephalitis and caused by a virus. (See ENCEPHALOMYELITIS, VIRAL, OF PIGS.)

Onychetomy
De-clawing. It is not a permitted MUTILATION in the UK.

Onychia
Onychia is an inflammation affecting the nails or claws of animals. (See NAILS, DISEASES OF.)

VetBooks.ir

-onychia
Suffix – a condition of the nails (toenails, fingernails).

Onycho-
Prefix – pertaining or related to the nails.

Onychomycosis
Infection of the claw with a fungus. In cats, *Microsporum canis* infection is not uncommon. (See RINGWORM.)

Oocyte
An immature ovum.

Oodinium
A dinoflagellate (aquatic protozoon) which lives on the skin of salmonids in salt water. It rarely occurs in sufficient numbers to cause a problem.

Oophorectomy
(See SPAYING.)

Oophoritis
Oophoritis is another name for ovaritis or inflammation of an ovary.

Oosporein
A mycotoxin which, in birds, produces enlargement of the circumference of the PROVENTRICULUS at the isthmus and the mucosa is covered with pseudomembranous (see PSEUDOMEMBRANE) exudates and necrosis of the isthmus may occur.

'Opening the Heels'
'Opening the heels' means the cutting of the horn at the angles of the heels of the horse's foot, by which the continuity between the horn of the wall and of the bar on either side of the foot is destroyed. It is performed by some farriers and owners in the hope that it will allow the heels to expand and so produce a 'fine open foot'. Actually, the operation results in an interference with the shock-absorptive mechanism of the foot, and eventually produces contraction of the heels. It is by no means to be recommended. (See FOOT OF THE HORSE.)

Open Joints
(See JOINTS, DISEASES OF.)

Ophidian Paramyxovirus
This affects snakes; in acute infection there are nervous signs, regurgitation of food and respiratory distress. In the chronic form there is weight loss, anorexia, lethargy, dyspnoea and diarrhoea. Some snakes may be symptomless shedders of the virus. Antibiotics may be used where there is secondary infection, otherwise only supportive therapy is required. Any snakes added to a collection should be quarantined and serum tested for antibodies.

Ophthalmia
Ophthalmia means inflammation of the whole of the structures of the eye, but is sometimes restricted to mean keratitis. Contagious ophthalmia is caused by *Rickettsia conjunctivae* in sheep, and by *Moraxella bovis* in cattle. Verminous ophthalmia also occurs in cattle. (See EYE, DISEASES AND INJURIES OF.)

Ophthalmic
Relating to the eye. (See OPHTHALMIA.)

Ophthalmology
The science of the study of the eye and its diseases.

Ophthalmoscope
Ophthalmoscope is an instrument used for the examination of the back of the eye.

Ophthalmoscopy
Examination of the internal structures of the eye. The use of an ophthalmoscope.

Opiates
Sedative narcotics containing opium or its derivatives. They are mainly used to induce sleep or suppress a cough.

Opioids
Any synthetic narcotic with opiate-like activities but which is not derived from opium. Examples are BUTORPHANOL, FENTANYL and PETHIDINE. The term also refers to endogenous naturally occurring peptides such as enkephalins and ENDORPHINS that produce opiate-like effects by interacting with opiate receptors of cell membranes.

Opisthotonos
Opisthotonos is the position assumed by the backbone during one of the convulsive seizures of tetanus, and also sometimes seen during epileptiform convulsions and strychnine poisoning. The spinal column is markedly arched with the concavity facing upwards away from the lower parts of the body, so that the head is drawn backwards, and the tail and hind-parts of the body pulled forwards. The condition is due to the spasmodic contraction of the powerful muscles lying above the vertebral column.

Opium
Opium is the dried milky juice of the unripe seed-capsules of the white Indian poppy, *Papaver somniferum*. Good opium should contain about 10 per cent of morphine, the chief alkaloid and active principle. It also contains other alkaloids, the most important of which are codeine, narcotine, thebaine, papaverine, apomorphine.

The preparations of opium used in veterinary medicine are now virtually nil, but have included

VetBooks.ir

the following: (1) Powdered opium, which is the dried juice powdered, contains about 9.5 to 10.5 per cent morphine. (2) Tincture of opium, or laudanum, consists of the powder treated with distilled water and alcohol, and contains about 1 per cent of morphine. (3) Opium extracts, one dry of 20 per cent morphine, and one liquid of 3 per cent morphine, as well as a fluid extract which contains about 5 per cent morphine. (4) Compound tincture of camphor, or paregoric. (5) Compound ipecacuanha powder, or Dover's powder, contains 10 per cent of opium. (6) Gall and opium ointment, containing 7.5 per cent of opium, is used as an astringent ointment. (7) Compound tincture of morphine and chloroform which contained morphine, chloroform, dilute prussic acid, as well as Indian hemp and capsicum, is similar to the proprietary mixtures which were called chlorodyne and are no longer available. Morphine, codeine, apomorphine, heroin and dionin are also preparations from or derivatives of opium. (See MORPHINE.)

Opportunist, Opportunistic

A term used to describe organisms which normally do not harm an animal or its organs or tissues. However if there is damage or injury to the animal, usually as a result of a PRIMARY INFECTION or a SECONDARY INFECTION, they can then cause further damage or illness in that animal.

O

Opsonins

Substances present in blood serum which facilitate the engulfment of bacteria (and other foreign proteins) by certain white cells. (See PHAGOCYTOSIS.)

Optical Implants

Used to treat some conditions in companion animals.

Optic Disc

The area of the FUNDUS of the eye where the OPTIC NERVE gains access to the RETINA.

Optic Nerve

Optic nerve is the 2nd cranial nerve running from the eye to the base of the brain. It conveys the sensations of light that are received by the retina, and registers them in the optic centres of the brain. (See EYE, VISION.)

Optic Nerve Hypoplasia

A congenital condition seen as an abnormally small optic nerve head associated with abnormal vision and usually blindness; it can affect one or both eyes. The condition may be inherited. It is seen in the miniature POODLE and miniature long-haired DACHSHUNDS.

Oral

(adverb, Orally)

Relating to the mouth.

Orbifloxacin

A quinolone antibiotic. (See QUINOLONES.)

Orbit

The eye socket — the hollow area in the front of the skull that houses the eyeball.

Orbital Gland

(See HARDERIAN GLAND and EYE, DISEASES AND INJURIES OF.)

Orbiviruses

These cause African horse sickness, bluetongue, and a haemorrhagic disease of deer.

Orchards

Animals grazing in orchards may run the risk of poisoning if fruit-trees have recently been sprayed with insecticides or fungicides. Orchards, like paddocks, sometimes become a reservoir of parasitic worm larvae. (See PADDOCKS; also ALCOHOL POISONING.)

Orchitis

Inflammation of the TESTICLE.

Oregano

A plant *Oreganum vulgare*, a species of the mint family. It contains many chemical constituents and can be used as an ANTISEPTIC, and it includes ANTIOXIDANTS such as phenolic acids and flavonoids. Feeding poultry with oregano oil reduces or stops the need for antibiotics, and has also been used in pigs.

Oregon Muscle Disease

A condition in turkeys and chickens in which the inner breast (deep pectoral) muscles become necrotic and greenish. The cause is possibly an inherited abnormality affecting the blood vessels.

Orexin

Also known as HYPOCRETIN, this is a neurotransmitter regulating appetite, wakefulness and arousal.

Orf

A disease of sheep, camelids and goats which has a very wide distribution and many names. Among its numerous designations are the following: 'ulcerative stomatitis', 'contagious pustular dermatitis'; 'contagious ecthyma'; 'necrobacillosis of sheep'.

Orf is enzootic in the Border counties of England and Scotland, but outbreaks may arise in

any county in Britain, as well as in Germany, France, Austria, the USA, and other sheep countries.

The disease attacks sheep of all ages, sexes, and breeds, and kept under all conditions of management. It frequently attacks lambs just before or after weaning, or after docking or castration, and from them it may spread to the teats of the ewes. In other cases it is common among gimmers until they are a year old.

Causes Essentially, a parapoxvirus; but secondarily *Fusobacterium necrophorum* (*Fusiformis necrophorus*). The virus is needed to produce pox-like lesions first, which the bacterium then invades.

Signs In the milder form of the disease, vesicles, followed by ulcers, appear on the lips – especially at the corners of the mouth. Sometimes healing takes place uneventfully; in other cases verrucose masses form and persist. The animal loses weight.

In the severe form the inside of the mouth becomes involved in most cases, and in addition other parts of the body such as the vulva and the skin of the face, legs, tail, etc. A greyish-black crust often appears which, if removed, leaves a raw, angry-looking surface.

Sheep with lesions on the head frequently rub their muzzles on their fore-feet, or scratch at their heads with their hind-feet. In this way the feet and legs often become affected. Abscesses may form in the region of the coronet. The sheep becomes extremely lame, so much so that it is frequently unable to put the affected leg to the ground, and hobbles about on three legs. If both fore-feet are affected – which is commonly the case – the animal may be observed feeding from a kneeling position. In severe cases the horn separates from the sensitive structures below, large quantities of foul-smelling thick pus are produced, and the hoof may be shed. The space between the claws, and the parts around the front and sides of the coronets, are the commonest situations of the lesions.

Less commonly the external genitals of both male and female are affected. (See also PENIS AND PREPUCE, ABNORMALITIES AND LESIONS - BALANOPOSTHITIS.)

Treatment As soon as a case of orf appears among a flock of sheep, it should be isolated at once. Isolated sheep that are already affected usually do best when they can be shut up indoors, given hand-feeding, and provided with clean dry litter. A dressing is applied over the raw ulcerated area and around its margin. Crystal violet is very suitable as a dressing, and antibiotics are useful in treatment. Cryosurgery may be helpful.

On farms previously heavily infected, and where orf was very common on the feet, passing the whole of the sheep through a foot-bath at three-weekly intervals has resulted in a complete disappearance of the disease. (See FOOT-BATHS FOR SHEEP.)

Orf is well recognised as an occupational hazard of shepherds, causing a pustular dermatitis of the hands and forearms. There can also be systemic signs.

Control A modified live vaccine is available; it is applied by scarifications. The resulting scabs can be a source of infection when they detach.

Orf in the dog Outbreaks of orf in hounds and sheepdogs are not unknown. They are characterised by circular areas of acute inflammation, with a moist appearance, ulceration and scab formation.

Public health Infections can occur from contact with sheep. It also occurs in abattoir workers, butchers, veterinary surgeons and veterinary students. In one five-year period there were 344 laboratory reports of patients with orf.

Severe mouth lesions have been successfully treated by DIATHERMY and CRYOSURGERY.

Organ

An organ is a collection of tissues forming a functional mass, e.g. liver, kidney, etc.

Organelles

Specialised structures within a CELL.

Organic

There are several definitions:

1. It is associated with an organ or organs or derived from an organism.
2. In chemistry it involves carbon containing substances.
3. It is also related to substances derived from living organisms.

Organic Diseases

Organic diseases, as distinct from 'functional diseases', are those in which some actual alteration in structure takes place, as the direct result of which faulty action of the organ or tissue concerned follows.

Organic Farming

A method of farming whose rules are set out in European legislation. It uses a holistic approach to farming and animals reared must be fed organically produced feeds. It aims to work with the environment. Stocking densities are kept low and use is made of as much home-produced feed as possible. Medicine usage is limited and usually involves increased withdrawal times. Often homeopathic methods of control and treatment are favoured. Application is required for permission before certain medicines are used.

VetBooks.ir

Organochlorine Poisoning
(See CHLORINATED HYDROCARBONS.)

Organophosphorus Compounds
These are used as insecticides and acaricides. Diazinon is an example; this can be used in sheep dips (appropriate precautions must be taken). There are topical applications for treating ectoparasites in dogs and cats.

Organophosphorus Poisoning
This may arise from contamination of crops, or other food material, with organophosphorus insecticides such as dimethoate, schradan, parathion or dimefox, or by skin contact or inhalation.

Signs are varied but include salivation, muscle tremors, slow heartbeat, constricted pupils, swaying gait, and recumbency.

For a case of laryngeal paralysis arising from organophosphorus poisoning of racehorses, see under LARYNX, DISEASES OF.

Treatment Atropine sulphate given intravenously or intramuscularly, and repeated in 30 minutes. Barbiturates may be needed to control excitement. Oxygen for distressed breathing, and gastric lavage are recommended in the human subject.

Protective clothing must be worn when dipping sheep in organophosphorus dips; only properly trained operatives may use sheep dips (see DIPS AND DIPPING).

O

Organ Transplantation
A common procedure in humans now involving transfer of many different organs, and usually first having been attempted in animals to determine techniques and post operative treatment. In dogs, it has been used to replace the kidney and heart.

Orifice
An entrance, hole or opening into a body cavity or organ.

Orifices, Immunity at
Defence mechanisms, directed against the invasion of pathogenic bacteria, exist in the natural orifices of the body. For example, research at IRAD, Compton, led to the isolation of a number of cationic proteins from the keratin of the teat-canal's lining, and these have been shown to inhibit the growth of mastitis strains of staphylococci and streptococci. These proteins, which are soluble in distilled water and carry a positive electrical charge, were shown to inhibit the growth of two strains of *Staphylococcus aureus* and one strain of *Streptococcus agalactiae*. The proteins in very low concentration caused a 50 per cent mortality in test bacterial cultures.

The secretions of the uterine cervix of the cow during oestrus also contain cationic proteins which possess antibacterial activity against staphylococci. In the laboratory these proteins were shown also to inhibit growth of *Brucella abortus*.

The anionic proteins from the cervical mucus, however, showed no inhibitory action on the bacteria. This difference 'suggested that the killing of the bacteria was preceded by an electrovalent binding of the positively charged cationic protein on to the negatively charged surface of the bacteria', and this has proved to be the case.

Antibacterial cationic proteins have also been isolated from cells normally present in cow's milk, and research has shown that synthesis of these proteins can be stimulated. Induction of a mild sterile mastitis by the injection of *E. coli* ENDOTOXIN through the teat-canal led to increased numbers of NEUTROPHILS in the milk from which was extracted cationic proteins with a higher antibacterial activity.

Ornamental Fish
Ornamental fish are widely kept in the UK. The species vary considerably and, therefore, so do their environmental requirements. A general rule is that when changing water, not all the old water should be removed; about a third should be left (unless advised otherwise in certain circumstances, such as where a disease is present). There is evidence that fish may secrete, in the mucous covering their skin, substances with antibiotic activity. Beneficial bacteria will also have become established in the water and enough should be left to re-establish numbers in the tank.

Stress is a factor in most diseases of fish. Imported fish can undergo considerable stress during catching and transport before reaching the hobbyist. Ulceration of the skin is not uncommon in goldfish and koi; the bacteria responsible vary. As with farmed fish, protozoal infestations by *Ichthyophthirius* (white spot), *Trichodina*, *Costia*, *Chilodonella*, *Scyphidia*, etc. can occur. Gill flukes may also present a problem: *Saprolegnia* is usually a complicating infection.

When fish are kept in ponds, great care must be taken to prevent spindrift from garden chemicals contaminating the water.

Ornithine
An amino acid, metabolised from arginine, involved in stimulating the release of growth hormone; it is beneficial to the immune system, and in the proper functioning of the liver (including regeneration). (See SOMATOTROPIN.)

Ornithobacterium rhinotracheale
A bacterium that can cause respiratory disease in many bird species, including chickens, turkeys,

VetBooks.ir

ducks, geese, guinea fowl, pheasants, partridges, quail and ostriches. It can infect wild birds including gulls, rooks and wild pigeons, The acute form in young birds causes high mortality by infecting the skull, with or without respiratory signs. In older birds there are respiratory signs with poor growth and downgrading of carcases. Adult laying birds show decreased egg production and quality, with or without respiratory signs. Infection can be transmitted to the next generation via their eggs. On post mortem 'yoghurt-like' exudate is found in the air sacs. Most strains are resistant to commonly used antibiotics. A vaccine is available to control the disease.

Ornithodorus savignyi

(See SAND TAMPAN.)

Ornithosis

The name formerly given to *Chlamydophila psittaci* infection in birds other than those of the parrot family. *C. psittaci* infections in all birds are now designated as psittacosis. (See CHLAMYDOPHILA.)

Oropharynx

The front part of the PHARYNX placed behind the soft palate, tongue and the EPIGLOTTIS.

Orphans

This term is applied to offspring that are abandoned by their dams as well as those whose dams have died. The young of wild animals and birds are often assumed, wrongly, to have been abandoned and well-meaning people interfere unnecessarily. However, in the case of domestic animals, when it is known that the dam cannot suckle or otherwise nurture its offspring, it may be necessary to hand-rear the young. This requires tube- or teat-feeding a milk substitute, specially formulated to suit the species, stimulating urination and defaecation and maintenance of a stable ambient temperature. Weaning and later environment enrichment are also required.

Orpington Chickens

(See BUFF ORPINGTON CHICKENS.)

Ortho-, Orth-

A prefix derived from Greek meaning correct, normal, straight. In chemistry it is used for an ISOMER.

Orthobunyavirus in European Ruminants

(See SCHMALLENBERG VIRUS.)

Orthomyxoviruses

A family of viruses which includes those that cause influenza in humans, mammals and birds. Another one (Isavirus) infects salmon.

Orthopox Viruses

This genus contains those pox viruses genetically and antigenetically related to smallpox virus. (See table under VIRUSES.)

Os

1. The Latin word for a bone. Examples: *Os cordis*, a bone (one of two) present in the hearts of cattle; *Os penis* in the dog.
2. Any body orifice or opening, e.g. the MOUTH for which the adjective is ORAL.

Osaterone

A drug used to control benign prostate hypertrophy in male dogs; when infection is also present it is used in combination with antimicrobials. It should be used with caution in animals with liver disease and is a potent steroid: women of childbearing age must take particular care when handling the product.

Ossification

Ossification means the formation of bone tissue. In early life the bones are represented by cartilage or fibrous tissue, and in these, centres appear in which the cells undergo a change and lime salts are deposited. This process proceeds until the areas or centres meet each other, and the tissue is wholly converted into bone. When a fracture occurs, the bone unites by ossification of the blood-clot which forms between the broken ends of the bone. (See FRACTURES.) In old age, ossification takes place in parts where normally there are cartilages found, such as in the larynx, in the rib-cartilages, in the scapular cartilages, etc., and these parts lose their normal elasticity and become easily broken. (See SIDEBONES.)

Osteitis, Ostitis

Inflammation of bone (see BONE, DISEASES OF).

Osteoarthritis, Osteoarthrosis (OA)

Inflammation/degeneration of the bone at a joint. In human medicine, the name 'osteoarthrosis' is now preferred, emphasising the view that this is a degenerative rather than an inflammatory disease. The primary disturbance is usually regarded as occurring in articular cartilage, and as resulting from a combination of ageing and mechanical factors. An alternative hypothesis is that the disease originates in the synovial lining cells (see ARTHRITIS).

Osteoblasts

Cells which assist in the formation of bone. (See also OSTEOCLASTS.)

Osteochondritis

Inflammation of bone and cartilage. (See HIP DYSPLASIA IN DOGS.) *O. dissecans* is characterised by separation of a piece of articular cartilage which,

VetBooks.ir

together with a small piece of underlying bone, forms a loose body within a joint (see below).

It is common in older animals especially horses and dogs. In horses, intra-articular CORTICOSTEROIDS are used especially TRIAMCINOLONE ACETONIDE in the high motion joints of the carpus, fetlock and distal interphalangeal joints, ideally on one occasion. Although there is no consensus, it is probably best following injection to allow a period of rest and then slowly return to exercise. HYDROTHERAPY and PHYSIOTHERAPY can sometimes beneficial. Once an end-stage joint occurs, which is no longer responsive to non-surgical methods, then surgical procedures are probably necessary, including joint replacement, ARTHROPLASTY and ARTHRODESIS.

Osteochondritis Dissecans (OCD)

Osteochondritis dissecans is part of OSTEOCHONDROSIS. It is a disturbance in the endochondral ossification (conversion of cartilage into bone) affecting the growth plates and the articular cartilage. This results in the splitting of a piece of articular cartilage due to fissure formation in an area of disturbed subarticular cartilage, which produces a flap, or separates completely and becomes a 'joint mouse' in the joint space. It is an inherited trait in some dog breeds but rapid growth in any animal may cause lameness and abnormal gait. There is pain around the affected joints. The condition occurs most commonly on the distal condyles of the long bones (humerus, femur) in dogs and pigs. Thus the stifle and hock may be more severely affected as they bear greater weight. Rest, and perhaps surgery, may be required. It is seen in many dog breeds including terriers with short legs, BORDER COLLIES, GREAT DANES, NEWFOUNDLANDS, OLD ENGLISH SHEEPDOGS, PEKINGESES, POODLES, PYRENEAN MOUNTAIN DOGS, ROTTWEILERS.

Osteochondritis Juvenalis

LEGG-CALVÉ-PERTHES DISEASE

Osteochondrosis

This is a developmental abnormality affecting cartilage differentiation similar in some respects to OSTEOCHONDRITIS, and may be a more accurate description in cases where there is no inflammatory response to the changes in bone and cartilage. If it results in a flap of articular cartilage it is called OSTEOCHONDRITIS DISSECANS (OCD). There may be necrosis of bone and separation of splinters or flaps of articular cartilage. A hereditary basis for the condition has been recorded in man, horse, dog (see BERNESE MOUNTAIN DOGS, BULL MASTIFFS, GERMAN SHEPHERD DOGS, GOLDEN RETRIEVERS, IRISH WOLFHOUNDS, LABRADOR RETRIEVERS) and pig. In pigs, in the past, as many as 80 per cent might show lesions at slaughter. Pigs fed diets enriched with the amino acids methionine and threonine, or with praline, glycine, copper and manganese, show a lower incidence.

In young horses, the most frequently diagnosed conditions are *O. dissecans* and a subchondral bone cyst. These are two separate entities, though often bracketed together under the osteochondrosis syndrome. Severe lameness may be caused by the former, and surgical treatment needed.

Osteochondrosis is seen more frequently in mares given concentrates during pregnancy, and foals kept exclusively at pasture had fewer problems.

Osteoclasts

Cells which aid the breakdown or resorption of excess bony tissue, laid down following fractures, as part of the repair process. (See also OSTEOBLASTS.)

Osteoderm

A protective bony plate in the dermis of lizards to which a large scale in the epidermis is attached. (See also GASTROPEGE.)

Osteodystrophia Fibrosa

A degenerative condition of bone resulting from over-activity of the parathyroid gland. Affected animals show lameness, pain, incoordination, paralysis, curvature of the spine, fractures and constipation. Diagnosis is confirmed by X-ray. Treatment is by giving mineral supplements; steroids and sex hormones have also been used.

The nutritional secondary form of the disease is seen in horses (called BRAN DISEASE), goats, pigs, dogs and cats but rarely cattle. It can occur in horses with chronic OXALATE poisoning. The renal secondary form mainly occurs in dogs and some cats with secondary HYPERPARATHYROIDISM and retention of PHOSPHATES.

Osteodystrophic Diseases

Osteodystrophic diseases are conditions in which the metabolism of the bone is upset. This may be caused by mineral deficiencies or imbalances in the diet or pasture.

Osteogenesis Imperfecta (OI)

A failure of bone to develop properly in young animals, giving rise to 'brittle bones'. Animals show incoordination, and pain at the joints; they may be prone to greenstick or complete fractures. Rest is necessary; anti-inflammatory medication will relieve the pain. Calves and lambs with the condition may be unable to rise. The problem is caused by a defect in the bone matrix formation due to a deficiency in procollagen-N-peptidase. It is seen in some breeds more commonly including BEDLINGTON TERRIERS, ELKHOUNDS. Genotyping is possible.

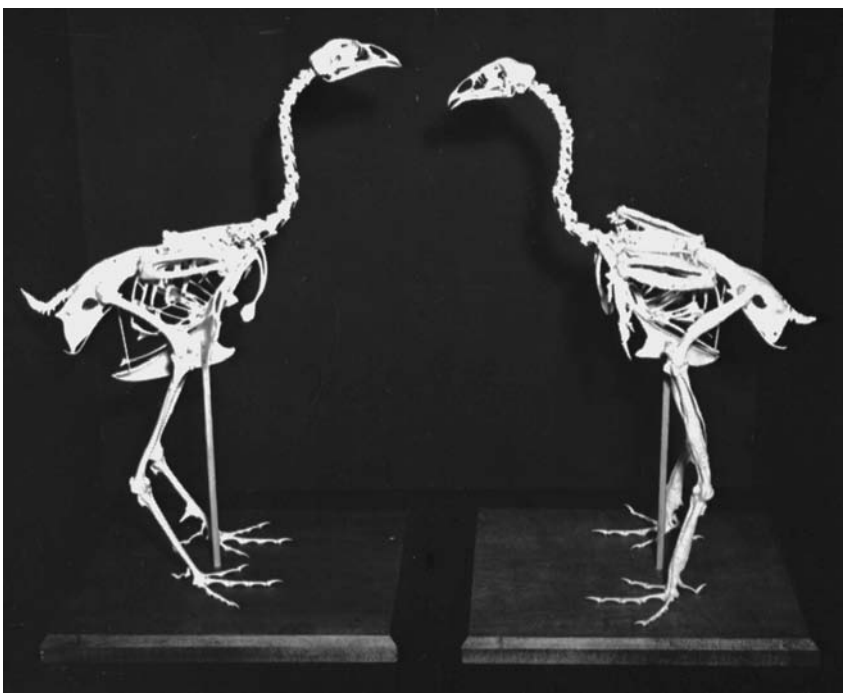
Osteolysis
The destruction of bone; it is seen as dark (radiopaque) shadows on radiographs. It particularly refers to a loss of calcium.

Osteomalacia
Osteomalacia is the equivalent of rickets occurring in the adult animal. The bones become softened as the result of the loss by absorption of the salts they contain. The cause of the disease is obscure, but it appears to be more common in pregnant females than in other animals, and it may be associated with a deficiency of vitamin D and/or phosphates. (See VITAMINS.)

The most serious feature is the deformity which occurs in the softened bones, owing either to the weight of the body or to the pull of the muscles upon them. When the deformity is located in the pelvis of the dam, great difficulty is often experienced at the birth of the young animal, and fractures of this part are not unknown.

Treatment Vitamin D and good nourishing food with an adequate phosphate content.

Osteomyelitis
Inflammation and infection of the bone marrow. It is sometimes a complication of atrophic rhinitis of pigs and of ACTINOMYCOSIS of cattle. (See BONE, DISEASES OF; MYELITIS.)



Osteopenia
A reduction in the body's bone tissue.

Osteopetrosis, 'Marble Bone' Disease
Osteopetrosis ('marble bone' disease) is characterised clinically by thickening of the legs of poultry (see illustration, below). On post-mortem examination, involvement of other bones is seen. The cause is a virus of the avian leukosis group.

Osteophagia
Osteophagia means bone-eating, and is a sign shown by sheep and cattle in certain parts of South Africa where soil and herbage are deficient in phosphorus and sometimes in calcium. (See LAMZIEKTE.)

Deer living wild in forests where there is a similar deficiency, as in many parts of the Scottish Highlands, exhibit osteophagia by chewing and actually eating portions of shed antlers. Sheep exhibit similar tendencies in the same areas.

Osteoporosis
Osteoporosis is a rarefying condition of bones which lose much of their mineral matter and

Two chicken skeletons at the Regional Poultry Research Laboratory at East Lansing, Michigan. One (left) is the skeleton of a 216-day-old normal White Leghorn cockerel. The other is the skeleton of a 202-day-old White Leghorn cockerel affected with osteopetrosis, a disease that causes an enlargement and hardening of the bones. (With acknowledgements to USDA, photograph by Madeleine Osborne.)

VetBooks.ir

VetBooks.ir

become fragile. It can occur in young animals through deficiency of protein in the diet, and in older animals through lack of exercise. For example, it is commonly seen in old pet rabbits confined to a hutch. In old animals appropriate sex hormones may be given; in younger ones the diet must be checked. Extra thiamine (vitamin B_1) may be useful. In laying hens additional vitamin K3, sodium fluoride and limestone in particulate form can have beneficial effects. There is a genetic predisposition to osteoporosis in some strains of layers.

Osteosarcoma

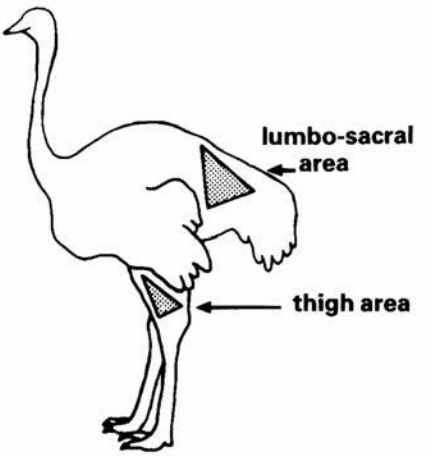
A malignant cancer of the bone. Some large breeds of dog appear to have a predisposition towards the disease.

Ostertagiosis, Ostertagiasis

Infestation with species of *Ostertagia* worms, which produce gastroenteritis. It is seen in calves and lambs. This is an important disease in Ireland. (See WORMS, FARM TREATMENT AGAINST.)

Ostreid Herpesvirus

An infection of high mortality recorded in Pacific oysters (*Crassostrea gigas*) seen in UK, France, Ireland, and the Netherlands, and appears to be a new strain OsHV-1 µvar. It has been added to Aquatic Animals Regulations 2011.



Ostrich, *Struthio Camelus*

Ostriches, once farmed extensively for their tail feathers, are now farmed mainly for their meat, which is low in cholesterol, although – the feathers, leather and eggs are also marketed.

An adult male may be up to 2.75 m (9 ft) tall and weigh 135 kg (300 lb). Ostriches can be dangerous and have been known to disembowel people when angry. That is why two areas of the drawing have been shaded – to indicate sites for the administration of pharmaceutical agents by means of a PROJECTILE SYRINGE.

Ostriches cannot fly, but they can run extremely fast. Unusually for a bird, they produce liquid urine.

Ostriches are included under the Dangerous Wild Animals Act 1976. In the UK, the melon-sized eggs are usually used for hatching only — although they are also edible.

Darting sites suggested for ostriches.

Diseases Among infectious conditions that have been reported are the following:

Newcastle disease in the ostrich usually affects the nervous system. Aspergillosis, zygomycosis and candidiasis are all considered primary pathogens but can all be followed by complicating infections of *Basidia*, *Mucor* and *Rhizopus* fungi. Avian influenza can cause severe mortality, particularly among young birds. Ostriches are susceptible to fowl pox; vaccination is recommended where this disease is prevalent. *Clostridium perfringens* type C can be a problem; vaccination should also cover other types of this organism. *Clostridium chauvoei* has been implicated in a condition resulting in partial paralysis and inability to urinate. Unusually for birds, ostriches are susceptible to anthrax; they can also be infected with avian tuberculosis, *E. coli*, salmonella and klebsiella, among other micro-organisms. Aspergillosis and candidiasis have been reported. *Houttuynia struthionis* is a tapeworm specific to the ostrich, imported into the UK with birds from Namibia. Nematodes specific to the ostrich include the wireworm *Libyostrongylus douglassi*, *Codiostomum struthionis* and *Dicheilonema spirularium*. The ostrich fluke (*Philophthalmus gralli*) is transmitted to ostriches via freshwater crustaceans. Feather lice are usually of the species *Struthioleupiris struthionis* and quill mites of the *Pterolichidiae* may be found. Occasionally ticks (*Ambyloma, Hyalomma* or *Rhipicephalu*s can be present. Borna disease has affected ostriches, causing paresis.

Ostrich Beak

A condition sometimes seen in young turkeys where the beak is flattened and so looks like that of an on ostrich. It is thought that the cause is attempting to reach feed by pushing its beak through wire. Unlike in SHOVEL BEAK, a complicating infection does not occur.

OTC

OVER-THE-COUNTER medicines.

Otic

Relating to or pertaining to the ear. (See AURAL.)

Otitis

Otitis means inflammation of the ear. (See EAR, DISEASES OF.)

VetBooks.ir

Otitis Externa
Inflammation of the external ear. It is seen in many conditions including FOOD ALLERGIES, OTODECTES spp. mite infestation, presence of AWNS/GRASS SEEDS and bacterial infections. (See also EAR, DISEASES OF.)

Otodectes
Mites which cause ear mange in dogs and cats. (See MITES, PARASITIC.)

Otodectes cyanotis A mite commonly found in cat and dog ears. It is a common cause of OTITIS EXTERNA in cats and an uncommon cause in dogs.

Otorrhoea
Otorrhoea means a discharge from the ear. (See EAR, DISEASES OF.)

Otterhound
A large dog with pendulous ears and a long, oily coat. HIP DYSPLASIA occurs and appears to be multifactorial. It is liable to an inherited disorder of the blood platelets, which is thrombopathic and is an autosomal dominant trait. There is a DNA test for GLANZMANN'S THROMBASTHENIA. The breed is on the Kennel Club's Vulnerable Native Breeds List and is one of the most vulnerable.

'Oulou Fato'
A form of rabies occurring among dogs in parts of Africa, and probably Asia also. People are rarely bitten, epidemics are uncommon; infected dogs may show either no, or transient, clinical signs followed by recovery. Repeated attacks prove fatal, however.

Outdoor Pigs
A management system used in Britain mainly for breeding sows and their offspring up until weaning. The system requires light free-draining soils and it allows animals to be kept freely in large groups and is considered welfare friendly. It requires good management, especially when weather conditions are very cold or hot. Wallows are required for hot weather. Very wet or cold conditions can make feeding and watering very difficult. Piglet mortality is usually higher than in indoor systems. Rhizomatous tall fescue on light soils allows reasonable pasture cover.

OV
(See OFFICIAL VETERINARIAN.)

Ovalbumin
This is a protein. It makes up most of the 'white' fraction of the contents of the eggs of birds and reptiles. Ovalbumin contributes nearly two thirds of the protein in the 'white'.

Ovarid
(See MEGESTROL ACETATE; OESTRUS, SUPPRESSION OF.)

Ovariectomy
Surgical operation for removal of a diseased ovary. In some countries it is used by some veterinary surgeons instead of OVARIO-HYSTERECTOMY. Techniques are available for LAPAROSCOPIC removal using a single small incision. (See also SPAYING.)

Ovaries
The female reproductive organs. They are suspended in a fold of peritoneum, called the 'mesovarium' from the roof of the abdomen.

Structure Each ovary is composed of a stroma of dense fibrous tissue in whose spaces are numerous blood vessels, especially towards the centre. On the surface of the organ is a layer of germinal epithelium from which arise the Graafian follicles. These vary very much in size: when young they are microscopic, and lie immediately under the outer surface, but as they grow older they become more and more deeply situated, and finally, as ripening occurs, they once more come to the surface. Growth or ripening of a follicle occurs following stimulation of the ovary by the follicle-stimulating hormone (FSH) from the pituitary gland. The follicle produces, also as the result of FSH, oestrogens which prepare the uterus, Fallopian tubes and vagina for the other processes of reproduction. In a ripening Graafian follicle there is one (rarely two) of the essential female germ cells, called an ovum. This is situated at the pinnacle of a mass of cells which project inwards from the inner surface of the follicle, and which is known as the cumulus.

Function When the follicle is ripe, a process known as ovulation occurs, in which the outer surface wall of the follicle ruptures and liberates the contained ovum, which escapes from the ovary. The ovum is caught by the oviduct, and either fertilised or passed on through the female system to the outside. The cavity of the Graafian follicle fills up afterwards with spindle-shaped cells, under the influence of the luteinising hormone (LH) from the pituitary. LH becomes more plentiful as FSH becomes less so, and the structure is called the CORPUS LUTEUM or yellow body.

If an ovum is fertilised, resulting in pregnancy, the corpus luteum persists and secretes progesterone, a hormone necessary for the maintenance of pregnancy.

If the animal does not become pregnant, the corpus luteum breaks down and disappears. (Occasionally, however, it fails to do so, and may

VetBooks.ir

then cause infertility, especially in the dairy cow.) (See also below for cystic ovaries – leading often to NYMPHOMANIA.) (See also OESTRUS and diagram under UTERUS; VITELLOGENESIS; also under INFERTILITY.)

Mare In the mare they are situated in the abdomen, lying a little below and behind the kidneys, usually in contact with the muscles of the lumbar region. Each possesses a groove which gives the organ a shape not unlike a bean, and which is called the *ovulation fossa*. It is into this groove that the ripe ova escape from the ovary, and it is the only part covered by germinal epithelium in the mare.

Cow In the cow the ovaries are oval in outline and possess no fossa. Each is situated about half-way up the shaft of the ilium of the corresponding side of the body. The ovaries of the sow are usually situated in a position similar to those of the cow, but their position changes somewhat after breeding has occurred. They are studded upon the surface with irregular prominences, so that the organs present a mulberry-like appearance, and are enclosed in a 'purse' of peritoneum.

Dogs and cats In dogs and cats the ovaries are contained in the ovarian BURSA, a pocket-like formation in the mesovarium. In the bitch the ovaries are situated in close proximity to, if not in actual contact with, the kidneys of the respective sides.

Birds In birds, the ovary is a single organ, situated on the left of the COELOM and near the left kidney.

Ovaries, Diseases of

In cystic degeneration, large cavernous cysts appear in the substance of the organ, and fill with fluid. For a time there are no definite signs shown, but after the cysts attain considerable size the animal begins to exhibit signs of fretfulness and excitability. As time goes on these signs increase in intensity until in the mare, in which the condition is quite common, it usually becomes dangerous to work her. Upon the slightest provocation, and often with no provocation at all, the mare starts to kick. After her bout of kicking is over she resumes her normal behaviour, but another attack may come on at any time afterwards.

Cysts are seen in cows where they may be occasionally associated with sterility, and are often the result of inadequate feed, and in bitches where they are frequently present along with tumour formation in the mammary glands. They are recognised as a cause of sterility in gilts – heat periods being irregular and the clitoris becoming enlarged. HYPOPLASIA of the ovaries may also occur.

Cancer occasionally occurs in all species.

Ovarian infections are not common.

(See NYMPHOMANIA; also under INFERTILITY.)

Ovario-Hysterectomy

Surgical operation for removal of the uterus and ovaries. This is carried out in the dog and cat in cases of PYOMETRA, and following dystokia where a recurrence is feared. It is the usual technique for spaying in the UK, especially of cats to prevent the birth of unwanted kittens. (See also SPAYING.)

Overfat Pets

(See also OBESITY; OVERWEIGHT ANIMALS.)

Overgrown Foot

Overgrown Foot is one in which the horn of the wall all the way round has continued to grow downwards and outwards, without any compensatory wear along its lower edge. A horse with overgrown feet which may arise either from overlong periods between successive shoeings, or from living on marshy land where the unshod foot gets no wear, is unable to walk correctly. The frog does not reach the ground, the toe is too long, and the heels are too high, so that the normal anti-concussion mechanism of the foot is thrown out of action. The condition predisposes to the occurrence of sprains and contractions of tendons, upright pasterns, and splitting of the horn, with the production of sandcracks as a consequence. Horses' feet that are shod should have the shoes removed at least once a month, and the growth since the last shoeing should be removed by rasping the lower edge of the wall. Young colts, running out at grass, should have their feet properly reduced at least once every two months or so. Overgrown foot is of importance in cattle and

Overgrown hoof, showing how much should be cut away at the next shoeing.

sheep, and in animals confined in zoos. In order to avoid welfare problems it is essential for livestock's feet to be examined and trimmed as frequently as environmental conditions dictate.

Overlying
Overlying by the sow is one cause of PIGLET MORTALITY and can be prevented by the use of farrowing crates, rails, and the roundhouse. It should be remembered, however, that an ill piglet is more likely to be crushed by the sow than a healthy one; and it has been shown that after one hour in an environmental temperature of 1.6° C to 4.4° C (35° F to 40° F) a piglet becomes comatose. (See under ROUNDHOUSE for an effective means of preventing overlying.) A similar condition can occur in the breeding bitch, which is best whelped in a special box with a rail on each wall just above the floor to allow the pup to crawl underneath away from the bitch's body.

Over-Reaching
A problem seen in horses when the toe of a hind leg strikes the back of the front leg on the same side. The injury caused is called an 'over-reach' or 'strike'. It usually occurs when the animal is travelling at a gallop; it is also seen in trotters and when jumping of rising ground. Special shoes, designed to hasten the breakover of the front feet and delay that of the hind, may prevent the problem.

Oversexed
(See HYPERSEXUALITY.)

Overshot
Protruding; often used of the jaw. (See BRACHYGNATHISM, PARROT MOUTH.)

Overstocking
The term refers to an excess of grazing animals on a given acreage of pasture. (See STOCKING RATES.) It is also used to describe the practice of leaving a cow unmilked in order to increase the size of the udder and impress potential buyers. It causes great distress to the animal and is illegal under the Welfare of Animals in Markets Order 1990. Both the owner of the cow and the operators of the market can be prosecuted if such a cow is exposed for sale.

Over-The-Counter (OTC)
These are medicines that can be bought in shops, not necessarily pharmacists or veterinary practices, without a prescription. Most are sold for human ailments and conditions.

Overweight Animals
In the UK, 25 per cent of dogs and 20 per cent of cats were considered overweight in 2008. By 2010 these numbers had risen to 33 per cent for dogs and 25 per cent for cats. Feeding high calorie diets results in HYPERTROPHY of the heart muscle but may not affect heart function. (See also OBESITY.)

Oviduct
(See FALLOPIAN TUBES; SALPINGITIS; EGG-BOUND; PROLAPSE OF OVIDUCT.)

Ovine
Of, related to or characteristic of sheep (*Ovis aries*).

Ovine Encephalomyelitis
(See LOUPING-ILL.)

Ovine Enzootic Abortion
(See ABORTION, ENZOOTIC, OF EWES AND GOATS.)

Ovine Epididimytis
Ovine epididimytis caused by *Brucella ovis* is a NOTIFIABLE DISEASE throughout the EU. It is of considerable importance in Australia and New Zealand. (See RAM; BRUCELLOSIS.)

Ovine Interdigital Dermatitis (OID)
This has been described in foot-rot free flocks in Australia, and is caused by *Fusiformis necrophorus*. (See also 'SCALD' and 'SCAD'.)

Ovine Keratoconjunctivitis (OKC)
The name for a group of infectious eye diseases of sheep. (See also EYE, DISEASES AND INJURIES OF.)

Ovine White Liver Disease
(See WHITE LIVER DISEASE IN SHEEP.)

Ovotransferrin
The TRANSFERRIN in eggs. It has been used as an aerosol in turkeys to prevent respiratory disease.

Ovulation
In the mare, cow, ewe, sow, and bitch, ovulation has no relation to coitus; whereas in the cat, ferret and rabbit it is coitus that determines the onset of ovulation. (See under OVARIES and OESTRUS.)

Ovum
Ovum is an egg cell. (See EMBRYOLOGY; OVARIES.)

Owls
There are five species in the Order Strigiformes resident in the British Isles and they are NOCTURNAL birds of prey: barn owl (*Tyto alba*), tawny owl (*Strix aluco*), little owl (*Athene noctua*), long-eared owl (*Asio otus*), short-eared owl (*Asio flammeus*). Usually they require veterinary care

following road accidents, other injuries or starvation. Under Wildlife and Countryside Act 1981 (amended by the Countryside and Rights of Way Act 2000) it is illegal to take a bird from the wild and keep it in captivity. It is possible to take as sick or injured bird for treatment, rehabilitation and release or for euthanasia. Infections are uncommon in wild birds but include AVIAN TUBERCULOSIS, owl HERPESVIRUS, TRITRICHOMONIASIS; parasites include flat/louse flies (*Hipposboscidae*); CAPILLARIASIS, COCCIDIOSIS (due to *Caryospora* spp.), and especially in barn owls there is widespread exposure to second generation anticoagulant rodenticides (BRODIFACOUM) after eating poisoned rodents.

Oxalate
A salt of OXALIC ACID.

Oxalate Calculi Calcium oxalate were the second most common bladder stones in UK dogs, with CHIHUAHUA, MINIATURE POODLE and YORKSHIRE TERRIER breeds being overrepresented.

Oxalate Toxicity, Oxalate Poisoning
This is poisoning with oxalic acid salts. Acute cases usually in sheep result from hypocalcaemia with muscular weakness, recumbency and death. Chronic cases result in oxalate crystals being deposited in the kidney tubules and causing NEPHROSIS. Long-term ingestion by horses can cause OSTEODYSTROPHIA FIBROSA. Plants causing it include MESEMBRYANTHEMUM and OXALIS spp.

Oxalic Acid
It is an organic acid and is produced in ASCORBIC ACID metabolism. It is found naturally in some plants as OXALATES and combines with CALCIUM to form CALCIUM OXALATE and thereby can cause HYPOCALCAEMIA.

Oxalis spp.
A plant Genus with 800 species of the Oxalidaceae Family and found in almost all parts of the world. The plants include wood sorrel (*Oxalis acetosella*) and dog's mercury (*Mercurialis perennis*). The plants can cause OXALATE TOXICITY.

Oxantel
A broad-spectrum anthelmintic used in dogs; it is effective against the adult forms of roundworms and tapeworms.

Oxfendazole
An anthelmintic of the benzimidazole group. It is administered in cattle as a pulse-release BOLUS for the treatment of adult and immature gastrointestinal roundworms, lungworms and tapeworms.

Oxford Down Sheep
A breed developed in the 1980s by crossing COTSWOLD and HAMPSHIRE sheep. They have short, large bodies are hornless, with brown face and legs covered in light brown wool. They are used for meat. Rams weigh 90 kg to 140 kg (200 lb to 310 lb) and ewes 70 kg to 95 kg (155 lb to 210 lb) with a fleece of 4 kg to 5 kg (9 lb to 11 lb).

Oxford Sandy-and-Black Pigs
A breed that has at times become more or less extinct. It derives its name from its colouration which allows it to be reared outside without problems of sunburn, and is related to the BERKSHIRE and TAMWORTH breeds. It is docile.

Oxibendazole
An anthelmintic of the benzimidazole group.

Oxiclozanide
Used in the treatment of chronic fascioliosis in cattle and sheep. It is not effective against immature stages of fluke in the liver.

Oxidation of Lipids
In fish diets, oxidation damages CYSTEINE, LYSINE, METHIONINE and TRYPTOPHAN pathways as well as those for vitamins A, D and E.

Oximeter
A sensor used for the non-invasive measurement of the PULSE and the OXYGEN SATURATION of HAEMOGLOBIN. The measurement relies on the light absorption characteristics of saturated HAEMOGLOBIN.

Oxygen
(See OZONE; AIR; RESPIRATION.)

Cylinders of oxygen are essential items of equipment for anaesthesia. They are fitted with a pressure gauge and a reducing valve. A flowmeter is incorporated in the anaesthetic circuit. (See ANAESTHESIA, GENERAL.)

Oxygen is used in the treatment of animals rescued from burning buildings and suffering from the effects of smoke inhalation.

Hyperbaric oxygen is that used at high pressures (e.g. 3 atmospheres) for the treatment of carbon monoxide poisoning; and it has also been used for gas gangrene in a dog.

Oxygen embolism is a potential danger when hydrogen peroxide is syringed into a deep wound.

Oxygen Debt
(See MUSCLE - ACTION OF MUSCLE.)

Oxygen Saturation
The percentage level of oxygen within the HAEMOGLOBIN. This is often referred to as "Sats" and can be measured by an OXIMETER.

Oxymetazoline
(See IMIDAZOLINE COMPOUNDS.)

Oxyntic Cells
These cells are also called fundic cells. They line the FUNDUS of the stomach and secrete gastric acid, intrinsic factor and OXYNTOMODULIN.

Oxyntomodulin
A hormone produced in the epithelial-lining OXYNTIC CELLS of the stomach; they suppress appetite.

Oxytetracycline
An antibiotic. (See TETRACYCLINES.)

Oxytocin
A hormone, secreted by the posterior pituitary gland, and also by the corpus luteum, which actuates the 'milk let-down' mechanism; and also stimulates contraction of the muscles of the uterus in late pregnancy.

Oxytriptan
Commonly known as 5-hydroxytryptophan. (See 5-HYDROXYTRYPTOPHAN.)

Oxyuris
Oxyuris is another name for the thread worm, which possesses a long finely-tapered tail. (See ROUNDWORMS.)

Ozaena
Ozaena is a chronic inflammatory disease of the nasal passages. (See NOSE AND NASAL PASSAGES.)

Ozone
The chemically highly reactive allotropic form of oxygen, (O_3). As a constituent of the upper atmosphere it forms a layer which protects people from excessive exposure to ultraviolet radiation from the sun. Ozone may be the main constituent of smog.

It has been described as the most hazardous of all the gaseous air pollutants because of its long-term association in laboratory animals with emphysema, lung cancer, accelerated ageing, increased neonatal deaths, decreased litter size, teratogenesis, and jaw anomalies. In animals exposed to ozone the mortality from lung infections is increased.

A method of converting oxygen to ozone within the packaging of meat has been developed to extend the shelf-life of such products. It kills bacteria and fungi but is unstable and reverts to oxygen in a few hours.

VetBooks.ir

P

Pacemaker
An electronic device implanted under the skin of the chest which stimulates the heartbeat.

Pacemakers have been successfully implanted into dogs and horses which showed an impaired conduction of the impulse that regulates the heartbeat, so that a lack of coordination between the beating of the atria and that of the ventricles occurs.

Pacheco's Disease
Pacheco's disease is caused by a herpesvirus which is present in South American psittacines (parrots, parakeets). In the wild it does not appear to cause any harm. In aviaries, however, sudden onset of disease and death may occur, with up to 100 per cent mortality. The birds become weak and have diarrhoea. Post-mortem examination shows necrosis of the liver and spleen.

Pachyderm
Large thick-skinned animals with hooves, such as ELEPHANTS, hippopotamuses, and rhinoceroses,

Pachymeningitis
Inflammation of the dura mater of the brain and spinal cord. (See MENINGITIS.)

Pacinian Corpuscles
(See under TOUCH, SKIN.)

Packed Cell Volume
(See under BLOOD – Composition; HAEMATOCRIT VALUE.)

Paddocks
Paddock grazing is a system of pasture management in which animals rotate around different patches of ground. Careful management is needed to avoid a build-up of parasitic worms, particularly where only one species is used to graze them. Ideally paddocks need 'resting' for 12 months, or grazing by a different species of animal, rotationally or using a suitable worming policy.

Pain
(For relief of pain, see ANALGESICS; ANAESTHESIA, GENERAL.) Pain can be defined as ACUTE or CHRONIC. Acute pain is generally associated with tissue damage or the threat of tissue damage. It results in a rapid alteration in behaviour in order to avoid damage or minimise any further damage. It optimises conditions under which healing can occur and stops once healing is complete. Chronic pain is of long standing and continues long after any acute signs and, in humans, it has an effect on the physical wellbeing of the person, as well as having a psychological impacts such as fear, anger, anxiety and depression. This reduces the patient's quality of life. In human and animal illness this affects the HEALTH-RELATED QUALITY OF LIFE. PAIN ASSESSMENT in these situations is difficult.

Animals which are natural hunters (predators) may cry out when suffering pain. Species which are, or were, normally hunted may not do so because it would reveal that they are injured or hiding. Thus, because an animal does not cry out, or show signs of restlessness, it should not be assumed that it is free from pain. The clinical signs of pain can differ from species to species. Pain can be a cause of aggressiveness. The effect of pain can last longer than the pain itself: it has been shown that as long as a month after foot pain has been corrected in cattle, cows still behave as if in pain, as the animal's body has not returned to normal. In sheep, this can last even longer. As a result, bodily condition and milk production may not return to normal until some time after the animal has made an apparent recovery.

Pain Assessment
The assessment of ACUTE pain is generally easy. The use of psychometric methods to measure acute pain in dogs can involve various methods including the GLASGOW COMPOSITE MEASURE PAIN SCALE. Psychometric methods can be used to provide valid, reliable, reproducible and responsive assessment to clinical changes in the underlying condition. This allows assessment and then decision making to be made, dependent on the degree of pain presented by the animal. CHRONIC pain is more difficult to assess. However, in dogs a subjective assessment can be made by the owner using a standard form to measure pain and thereby allow a HEALTH-RELATED QUALITY OF LIFE assessment. This can be used together with an assessment by the veterinary surgeon. Together, they allow the practitioner to manage and treat chronic pain in animals under their care.

Paint
(See HOUSE DECORATING, POISONING; LEAD POISONING, CAGE AND AVIARY BIRDS, DISEASES OF.)

Palatability
(See under DIET AND DIETETICS.)

Palate
The palate is the partition between the cavity of the mouth below, and that of the nose above. It

VetBooks.ir

consists of the hard palate and the soft palate. The hard palate is formed by the bony floor of the nasal cavity covered with dense mucous membrane, which is crossed by transverse ridges in all the domesticated animals. These ridges assist the tongue to carry the food back to the throat. The hard palate stretches back a little beyond the last molar teeth in animals, and ends by becoming continuous with the soft palate. This latter is formed by muscles covered with mucous membrane. The act of swallowing causes the distal soft palate to press against the back of the pharynx and prevent food entering the nose. In the horse, the soft palate acts as a sort of curtain between the cavity of the mouth and that of the pharynx. Material brought up from the stomach must pass out by way of the nostrils. In racehorses, distressed breathing may arise as the result of inflammation or partial paralysis of the soft palate, which may be linked with paresis or paralysis of the vocal cords. Partial resection of the soft palate has been carried out as treatment for this latter condition. (See GUTTURAL POUCH DISEASE.)

Prolonged soft palate is a recognised inherited abnormality of the short-nosed breeds of dogs, e.g. boxers, bulldogs, Pekingese, pugs, cocker spaniels. It makes breathing difficult at times, with snoring or even loss of consciousness resulting. An operation to correct the condition is often very successful.

Severe injury to the hard palate is not uncommonly seen in cats which have fallen from a height, and suturing may be required.

Palatitis
Inflammation of the mucosa covering the hard and/or soft palate.

Palatoschisis
(See CLEFT PALATE.)

Pale Soft Exudative Muscle (PSE)
(See PORCINE STRESS SYNDROME.)

Palliative Medicine, Palliative Treatment
This involves treatment of an animal to alleviate pain or distress but without attempting to treat the condition.

Palm Kernel
A by-product of oil manufacture produced by expelling and/or extraction. Used in ruminants, pigs and poultry. It has high protein (CP 18 per cent), high energy (ME about 12.5 MJ/kg in ruminants; about 14.0 MJ/kg for pigs) and a high fibre level (crude fibre about 17 per cent). High arsenic levels were found in palm kernel expeller imported from Malaysia to the EU for cattle feed in 2011.

Palo Santo Trees
The leaves, fruit, and seeds cause poisoning in cattle in South America. Signs include tympany, depression, and convulsions.

Palpebral
Relating to the eyelids.

Pan-
Pan- is a prefix meaning all or completely.

Pancreas
The pancreas is partly an endocrine gland, producing hormones; and partly an exocrine gland, producing the pancreatic juice for digestive purposes.

The pancreas is situated in the abdomen, a little in front of the level of the kidneys and a little below them. When fresh it has a reddish-cream colour. It can be seen using ULTRASOUND, COMPUTED TOMOGRAPHY, MRI or EXPLORATORY LAPAROTOMY.

The pancreatic juice is secreted into the small intestine to meet the food which has undergone partial digestion in the stomach. The juice contains alkaline salts and at least nine enzymes: e.g. trypsin, which carries on the digestion of proteins already begun in the stomach; amylase, which converts starches into sugars; and lipase, which breaks up fats; as well as a substance that curdles milk. (See DIGESTION, ABSORPTION AND ASSIMILATION - INTESTINAL DIGESTION.)

The pancreas also has groups of cells, the islets of Langerhans. (See INSULIN; DIABETES MELLITUS; GLUCAGON; HORMONES.) Here alpha-cells produce glucagon, and beta-cells, insulin.

Pancreas, Diseases of
These include DIABETES MELLITUS, inflammation, suppuration, atrophy, tumour formation, etc. (See INSULINOMA.)

Acute pancreatitis occurs in obese dogs, more rarely in cats, where it can be associated with CHOLANGITIS. Signs include abdominal tenderness or pain. Hyperglycaemia and shock may follow. Treatment includes withholding food, and intravenous fluid therapy to maintain the balance of fluid and electrolyte.

Exocrine pancreatic insufficiency in dogs has three main causes: congenital hypoplasia, degenerative pancreatic atrophy and chronic pancreatitis. Signs include a ravenous appetite, loss of weight, fatty faeces and a dry scurfy coat. Treatment includes supplementation of the diet with pancreatin as oral powder or granules. Cimetidine may be used in addition in severe cases.

VetBooks.ir

Parasites which may be found in the pancreatic ducts include *Toxocara canis* and, in cats in America, the pancreatic fluke *Eurytrema procyonis*. The latter may interfere with the gland's exocrine function to a great extent. FENBENDAZOLE is effective against the fluke.

Pancreatic Peptide YY3-36
Also known as Peptide YY, Peptide Tyrosine Tyrosine, or PYY. An amino acid produced in the ileum and colon that reduces appetite in response to feeding. A deficiency of this peptide or its lack of secretion has an influence on the development of obesity.

Pancreatin
A preparation of the exocrine part of the pancreas used to treat pancreatic deficiency in dogs and cats.

Pancreatitis
Inflammation of the pancreas. (See PANCREAS, DISEASES OF.)

Pancytopenia
A reduction in the number of red cells, white cells, and platelets in the blood; usually due to a bone-marrow DYSCRASIA. (See BOVINE NEONATAL PANCYTOPENIA; FERRETS.)

Panhypopituitarism
A condition caused by development failure of the pituitary gland, destruction of the pituitary tissue or a cyst or tumour in the gland. In puppies, the milk teeth and puppy coat are retained for longer than normal and the animals are stunted. There may be alopecia with skin pigmentation. The gonads may be abnormally small. Polydipsia and polyuria may develop; affected animals may be aggressive. Treatment will depend on the cause.

Panleucopenia
(See FELINE INFECTIOUS ENTERITIS).

Panniculitis
(See under NODULAR PANNICULITIS.)

Pannus
A chronic condition of the cornea where there is superficial vascularisation and then chronic inflammatory changes resulting in a cloudiness. It is common in certain dog breeds including GERMAN SHEPHERD DOGS. (See EYE, DISEASES AND INJURIES OF.)

Panosteitis
A condition in which an entire bone is inflamed.

Pansteatitis
(See STEATITIS.)

Pantothenic Acid
(See VITAMINS - VITAMIN B.)

Papain
An enzyme extracted from the pawpaw (custard apple) and used to tenderise meat.

Papilla
A small projection.

Papilloma
A wart (see WARTS; also VIRAL INFECTIONS OF COWS' TEATS; TUMOUR). In some animal species a papilloma may, through the action of sunlight, lead to a squamous cell carcinoma.

Papillomatosis
The development of WARTS. In rabbits and parrots these can occur in the oral cavity, as well as the anus in rabbits and the cloaca in parrots. They may be self-limiting or need partial or total surgical excision to stimulate an immune response and thereby instigate resolution. In beef cattle on poor pastures, eating bracken over prolonged periods, warts can become activated into squamous cell carcinomas (see CANCER).

Papilloma Virus Group
Papilloma virus group includes viruses infecting cattle, sheep, goats, horses, dogs, rabbits, etc.

Papillon Dogs
A breed of small dog with ears that, when erect, resemble a butterfly, hence its name. PROGRESSIVE RETINAL ATROPHY may be inherited as a recessive trait and PATELLAR LUXATION occurs. There is a DNA test for VON WILLEBRAND'S DISEASE. (See EYE, DISEASES AND INJURIES OF.)

Papule
A solid elevated lesion of the skin less than 1 cm in diameter, commonly referred to as a pimple. It may have many pathological causes. (See also MACULES.)

Para-
Para- is a prefix meaning near, aside from, or beyond.

Parabronchus
(plural, Parabronchi)
Small tubes which form most of the avian lung. There are many of these and radiating out from their sides are air vesicles called atria, where gas exchange occurs.

Paracentesis
The technique of puncturing a body cavity, e.g. the abdomen, with a hollow needle or by means of a

trocar and cannula in order to extract fluid; or to obtain a tissue sample for biopsy.

Paracetamol, Acetaminophen

An analgesic. It is generally included in the class of NON-STEROIDAL ANTI-INFLAMMATION DRUGS (NSAID), although it does not have anti-inflammatory properties although it is anti-pyretic as well as a painkiller. It should not be given to cats, in which it is toxic. Signs include cyanosis and facial oedema. METHAEMOGLOBIN levels may arise in the blood and it may also occur in the urine. ACETYLCYSTEINE, given orally, is an antidote.

Paraffin

Paraffin is the general term used to designate a series of saturated hydrocarbons. The higher members of the series are solid at ordinary temperatures, some being hard and others soft. Lower in the scale comes petroleum, which is liquid at ordinary temperatures. Naphtha, petroleum spirit, and hydramyl are members of the series lower still, which are very volatile bodies, and finally lowest comes methane or marsh-gas.

As a fuel it can be toxic. Kerosene as a jet fuel leaked out from a cracked underground storage tank at an airport with an estimated 250,000 litres reaching a nearby river. Deaths of aquatic life followed and animals drinking water from the river experienced severe colic. (See KEROSENE POISONING.)

Uses Internally, only medicinal liquid paraffin is used; it is a gentle, lubricant, laxative, but it is liable to become tolerated by the system and lose its effect when given continually as a routine laxative. It should not be given regularly as it prevents the absorption of vitamin D and may cause rickets. Great care should be taken with its administration to large animals as inhalation can prove fatal.

As liquid paraffin is tasteless, it should not be given on its own, and as the animal may resist it being administered, all or some of the dose may enter the RESPIRATORY SYSTEM.

Externally, the hard and soft paraffins are used in the preparation of various ointments and lubricants.

Parafilaria

A genus of filarial worms. *P. bovicola* causes serious skin lesions in cattle in several parts of the world. (See FILARIASIS.)

Paragle Fly

(See under FLIES.)

Paragonimiasis

Infestation with LUNG-FLUKES of *Paragonimus* species in dogs, cats, foxes, mink.

Parainfluenza 3 Virus

Infection with this is widespread in sheep in the UK; the virus is also a cause of CALF PNEUMONIA and of respiratory diseases in the horse. (See EQUINE RESPIRATORY VIRUSES.) Parainfluenza 3 infects the dog, and may be associated with KENNEL COUGH. (See also INFLUENZA.)

Parakeets

A popular group of different cage and aviary bird which are small or medium-sized parrots but larger than budgerigars. Most have long tails. They include rose-winged or ring-necked parakeets (*Psittacula krameri*). Some of these, mainly from South America, are called CONURES. They have escaped from captivity in Britain and there are colonies successfully surviving and breeding in Britain (including London and south east England). (See CAGE AND AVIARY BIRDS, DISEASES OF.)

Parakeratosis

The name applied to a scaly, elephant-like skin. The condition has been seen in pigs suffering from a zinc deficiency. It occurs in pigs fed dry meal *ad lib*, and gradually clears up when a change to wet feeding is made. It often begins with a red pimply condition of the skin on the flanks, abdomen, etc. Thin, dry yellowish or greyish scales may be seen on the skin, which later becomes thickened. It responds to small doses of zinc sulphate. (See CALCIUM SUPPLEMENTS.)

Inherited parakeratosis has been reported in calves of Friesian descent, and although a zinc supplement proved successful in treating the encrusted skin of head, neck and limbs, the lesions returned after cessation of the supplement.

Paraldehyde

A narcotic. It is used in some slug pellets and poisoning in domestic pets can follow ingestion.

Paralysis

Paralysis, in its widest sense, may mean loss of nerve control over any of the bodily functions, loss of sensation and loss of the special senses, but the term is usually restricted to mean loss of muscular action due to interference with the nervous system. When muscular power is merely weakened, without being lost completely, the word 'paresis' is often used.

Various terms are used to indicate paralysis distributed in different ways. (See HEMIPLEGIA; PARAPLEGIA; QUADRIPLEGIA.)

Paralysis should be regarded as a sign rather than as a disease by itself.

Varieties of paralysis *Cerebral paralysis*: conditions resulting from brain lesions, such as

VetBooks.ir

encephalitis, tumour formation, fracture of the skull with depression of a portion of bone, haemorrhage, etc., are accompanied by severe general or local paralysis, either of the whole body (when death usually follows very rapidly), or of one side (hemiplegia).

Paralysed limbs when examined are found to be flaccid, with the muscles totally relaxed, and passive movements are not resisted. Sensations of pain may be felt, however, and an indication that sensation is not destroyed is shown by raising the head, or struggling with the sound limbs when a pinprick is made in a paralysed part.

In cases of cerebral haemorrhage, the seizure is sudden; in encephalitis there is usually some co-existing disease, such as influenza or distemper, and the brain signs develop as a complication – or the encephalitis may be the result of a primary viral infection, such as equine encephalitis or rabies. With fracture and depression there is an immediate loss of power, just as when an animal is stunned.

Spinal paralysis or paraplegia is most often due to fracture of, or severe injury to, the vertebrae. (See PARAPLEGIA.)

In *complete paralysis* death usually takes place within 12 to 48 hours after the injury. (See SPINE AND SPINAL CORD, DISEASES AND INJURIES OF; and, for horses, EQUINE VIRAL RHINOPNEUMONITIS.)

Peripheral paralysis: there is usually some injury to a nerve trunk, or lesion of the nerve-endings in the muscle fibres. (See SUPRASCAPULAR PARALYSIS; RADIAL PARALYSIS.)

Brachial paralysis results from road accidents, collisions, or stake wounds. Gluteal paralysis is very uncommon: wasting of the muscles of one hindquarter and a tendency to carry the limb out to one side occur. 'Paralysis of the sciatic nerve' causes a loss of power in all the muscles of the thigh except those situated above and to the front of the stifle joint, i.e. the quadratus group. The limb hangs loosely and the animal jerks it forward when attempting to walk; although the stifle is advanced, the hock and the fetlock remain flexed and the front of the foot comes to the ground.

When there is severe injury to the side of the thigh from a fall, kick, or other similar cause, paralysis of the external popliteal nerve (common peroneal) may occur, resulting in an inability to extend the foot or flex the hock. When the horse is made to walk, the limb is drawn out backwards into a position resembling that seen in dislocation of the stifle, but the fetlock is flexed instead of being fully extended. The limb is then carried a short distance forward and the foot comes to rest upon the ground on its anterior face instead of on the sole. In 'crural paralysis' (paralysis of the femoral nerve) the quadriceps muscles above the stifle, which normally extend that joint, are paralysed. When weight is put upon the limb the stifle sinks to the level of the hock or below it, all joints are flexed, and there is a peculiar drop of the hindquarter on the same side. (See also PARAPLEGIA.)

Paralysis in the dog (See also DISTEMPER; BOTULISM; THROMBOSIS; SPINE AND SPINAL CORD, DISEASES AND INJURIES OF; TICK PARALYSIS; LEAD POISONING; RABIES; RACCOONS; ORGANOPHOSPHORUS POISONING.)

Aid A wheeled trolley which supports the hindquarters can be an alternative to euthanasia for some paraplegic dogs.

Paralytic Myoglobinuria

(See MUSCLES, DISEASES OF - NUTRITIONAL MUSCULAR DYSTROPHY.)

Paraminobenzoic Acid

A growth factor produced in bacteria which is blocked by certain antibacterials, such as sulphonamides.

Paramphistomes

Members of the family *Paramphistomatidae* (RUMEN FLUKES) especially in cattle, buffaloes, goats and sheep.

Paramphistomiosis, Paramphistomiasis

A disease caused by RUMEN FLUKES of the genus *Paramphistomum*.

Paramyxoviruses

An important group of disease-causing viruses. Parainfluenzavirus, morbillivirus and pneumovirus are the three genera of paramyxovirus. (See Paramyxovirus parainfluenza 3 virus in the table under EQUINE RESPIRATORY VIRUSES). Two paramyxoviruses infecting dogs are the canine distemper virus (a mobillivirus), and canine parainfluenza virus/SV5. (See also PIGEONS and NEWCASTLE DISEASE.)

Paraphimosis

The inability to withdraw the penis into the prepuce. It can be constriction of the opening of the prepuce trapping the erect penis and preventing blood drainage from it so that the organ remains distended and erect. In long-haired animals it may be due to hair encircling the exposed organ. This is not uncommon in the dog, and is serious, for gangrene may occur unless relief is afforded. As a first-aid measure, immerse or swab the penis with ice-cold water. Surgical interference under

anaesthesia may be necessary. The use of hyaluronidase in normal saline, by injection, has been recommended.

For paraphimosis in horses and cattle see under PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.

Paraplegia

PARALYSIS of the hind-legs. It may be accompanied by paralysis of the muscles which control the passage of urine and faeces to the outside. It is seen following accidents involving injury to the spine – frequently in the dog knocked down by a car – and may also be associated with spinal 'disc' lesions. A rare cause is thrombosis of the femoral arteries. In the dog, this may occur suddenly – the animal playing one minute, and collapsing with a yelp the next. Absence of pulse in the femoral arteries assists a diagnosis. (See also under THROMBOSIS; COMENY'S INFECTIOUS PARALYSIS OF HORSES.)

Parapox Viruses

Synonym: PARAVACCINIA VIRUS. (See also MILKER'S NODULE.)

Apart from those affecting domestic animals (see table under VIRUSES), a parapox virus carried by grey squirrels, but apparently harmless to them, has had a devastating effect on the native red squirrel. A parapox virus is also thought to be the cause of high mortality in British frogs in certain parts of Britain. Inactivated parapox ovis virus is used as an IMMUNOSTIMULATOR for the horse's immune system to reduce the effects of infectious respiratory disease.

Paraquat

This herbicide has caused fatal poisoning in man, usually through accidental ingestion of the undiluted concentrate; an emetic is now included. Poisoning in the dog gives rise to lung OEDEMA, CONGESTION and CONSOLIDATION; also kidney damage. Three cases, and the outcomes, are reported below.

Paraquat has been detected in the urine of some dogs showing acute respiratory distress, led to CYANOSIS after four days' illness. Some dogs die, and euthanasia may have to be undertaken. Signs have been seen in dogs and cats that eat grass especially from a lawn in which the weedy areas had been treated with diluted or undiluted (20 per cent paraquat) Gramoxone. In such animals vomiting is a sign, as well as distressed breathing.

Cyanocobalamin has been suggested as an antidote for small animals, though it is generally held that there is no effective antidote. However, complete recovery was achieved for a dog taken to the University of Dublin's veterinary clinic, with a history of weakness, and rapid breathing over the previous six hours.

The animal's condition deteriorated, despite intensive treatment. Nursed at home, the patient was seen at the clinic daily. On the 15th day came improvement: although the dog was still breathing through its mouth, respirations were down to 120 per minute. It was seven weeks before they had come down to 60.

The patience and perseverance of both owner and clinic staff were rewarded, for when seen again 6 and then 18 months later, the dog was well and fully active again.

Parasites

Parasites and Immunity

Parasite antigens are a potent stimulus for antiparasite antibodies of the IgE class (see IMMUNOGLOBULINS), and parasite infection can potentiate a pre-existing IgE response to an unrelated antigen.

Examples of the effect of parasitism on the immune response are given under CANCER and ALLERGY.

Parasitic Bronchitis

This is caused in cattle, deer, horses, sheep and goats by different species of parasitic worms; on account of the husky cough produced, the disease is commonly called 'HUSK' or 'HOOSE' in the UK.

Although of greater economic importance in calves, nevertheless the cost of an outbreak in a dairy herd may be very high – not so much as a result of deaths (which do occur in adult cattle) but on account of reduced milk yields and the need for extra feed. Marshy land and mild, wet weather both favour the parasites, as does overstocking.

Cause In cattle the lungworm *Dictyocaulus viviparus* is the important species (see ROUNDWORMS; also illustrations on page 641). Parasitic bronchitis normally affects cattle in their first grazing season. Affected animals experience a drop in the saturation level of oxygen in their blood to 70 per cent even before clinical signs become apparent. In clinical cases the percentage may be reduced to 30.

Workers at Glasgow University defined infection with the parasite into five phases: penetration, pre-patent, patent, post-patent, and reinfection. In all but the first phase, oedema and emphysema are found. Survival time of the worm larvae on pasture is unknown but their spread is assisted by their rocket-like propulsion by the fungus *Pilobolus*, which is found in faecal deposits on pasture. The worm larvae are projected along with the fungal spores, often between 10.00 and mid-day.

VetBooks.ir

Signs The characteristic husky cough is a sign in the milder cases, but in acute cases may be absent, with the main sign being dyspnoea (laboured breathing). In calves, death may occur from actual suffocation due to masses of worms obstructing the air passages, or it may result from general debility or pneumonia. In adult cattle pneumonia develops, with *Actinomyces pyogenes* acting as a secondary invader. Oedema of the lungs may occur, and cause death.

Prevention and treatment Live oral vaccines are available and are the best method of control. A number of ANTHELMINTICS, including albendazole, ivermectin and fenbendazole, may be used to treat infected cattle. Some anthelmintics are available in bolus form. If the animal is exposed to infection while the anthelmintic bolus is active, the animal will develop immunity without showing signs of the disease. (See under WORMS, FARM TREATMENT AGAINST.)

VetBooks.ir

Adult worms in the air passages of a calf's lungs. In a heavily infected animal several thousand lungworms may be present.

In a case of parasitic bronchitis, the neck is held extended and there may be continual coughing and/or distressed breathing.

Horses The cause is *Dictyocaulus arnfieldi*, with donkeys acting as symptomless carriers. Treatment is with anthelmintics but there is no vaccine for control. (See AELUROSTRONGYLOSIS; AELUROSTRONGYLUS.)

Parasitic Disease, Nature of

Parasitic diseases are caused by organisms that live within an animal (endoparasites) or on its surface (ectoparasites). Endoparasites include worms and flukes; ectoparasites include fleas, mites and ticks. Disease is seldom caused by one or a few parasitic organisms, but as a rule depends on mass infestations. There are exceptions to this, however, as a single *Ascaris* may obstruct the bile-duct with fatal results. Parasites, with few exceptions, do not spend all their lives in the animal body, but always need to spend a certain proportion of their life-cycle outside the host. They may cause damage to the host in the following ways:

1. By abstraction of nourishment properly belonging to the host, e.g. many of the intestinal worms;
2. By mechanical obstruction of passages or compression of organs, e.g. gapes (in chickens) and hydatid;
3. By feeding on the tissues of the host, e.g. blood-sucking worms or flies;
4. By production of toxins with varying effects;
5. By actual traumatic damage, e.g. by piercing and destroying skin (ticks, mites, flies, etc.), by depositing eggs in the tissues (lungworms), by migrations of larvae (*Ascaris* and *Trichinella*), by clinging to surfaces by means of sharp hooks (tapeworms), and in many other ways;
6. By facilitating the entrance of bacteria, e.g. stomach worms in pigs allow the entrance of *Fusiformis necrophorus* (the necrosis bacillus);
7. By transmitting diseases for which they act as intermediate hosts, e.g. ticks and babesiosis;
8. By causing inflammatory or neoplastic reactions in the invaded tissues, e.g. pneumonia, gastritis, and fluke adenomata in the liver.

These are only some of the more obvious methods of injuring the host. Apart from the loss due to actual deaths, the depreciation in value of hides, meat, milk, and work is enormous, and, although less spectacular than a bacterial epizootic, the loss is more constant, and in the aggregate is probably even greater than the loss due to bacterial diseases. (See BRAIN DISEASES Parasites, for parasites which migrate to the brain.)

VetBooks.ir

Parasitic Gastroenteritis of Cattle

This is an insidious and economically important disease, and the cause of death in many calves and yearlings. It is known that the output of worm eggs in the faeces does not bear any constant relation to the number of worms present. It rises to an early peak and then declines, and is not a reliable guide to the degree of infestation.

Cause Infestation with various species of ROUNDWORMS.

Signs A gradual loss of condition, usually gradual but occasionally rapid; a harsh, staring coat; usually, but not always, there is moderate to severe scouring; pale mucous membranes; progressive weakness and emaciation. In adult cattle, which acquire a high degree of resistance (only broken down when under-feeding, chilling, pregnancy, or massive contamination of pasture occurs), no signs may normally be shown, but nevertheless the animal's efficiency is lowered.

Treatment Dosing with an appropriate anthelmintic should not be delayed until the stock are weak.

Prevention Calves should be dosed once with an anthelmintic in mid-July and moved to pasture which has not been grazed that season by other cattle. Dose again in the autumn. (See WORMS, FARM TREATMENT AGAINST; PASTURE, 'CLEAN'.)

Parasitic Gastroenteritis of Goats

The worms in goats and sheep are mainly similar. However, goats evolved as browsing animals, not grazers, and do not have innate resistance to nematode worms. Thus, if intensively grazed and wormed frequently anthelmintic resistance can develop. They should only be wormed if there are clinical signs or faecal egg counts indicate infection.

Parasitic Gastroenteritis of Sheep

It is likely that outbreaks in early lambs in March and April are the result of over-wintered larvae. In one experiment, worm-free lambs were turned on to a pasture – 'rested' during the winter – in the spring and became infested with 12 species of gastrointestinal worms.

Lambs may also be infected by eggs in the dung of ewes at lambing, when a periparturient rise occurs.

Treatment and prevention Routine use of e.g. Tetramisole. (See WORMS, FARM TREATMENT AGAINST; PASTURE, 'CLEAN'.)

Parasitic Tracheobronchitis

(See TRACHEAL WORMS.)

Parasitism

Parasitism is the association of two organisms, one of which (the parasite) benefits by nourishing itself at the expense of the other (the host) but without normally destroying it.

The following types of parasitic relations are recognised: 1 (a) ectoparasites, which live on the host; and (b) endoparasites, which live within the body of the host; 2 (a) accidental parasites, which are normally free-living animals but may live for a certain period in a host; (b) facultative parasites, which are able to exist free or as parasites, e.g. blowfly larvae; and (c) obligatory parasites, which are completely adapted to a parasitic type of life and must live in or on a host, e.g. most parasitic worms; 3 (a) temporary or transitory parasites, which pass a definite phase or phases in their life-history as parasites and during which time the parasitism is obligatory and continuous, e.g. botflies, ticks; (b) permanent parasites, which always live for the greater part of their life as parasites, e.g. lice, tapeworms, coccidia, etc.; and (c) periodic, occasional, or intermittent parasites, which only visit the host for short periods to obtain food, e.g. blood-sucking flies, fleas; 4 (a) erratic parasites, which occur in an organ that is not their normal habitat, e.g. *Fasciola hepatica* in the lungs; (b) incidental parasites, which, exceptionally, occur in an animal that is not their normal host; they are incidental only in this first host, e.g. *Dipylidium caninum* is incidental in man; and (c) specific parasites, which occur in a particular species of host or group of hosts, e.g. *D. caninum* is specific for dogs and cats.

Parasympathetic Nervous System

The parasympathetic nervous system is one division of the autonomic nervous system; the other division being the sympathetic. (See AUTONOMIC NERVOUS SYSTEM; CENTRAL NERVOUS SYSTEM.)

Parathion

Parathion is organophosphorous insecticide (diethyl-*para*-nitrophenyl-thiophosphate) used for agricultural purposes. In man and domestic animals it is a cumulative poison which readily enters the system through inhalation, by the mouth or by absorption through the skin. Animals should not be allowed to graze under trees sprayed with parathion for at least three weeks. In man, symptoms of poisoning include headache, vomiting and a feeling of tightness in the chest. Later there is sweating, salivation, muscular twitching, distressed breathing and coma. (See ORGANOPHOSPHORUS POISONING.)

In animals, copious salivation and lachrymation, twitching and increased intestinal movement are shown. Cattle are apparently tolerant of parathion, being able to break it down chemically.

The danger of spray drift, and the risk to dogs and cats wandering in sprayed areas, are obvious.

Parathyroid Glands

Parathyroid glands are small structures situated either wholly within, or upon the surface of, the thyroid gland. Their secretion, the parathyroid hormone, is important in the control of the level of blood calcium. Insufficiency of this hormone leads to muscular twitchings or tremors or, in more severe cases, to convulsions. (See TETANY.) The hormone also controls phosphate excretion via the urine. (See table below.)

Hyperparathyroidism in dogs Of 21 dogs with primary hyperparathyroidism, 20 had a parathyroid adenoma and one had a parathyroid carcinoma. The most common clinical signs were polydipsia/polyuria, listlessness, muscular weakness and inappetence. The only consistent biochemical abnormality was persistent hypercalcaemia (12.1 to 19.6 mg/100 ml). The external parathyroid tumours, found in nine of the 19 dogs which underwent surgery, were easily removed; internal parathyroid tumours were removed by thyroidectomy.

Primary hyperparathyroidism in a cat A 12-year-old cat showed clinical signs of lethargy, reluctance to move and pain along the back. Radiological examination revealed multifocal lesions, particularly in the skeleton. There was bilateral parathyroid hyperplasia but no evidence of neoplastic change. Histological examination revealed that a large proportion of bone had been resorbed and replaced by fibrous connective tissue and that osteoclasts were numerous. It is suggested that hyperparathyroidism should be considered in the differential diagnosis of conditions involving skeletal pain and lethargy in the cat.

Paratuberculosis

A synonym for JOHNE'S DISEASE.

Paratyphoid

Infection with any species of salmonella; a synonym for SALMONELLOSIS.

Paravaccinia Virus

(See PARAPOX VIRUSES.)

Parenchyma

Parenchyma is a term used for the functional cells of an organ, as opposed to its supporting, connective tissue (interstitial) cells. In a gland the parenchyma is the mass of secreting cells; in the lung, similarly, the parenchyma comprises the cells concerned with respiration, not the fibrous supporting tissue.

Parenchymatous

Related to the parenchyma. (See NON-PARENCHYMATOUS.)

Parenteral

Administration of a medicinal substance other than via the digestive system, e.g. by injection.

Paresis

A state of slight or temporary PARALYSIS, also called 'fleeting paralysis'. (See MILK FEVER; MUSCLES, DISEASES OF - NUTRITIONAL MUSCULAR DYSTROPHY; LEAD POISONING; GUTTURAL POUCH DISEASE.)

SOME OF THE EFFECTS OF PARATHYROID HORMONE AND CALCITONIN, THE 2 MAJOR HORMONES CONTROLLING THE REGULATION OF BLOOD CALCIUM

	Parathyroid hormone	Calcitonin
Mode of action	Separates fast and slow components Increases cell membrane permeability Activates adenyl cyclase enzyme systems	Uncertain
Effect on kidney	Increases P excretion by decreasing tubular reabsorption Decreases Ca excretion by increasing tubular reabsorption Increases Na excretion by decreasing tubular reabsorption	Increases Ca, P, An and K excretion Decreases Mg excretion
Effect on intestine	Increases Ca, P and Mg absorption	? Decreases P absorption Decreases volume and acidity of gastric juice
Effect on bone	Increases resorption Stimulates osteoclast and osteocyte activity Inhibits formation Suppresses osteoblast activity	Inhibits resorption
Resultant effect on blood calcium	Elevated	Diminished

(With acknowledgements to Professor D. Bennett and to the Veterinary Record.)

VetBooks.ir

Parietal
Parietal is the term applied to anything pertaining to the wall of a cavity, e.g. parietal pleura, the part of the pleural membrane which lines the wall of chest.

Parity
The number of times a female animal has given birth.

Paronychia
Paronychia is infection of the nailbed (carium of the claw) or claw. There are many causes including bacteria of various species, fungi, mites and AUTOIMMUNE DISEASE. (See RINGWORM.)

Parotid Gland
The parotid gland is one of the salivary glands. It is situated just below and behind the ear on either side, in the space between the angle of the jaw and the muscles of the neck. From its base commences a duct, the parotid duct, or Stenson's duct, which in the horse runs within the border of the mandible for a distance, and then turns round its rim to the side of the face in company with the external maxillary artery and vein, and ends by opening into the mouth opposite the anterior part of the third upper cheek tooth; in other animals it runs straight across the face instead of along the lower jaw bone.

The SALIVARY GLANDS are composed of collections of secreting acini held together loosely by a certain amount of fibrous tissue, but they do not possess a distinct capsule.

Parovarium
Parovarium is the name of rudimentary structures situated near the ovary, which are the remnants of the Wolffian bodies. The name Paroophoron is also used. These structures are often the seat of cysts in the young adult. (See OVARIES, DISEASES OF.)

Paroxysm
(adjective, Paroxysmal)
A sudden attack, recurrence or worsening of a disease.

'Parrot Fever'
(See PSITTACOSIS.)

Parrot Mouth
A description of a jaw which is BRACHYGNATHIC or OVERSHOT.

Parrots
These are birds of the tropics, subtropics and some temperate regions in the Southern Hemisphere, known as PSITTACINES and are in the Order Psittaciformes. The variety of species is seen mostly in South America and Australasia. They include many species (about 372) in 86 Genera. There are three Superfamilies: *Psittacoidea* (true parrots); *Strigopoidea* (New Zealand parrots); and *Cacatuidea* (cockatoos). They have strong powerful curved beaks and an upright stance. They are intelligent and the ratio of brain to body weight is similar to that of higher primates.

In African grey parrots (*Psittacus erithacus*), food transit time was 120 to 130 minutes as measured by radiograph and 262 minutes by fluoroscopy.

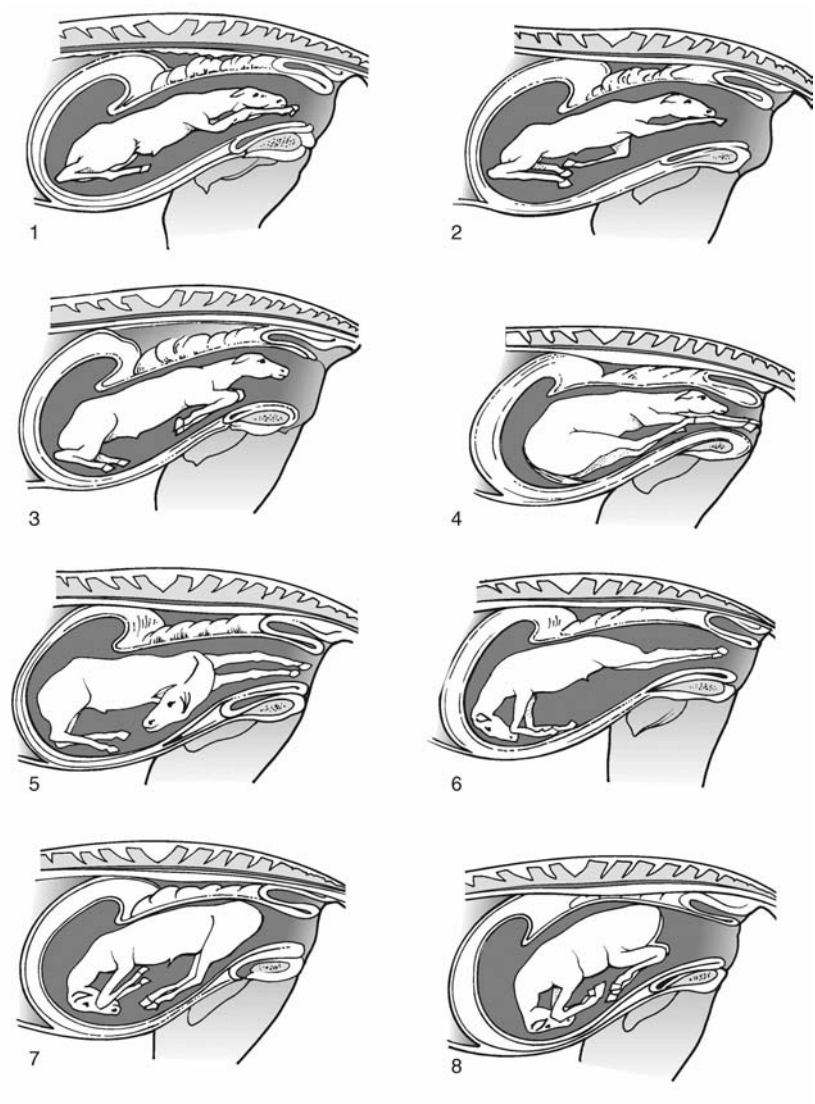
(See PSITTACOSIS; also BIRD IMPORT CONTROLS and PACHECO'S DISEASE.)

Parsley
This may be included in herbal remedies for the relief of arthritis, skin and kidney disorders in dogs and cats. It is a useful source of iron and vitamin C.

Parsnip
A root crop with a relatively high energy content. The leaves contain furnocouramins and if ingested by monogastric animals they can lead to photosensitisation. In pigs it can be accompanied by nervous signs resulting in an abnormal gait such as goose-stepping, crab-walking, stiffness, back dipping, walking cautiously and also twitching tails.

Parson Jack Russell Terrier Dogs
A medium-sized terrier. (See JACK RUSSELL TERRIER.)

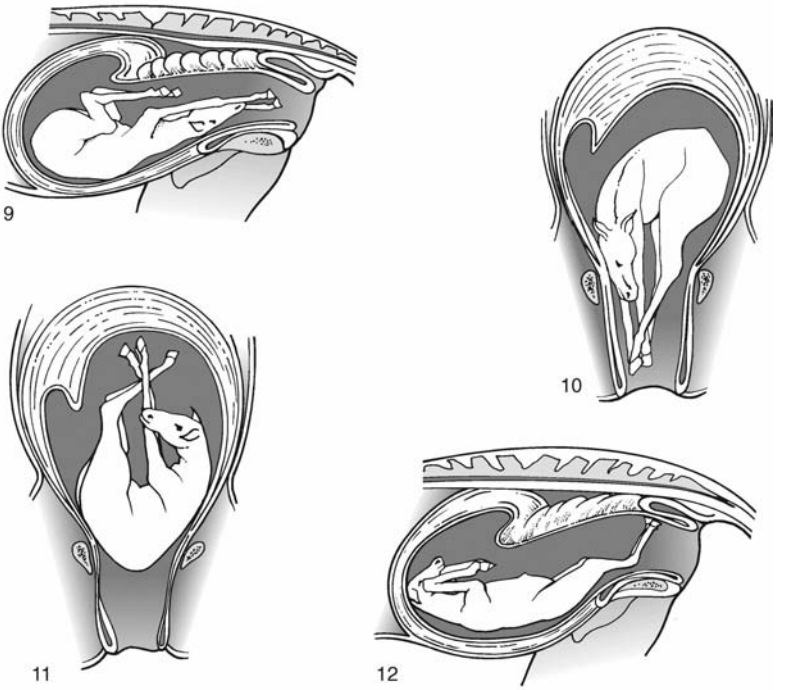
Parthenogenesis
Asexual reproduction, in which the ovum develops into an embryo without fertilisation by a spermatozoon. This is a common method of reproduction among invertebrate animals, particularly insects, including ants and bees.



Partridges
Grey (or English) partridges (*Perdix perdix*) were once the most common game bird in England but declined by 88 per cent from 1967 to 2006 owing to changed agricultural practices. It is rotund with a brown back, grey flanks and chest. The red-legged partridge (*Alectoris rufa*), also called the French partridge, is a rotund bird with a light brown back, grey breast and buff belly. During the 1930s the parasite *Trichostrongylus tenuis* caused high mortality in partridges. *Heterakis* spp. are common in juvenile birds. (See GAME BIRDS, MORTALITY.)

Parturient Paresis
(See MILK FEVER and 'DOWNER COW' SYNDROME.)

Parturition
Parturition is the expulsion of the fetus (and its membranes) from the uterus through the maternal



passages by natural forces, and in such a state of development that, in domesticated animals at least, though not in the marsupials, the fetus is capable of independent life. The process is called 'foaling' in the mare, 'calving' in the cow, 'lambing' in the ewe, 'kidding' in the goat, 'farrowing' in the sow and 'whelping' in the bitch. It is more likely to proceed successfully without than with human interference in the great majority of cases. (See CALVING, DIFFICULT for information on traction.)

VetBooks.ir

Different varieties of presentations of the foal.1. Normal anterior presentation – nose and both fore-feet in passage.2. Anterior presentation with 1 fore-limb retained completely. This should be brought forward by hand, or by passing rope round flexure of knee.3. Anterior presentation with both fore-limbs retained at the knees, corrected as in No. 2.4. 'Dog-sitting' presentation – nose and all 4 limbs presenting. The 2 fore-limbs should be corded and the hind-limbs repelled or pushed back.5. Anterior presentation with head and neck retained. Delivery may often be effected by traction on fore-limbs in foal, the head being pressed into the soft abdomen. In calf, owing to the short neck, this is not usually possible. Where possible, fore-limbs should be corded, pushed back, and the head brought round by the hand or, in difficult cases, by hooks and cords.6. Posterior presentation. Successful delivery often possible if the birth is speeded up by traction to avoid suffocation (see text).7. 'Breech presentation'. Delivery difficult, foal nearly always dead. Cords in front of the foal's stifles and round buttocks may be applied if mare is large and foal is small, but usually necessitates amputation of one or both hind-limbs.8. 'Thigh and croup presentation'. Cord round hocks may be successful in converting this into an ordinary posterior presentation. Quarters must be firmly pushed back after hocks are corded.

VetBooks.ir

9. 'Upside-down' anterior presentation. Occasionally delivery may be effected without adjustment, but assistance is always necessary. Removal of one or both fore-limbs, with or without head and neck, often essential.10. Ventral transverse presentation. This and No. 11 are the two worst positions in which foal can lie. Each case must be treated differently. Fore- or hind-limbs may be pushed back or brought forwards according as they lie back in the passage or advanced. Removal of the foal in portions, a limb at a time, is often necessary.11. Dorsal transverse presentation. Foal usually requires to be dissected and each half removed separately.12. 'Upside down posterior presentation'. Delivery may be possible as soon as limbs have been adjusted, or amputation or version may be carried out.

Stages in parturition Although the act is really a continuous one, it is customary to divide it into four stages: 1. Preliminary stage; 2. Dilatation of the cervix stage; 3. Expulsion of the fetus stage; 4. Expulsion of the membranes stage. In the following text, the horse is taken as the main example:

1. Preliminary stage may occupy some hours or even days. The udder swells, becomes hard and tender, and a clear waxy fluid material oozes from the teats or may be expelled by pressure of the hand. The external genitals become swollen, enlarged and their lining is reddened. A vaginal secretion appears. The abdomen drops and becomes pendulous. The quarters droop and the muscles and ligaments of the pelvis slacken. The animal separates itself from its fellows if at pasture; if at liberty, it seeks a remote or an inaccessible place in which to bring forth its young, and some, such as the sow, bitch and cat, prepare a bed or nest.

2. Dilatation of the cervix stage merges with the preceding. Restlessness is evident. The mare paces around the loose-box (often with tail raised) – perhaps lying down and rising again several times. Sweating occurs under the mane and tail, and soon over most of the body.

During the second stage of labour, the mare is usually lying down on her side, and in some cases will show signs of COLIC, i.e. kicking at the belly, turning and gazing at her flanks, or wandering round in an aimless fashion. Meanwhile, the labour pains have been getting more and more powerful and the intervals between them shorter. The pulse is quickened, and the breathing rapid. When a pain has passed the animal calms down and remains so till the next takes place. After a variable time – from about a half to three hours – the 'water-bag' appears at the vulva. It is tense and hard during a pain, but becomes slack and flaccid in the intervals. It is found to be empty at first, but the fore-feet of the young animal can be felt in it later. At this time the cervix is fully dilated, and the third stage follows without any appreciable break in the sequence of events.

3. Expulsion of the fetus stage In this stage the severity of the pains is greatest, and the

VetBooks.ir

auxiliary muscles of the abdomen assist in the contractions. The animal may remain standing, may lie down in the recumbent position, or may alternately lie and stand. The back is arched, the chest expanded, and the muscles of the abdomen become board-hard with each labour pain. The animal may groan, or squeal or even scream with each effort. Frequently the rectum forcibly discharges its contents and the urinary bladder does likewise. At each contraction the 'water-bag' protrudes farther and farther from the vulva until it finally ruptures in its most dependant part. There is a rush of fluid from the uterus to the outside and the animal has a period of ease. Then fore-feet, and the muzzle lying behind and over them, appear at the vulva, forming a kind of cone which dilates the softer tissues of the genital canal. In the larger animals the feet come first, but in the carnivora, where the head is large, the head precedes the fore-feet, which are tucked against the young animal's chest and sides. When the head has cleared the vulva there is usually another pause, which allows the tissues to become accustomed to the great distension, and prepares them for the still greater distension and strain that is soon to follow. The thorax and shoulders are now in the pelvis of the dam, and are driven slowly through it by the most powerful and painful of the contractions that occur during the process. As this part of the fetus reaches the outlet of the pelvis there is generally a more energetic and painful effort than all the others – which pushes the fetal trunk to the outside. This culminating effort may cause the bitch or cat to cry out.

Sometimes the foal's umbilical cord does not rupture, in which case the mare will usually gnaw through it, and so liberate the foal. It sometimes happens that a foal is born completely enveloped in its membranes; in such instances, unless assistance is at hand to free the foal, it will be rapidly suffocated.

In cows the umbilical cord is much shorter and it ruptures before the hind legs of the calf have passed to the outside. Owing to the cotyledonary attachment of the placenta the membranes are seldom born along with the calf. In the smaller animals, especially in the sow, bitch, and cat, the young are frequently born in their membranes, and these are licked away and cleared from the young by the dam, the umbilical cord being broken or bitten through in the process.

4. Expulsion of the membranes stage, or the 'delivery of the afterbirth', may occur with, immediately following, or not for some considerable time after, the production of the young in an animal.

Very soon after the young animal is born the uterus contracts and becomes smaller – a process known as 'involution' – so that its capacity is decreased. The attachment between the membranes and the mucosa of the uterus is loosened and the placenta is separated from the uterus. These contractions also serve to push out the membranes through the wide open cervix.

With the mare, owing to the diffuse and not very intimate adherence between the uterine mucous membrane and the placental membrane, the separation and the discharge of the envelopes are soon accomplished. In fact, if these are retained for more than a very few hours (four or six or so), serious results are probable, but retention of the membranes is rare in the healthy mare.

In the cow, the attachment is limited to the surfaces of the cotyledons and is very close, and where the shrinkage in the uterine wall (i.e. involution) does not tend greatly to upset the intimacy of the adhesion, the calf is not born in its membranes, and retention of these is more common. They are generally discharged within a few hours of the birth of the calf, but the time varies.

Animals which produce more than one young at a time generally discharge the membranes of each at the same time as or soon after it is born, with the exception of the last of the litter, whose membranes are occasionally retained in the extremity of one horn of the uterus.

In animals that are really uniparous (i.e. produce only one fetus at a birth but which have been modified by breeding so that they often produce two or more young, such as the sheep and goat) the membranes of the first twin come away with the second, and those of the second are expelled after it has been born.

Early discharge of the membranes is desirable, because as long as they remain in position they are likely sources of infection to the uterus, and they prevent that organ from returning to normal. After they have been evacuated the involution of the uterus becomes more and more complete, until in a few days it has shrunk to less than half its former size. It never decreases to its original virgin size.

The mare should have been housed in the 'foaling-box' for a month or so previously, so that she shall feel quite at home (see PREGNANCY AND GESTATION – Care of the dam during pregnancy), and the ventilation, warmth, bedding, cleanliness, etc., should be as close to ideal as the circumstances will allow. If possible, the cow should calve in a separate loose-box. Ewes lamb out in the open and do quite well, but if the weather is cold or stormy, or if the ground is very wet, it is better to provide a 'lambing-pen', especially with Lowland breeds which have not the same hardiness as the mountain varieties. Sows should on all occasions have a pen to themselves, for if other pigs are present the little pigs will most probably be eaten as soon as they are born.

VetBooks.ir

When the birth process has begun, the attendant may need to soothe and quieten the dam if she becomes very excited, but beyond this the prospective mother should be left alone for some time. If all is going well, the 'water-bag' will soon appear and later burst. No hard-and-fast rule can be laid down, but if the fore-legs and nose of the fetus do not appear within 10 to 20 minutes in the mare, and in double that period in the cow, a simple examination should be made by the attendant to ensure that the presentation is a normal one. After washing hands and arms in mild antiseptic, such as Dettol or Cetrimide solutions, and thoroughly lubricating them with a vaginal lubricant, the hand should be gently inserted into the posterior genital passage to explore by touch whatever presents itself. The two fore-feet should be distinguishable in that part of the passage that lies lowermost when the dam is standing. Above them and slightly behind, the nose and mouth should be felt. These structures are often covered with fetal membrane, but in a normal case can be located. In such cases as this, nothing further need be done in the meantime; the dam will probably produce her young quite normally, and any attempts at assistance will only irritate and perhaps exhaust her.

It may happen, however, that one or both of the fore-legs or the nose cannot at first be found. On introducing the arms still further these parts can sometimes be discovered, and, by gentle pulling or readjustment, can be brought into the normal position. Before the process of parturition has advanced very far, abnormal positions of the fetus can be comparatively easily corrected, and serious trouble from subsequent jamming may be avoided. If all efforts at correction prove futile, a veterinary surgeon should be called in.

Upon comparatively rare occasions none of the foremost positions of the body can be felt, but the two hind-feet or legs (distinguishable by the difference between knees and hocks), and perhaps the tail of the young animal, are discovered. This is a posterior presentation, and as the head is the last part of the fetus that will be born, respiration cannot begin until birth is complete, and the risk of suffocation is great. Accordingly, it is necessary to attempt to hurry the whole process and a veterinary surgeon should be called.

Attention to offspring As soon as the young animal is born and free from the maternal passages, it is absolutely essential to ascertain that the fetal membranes are not obstructing its mouth or nostrils. It generally gives one or two spasmodic gasps or struggles, and then begins to breathe. Each respiration is shallow and weak at first, but in a very few minutes the breathing settles down to the normal.

Suspended animation Occasionally, foals and calves are born in a state of suspended animation, and ARTIFICIAL RESPIRATION will be needed.

The umbilical cord This is best not interfered with. In the foal, early severance of the cord can lead to the loss of 1000 to 1500 ml of placental fetal blood, whereas under 'natural' conditions the amount concerned is probably well under 200 ml. The well-being of the animal is better served when it is allowed to retain the blood, as would usually be the case under natural conditions. The umbilical cord has a point at which it will rupture normally, generally by movement of the mare, after a period during which mother and foal rest. Since haemorrhage from either end of the severed cord is then extremely rare, the cord should require no human attention after a normal birth. The natural sealing of the umbilical cord provides an effective barrier against both bleeding and infection.

The Animal Health Trust's Equine Research Centre has commented: 'It is difficult to imagine a worse procedure than leaving a substantial "meaty" mass of umbilical cord at the navel as happens so commonly after cutting the cord with scissors. This provides an ideal medium for the passage of micro-organisms whose entrance to the abdominal portions of the umbilical vein and arteries are not hindered in any way by the tape so frequently used to "tie off" the stump. Almost as undesirable a procedure is the application of strong antiseptics (notably iodine), destructive as they are to tissue with which they come in contact.'

Other advice If a young mare, for instance, does not at once begin to dry and cleanse her foal, a little salt rubbed over its coat may induce her to do so. Should the mother refuse to perform this office, the offspring must be dried with a towel, cloth, wisp of hay, etc., so far as is possible.

Suckling The first suck is of great importance. Within about half an hour the young of the domesticated animals are usually able to stand on their feet – although they are shaky at first – and as soon as they master this feat they make endeavours to reach the teat. The first milk contains a natural laxative, and it is essential that the newly born should obtain some of this as soon as possible. Colostrum – the first milk – promotes a secretion from the intestinal glands and stimulates peristalsis, so that the debris and black, gummy, faecal material (called 'meconium') that has been lying in the bowels of the foal is evacuated and the way prepared for the digestion of food. When a dam dies before the foal obtains any colostrum, it is necessary to supply colostrum provided by another animal or a substitute such as melted butter and milk.

VetBooks.ir

Attention to the dam Where parturition has been easy and normal, the dam rapidly recovers, and may be up on to her feet within a few minutes of the discharge of the fetus. It is usually better to allow her to remain lying as long as she wishes while attention is being paid to her offspring. It is good practice to offer a drink of warm barley-water or thin oatmeal gruel containing a tablespoonful of common table-salt, as soon after the act as convenient. Her system has undergone a considerable shock, and has lost quantities of fluid which should be replaced. The larger animals may require a rug if the weather is at all cold. After three to six hours or thereabouts, a pailful of bran mash and a little hay should be given.

Afterwards the parts must be covered with a warm and dry blanket, to prevent any chilling. The loose-box must be warm yet well ventilated, and the dam should be encouraged to rest as much as possible.

Subsequent management No oats or concentrated food-stuff should be given to the dam for the first two days after parturition; her rations should consist of water, bran mashes, and hay or green food given three times daily. After that time a gradually increasing amount of crushed oats and cut hay or chaff may be added to the mash daily, until at the end of a week or 10 days she is back on to her usual diet. Gentle exercise is as necessary for the foal or calf as it is for their dams, and if the weather is suitable the dam and her progeny should be allowed out on to a sheltered meadow for an hour or so twice daily, after the first three or four days following the birth of the young. This period is gradually increased until in two weeks' time the pair may be left out from 09.00 till 17.00, or even may be allowed to sleep out all night if the weather permits. In this connection it should be remembered that cold dry nights are much less harmful than those that are wet or foggy. Young animals of all species withstand dry cold very much better than wet cold, and it is inadvisable to allow foals or calves less than a month old to sleep out on a wet or marshy meadow. A useful method is to erect a covered-in shed in a corner of the meadow, containing a feeding-trough and well littered with straw, into which both dam and her offspring may retire whenever they wish. The amount of hand feeding which the dam receives must be judged according to circumstances. If the grass is rich and well forward, one feed of oats and hay may be sufficient after the first three or four weeks, but it is always better to err on the safe side and keep the dam in good general condition, for much of the subsequent quality of the offspring depends upon the start in life that it receives through its mother's milk, and if she herself is in poor condition her milk will be inferior.

Parturition, Drug-Induced

Prostaglandins are frequently used to induce parturition in pigs, and sometimes in other livestock, so that it occurs at a planned date. It is a technique also used in some cases of debility of the dam in late pregnancy, where there is some abnormality associated with the pregnancy, to avoid dystokia in the cross-breeding of dairy cows for beef production.

Parvovirus

This has been associated with infertility in the sow, and is a cause of mummified fetuses and small litter size. (See VIRUSES Classification table; CANINE PARVOVIRUS (CPV); GOOSE PARVOVIRUS; PORCINE PARVOVIRUS; and FELINE INFECTIOUS ENTERITIS.)

Human parvovirus infection This is most common in children, and is associated with a rash and fever; and sometimes pain in the joints.

PAS

1. (See PERINATAL ASPHYXIA SYNDROME.)
2. Abbreviation for para-aminosalicylic acid, a drug which has been used in the treatment of tuberculosis in zoo animals.

Passage

Passage (pronounced as in the French) is a term meaning the passing of a strain of organisms through a series of animals to decrease virulence. For example, passage of cattle plague virus through goats is done to reduce its virulence for cattle, and is a technique used in the production of cattle plague vaccine.

Passerine

A bird that is a member of the Order *Passeriformes*, also known as the perching birds, or less accurately songbirds. It includes over half of all bird species.

Passports, Cattle

(See CATTLE PASSPORTS; IDENTIFICATION OF CATTLE.)

Passports, Horse

(See HORSES, IDENTIFICATION OF.)

These must record any use of PHENYLBUTAZONE for that animal.

Pastern

The name given to the first (long) and second (short) phalanges of the fore-limb, and to the joint so formed.

Pastern Dermatitis

An infection with *Dermatophilus congolensis*. It is particularly found in the featherings of the legs, of horses and goats. Commonly called MUD FEVER.

VetBooks.ir

Pasteurella

A genus of bacteria, which are small, ovoid, Gram-negative, bipolar staining. Both non-motile and motile species occur, and they are aerobic or facultatively anaerobic. For the diseases they cause, see following entries.

Pasteurella multocida A GRAM-NEGATIVE bacterium which has strains that affect many animal and bird species. They are divided into five serogroups (A, B, C, D, E) and also serovarieties. The infection can result in a bacteraemia and infections in different organs. Respiratory disease is common, but endocarditis, mastitis, meningitis and osteomyelitis all can occur. Infections include: HAEMORRHAGIC SEPTICAEMIA in buffaloes, BOVINE RESPIRATORY DISEASE COMPLEX, HAEMORRHAGIC SEPTICAEMIA, CALF PNEUMONIA, PASTEURELLOSIS IN CATTLE, 'SHIPPING FEVER' in cattle, ATROPHIC RHINITIS, PASTEURELLOSIS IN PIGS, PORCINE RESPIRATORY DISEASE COMPLEX in pigs, FOWL CHOLERA in poultry and MASTITIS IN RABBITS.

Pasteurellosis in Cats

(See YERSINIOSIS and BUBONIC PLAGUE; see BITES, STINGS AND POISONED WOUNDS for human infection with *Pasteurella multocida*, formerly known as *P. septica*.)

The cat harbours *P. multocida* as one of its bacterial flora.

Pasteurellosis in Cattle

This includes HAEMORRHAGIC SEPTICAEMIA of cattle and buffaloes in the tropics; 'SHIPPING FEVER' ('Transit fever') of the American feedlots and elsewhere; and other pneumonias occurring in Europe.

In calves, *Mannheimia (formerly Pasteurella haemolytica* serotype A1 may be the primary pathogen. Serotype A2 and *P. multocida* may also be isolated. Both bacteria are normal inhabitants of the upper respiratory tract. Under stress, or infection by viruses, the bacteria multiply rapidly, causing disease. Signs include a nasal discharge, a respiratory rate of 60 to 100 per minute, and a temperature of up to 41.6° C (107° F).

(See CALF PNEUMONIA for viruses which may be involved, and for synergism between Pasteurella and Mycoplasma.)

Pasteurellosis in Chickens and Turkeys

(See FOWL CHOLERA.)

Pasteurellosis in Ducks

Caused by *Pasteurella anatipestifer*, this is a disease of considerable economic importance in ducklings, with a mortality sometimes as high as 70 per cent. Less acutely infected birds may shake their heads or draw their heads close to their bodies. Sulfadimidine has been used in treatment.

Pasteurellosis in Man

Pasteurella multocida is a commensal organism in the mouth and naso-pharynx of many animals. In humans, superficial infections of the skin and mucous membranes, such as corneal, oral or leg ulcers and infections of compound fractures, conjunctivitis or sinusitis and panophthalmitis may result from animal bites or scratches. In these infections *P. multocida* is likely to have been acquired when saliva from the animal contacted injured tissue. Pasteurella organisms may also invade the body via the respiratory system or, less commonly, via the alimentary tract and skin lesions. The most commonly seen internal infections of *P. multocida* are associated with chronic obstructive lung disease. A third category of infection is suggested: septicaemia and bacteraemia in patients with chronic disease, especially chronic liver disease. *P. multocida* may result from handling raw poultry carcases. Small domestic pets may be carriers of *P. multocida*. Internal infections may derive from farm animals; in one study, 27 of 37 patients with internal infection lived on farms. Other *Pasteurella* species that affect animals rarely occur in man.

Pasteurellosis in Pigs

Bronchial pneumonia, sometimes with PLEURITIS and PERICARDITIS, is the commonest sign; *P. multocida* is the usual cause but clinical pasteurellosis may be a complication of mycoplasmal pneumonia.

Signs There is fever, and the animals maybe seen struggling for breath, with frothing in the mouth. Death may follow.

Treatment and control Antibiotics should be given; antiserum is effective if the causal bacteria is known. Vaccination is used for control where there is a known risk of pasteurellosis.

Pasteurellosis in Rabbits

Pasteurella spp. are very commonly found in rabbits. They are isolated from many lesions, especially abscesses, in virtually all internal organs. They easily spread SYSTEMICALLY. (See also HEAD-TILTING; MASTITIS IN RABBITS; TORTICOLLIS). Infection by *P. multocida*, commonly called 'snuffles', usually affects the upper respiratory tract, with a watery or yellowish nasal discharge, sneezing and snoring caused by mucus accumulating in the nasal passages. Infection may spread to the eyes and ears. The condition may become chronic if not treated early with a suitable antibiotic.

VetBooks.ir

Pasteurellosis in Sheep

Pasteurellosis in sheep is caused occasionally by *Pasteurella multicocida* but far more commonly by *P. haemolytica*, and subclinical infection may develop into pneumonia if parainfluenza III virus is present too.

Formerly *P. haemolytica* was divided into biotype A, which causes enzootic pneumonia, and biotype T (then called *P. tehalosi* and now *Bibersteinia trehalosi*) is mainly associated with septicaemia. Both may be isolated from cases of arthritis. *M. haemolytica* also causes mastitis in ewes, and meningitis – especially in lambs.

Young sheep are liable to die from the acute septicaemic form, while older ones show a slower type of the disease, in which the pneumonic lesions predominate.

Signs The acute cases are ushered in by high temperature, great dullness and nervous depression, difficult respirations and muscular tremors, followed by rapid collapse and death within three days.

In the less acute cases, similar but slightly milder signs occur. These are accompanied by a discharge from the eyes and nose, loss of appetite and absence of rumination, with signs of pneumonia or pleurisy.

Diagnosis The acute form may be confused with ANTHRAX or BRAXY.

Immunisation Vaccines containing several strains of *M. haemolytica* and *B. trehalosi* are available; also a combined clostridial and pasteurella vaccine. A serum has also been prepared. (See also PNEUMONIA IN SHEEP.)

Pasteurisation of Egg White

This can be undertaken to remove infections.

Pasteurisation of Milk

High temperature pasteurisation consists of heating the milk for 10 to 20 minutes at a temperature of 75° C (167° F). This is sufficient to render harmless the germs of enteric and scarlet fever and diphtheria, and also bacteria which give rise to summer diarrhoea in children. It also affords a considerable measure of protection against tuberculosis. Usually today the temperature used is 71.7° C (162° F) for 15 seconds. This considerably reduces bacterial numbers.

Low temperature pasteurisation consists of maintaining the milk for at least half an hour at a temperature between 63° C and 65° C (145° F and 150° F). This has the effect of considerably reducing the number of bacteria contained in the milk and greatly delaying souring and similar changes. This procedure is sufficient for the sale of milk as 'pasteurised milk' in England. (See also ULTRA-HIGH-TEMPERATURE TREATMENT OF MILK.)

Unpasteurised milk (See MILK-BORNE DISEASE.)

Pasture, 'Clean'

Pasture that has not been grazed by the same species for some time. The actual period varies with the parasites involved, climate and other factors. Criteria for clean pasture vary with the time of year. In spring, it is pasture not grazed by the same species in the previous grazing season – that is, a new ley, an area grazed by another species or used for conservation. In the summer, clean pasture is defined as an area not grazed by that species the same year up to mid-June, for sheep, and mid-July for cattle. However, pasture rarely becomes completely free from parasites.

Professor James Armour and colleagues at the University of Glasgow veterinary school found clinical parasitic bronchitis ('husk'), due to the lungworm *Dictyocaulus viviparus*, and gastroenteritis due to *Osertagia ostertagi*, in young cattle grazing aftermath pasture in late summer. Calves on pasture lightly infested with *Ostertagia* were effectively treated with an anthelmintic and transferred to a silage aftermath in late July. A marked increase in third-stage larvae numbers on the aftermath occurred within the first week, and clinical signs of type I ostertagiasis were observed four weeks later.

Research in the USA showed that if *Ostertagia* eggs are buried to a depth of 12.5 cm under pasture, or beneath 15 cm of soil in the laboratory, third-stage larvae develop and migrate vertically through the soil. However, the good husbandry rule of keeping young stock off pasture previously grazed in the same season by adult stock is, obviously, still worth applying as a means of avoiding even worse outbreaks.

Pasture, Contamination of

This may occur in the vicinity of smelting works (see under FACTORY CHIMNEYS), or as the result of droplets of chemical sprays being carried by the wind to adjoining fields. (For a list of chemical sprays, see under WEEDKILLERS and INSECTICIDES.) Contamination may also occur as the result of atomic fall-out. (See RADIOACTIVE FALL-OUT.) Bacterial contamination can result from organisms that are able to exist for long periods outside the animal body. Examples are bovine tuberculosis (at least 4 months), Johne's disease (at least a year), anthrax (at least 30 years) and clostridial spores. Resting pasture for three

VetBooks.ir

weeks provides a measure of control of foot-rot, the organism responsible being unable to survive for more than a fortnight. For contamination by worm larvae, see PARASITIC BRONCHITIS; GASTROENTERITIS; PASTURE, 'CLEAN'. For contamination by organic irrigation see under SLURRY. (See also BASIC SLAG; FERTILISERS.)

The average cow defecates about 12 times daily and each pat weighs about 2.5 kg (5½ lb); in a 180-day grazing season, she will put about 5 tons of faeces (containing about 680 kg (1,500 lb) dry matter) on to the pasture. (See DAIRY HERD MANAGEMENT.) (For contamination by slurry applications, see SLURRY and 'MILK-SPOT LIVER'; also SOIL-CONTAMINATED HERBAGE.)

Contamination of pasture may occur during flooding and, in a sense, when ticks are left behind by a batch of cattle infected with piroplasms; the ticks then infect other cattle put on to that land. (See RED-WATER FEVER.)

'Pasture Fever'

(See TICK-BORNE FEVER OF CATTLE, etc.)

Pasture Management

Pasture management is of the greatest importance in relation to diseases such as BLOAT, HYPOMAGNESAEMIA, PARASITIC GASTROENTERITIS and PARASITIC BRONCHITIS. (See also under DEEP-ROOTING PLANTS, TOPPING OF PASTURES, and WILTING.) Controlled grazing is effected by means of an electric fence. (See STRIP-GRAZING and PADDOCKS.)

It is important that heavy application of nitrogenous and potash fertilisers to grassland should be made at the right time, or animals grazing there will be exposed to a greatly increased risk of HYPOMAGNESAEMIA. (See also HOOF-PRINTS.)

The sudden (and harmful) change of diet which may occur when stock are turned out in the spring, or brought off pasture into yards for the winter, are discussed below.

In spring, it is a mistake to turn calves straight out on to grass. This means a sudden change from protein-poor food to the rich protein of the early bite, and the resulting effect upon the rumen will set them back. It is wise to get them out before there is much grass for a few hours each day; let them have hay and shelter at night to protect them from sudden changes of weather. Hypomagnesaemia, too, is far less likely under these circumstances.

Before yarding cattle in the autumn, it is wise to make a gradual change from sugar-poor autumn pasture to things like roots, and to accustom them to concentrates. Otherwise digestive upsets are very likely to occur.

It should be borne in mind that *Trichostrongylus axei* is a parasite common to cattle, sheep, goats, and horses, and grazing one species of animal after another in a field could give rise to a very heavy contamination with this one parasite.

Prompt removal of faeces from pasture has been found effective in reducing the worm burden, and practicable where acreage is small, labour cheap, or racehorses are concerned.

Use of goats in sheep grazing systems. Goats are browsers and prefer to graze plant species not readily eaten by sheep; also, given the choice, goats will discriminate against plant species such as clover which are important and beneficial in sheep production systems. The introduction of goats can benefit the sheep stock by helping to prevent the degeneration of the improved areas and by keeping the indigenous vegetation in a more productive and nutritious state, while at the same time not competing with the sheep for the more valuable plant species. Goats are very susceptible to alimentary parasites and, while grazing, need monitoring for parasites and treatment when necessary. Over-treatment can result in anthelmintic resistance.

Other aspects of pasture management are referred to under the following: PASTURE, CONTAMINATION OF; BRACKEN POISONING; RAGWORT POISONING; DIGITALIS - DIGITALIS POISONING; WORMS, FARM TREATMENT AGAINST; EXPOSURE; STRESS; 'POACHING'; BEEF CATTLE HUSBANDRY IN BRITAIN; SHEEP BREEDING AND MANAGEMENT; SILAGE; FOG FEVER; HAY; STOCKING RATES; TOPPING OF PASTURES.

Grass varieties Plant breeding for improved pastures is in its infancy as compared with that for the agronomically less complex arable crops.

Yield (whether annual or seasonal) is only one of four criteria useful in judging a new variety of herbage. Its persistency, palatability and nutritive value are important criteria, too; a high-yielding variety may be contraindicated if animals lose weight on it, as they do with one variety of *Phalaris.* The effect which the system of grassland management has, and how varieties will stand up to a given system, must also be considered. For example, with regular defoliation, perennial rye grass yields more than Italian rye grass; whereas with infrequent cutting, Italian rye grass yields more.

For systems of farming at high production, consideration should be given to a species like tall fescue, whose biological potential is known to be very high, and whose reaction to intensive systems of defoliation is favourable.

Horses Pasture grasses and herbs recommended by the Animal Health Trust for horses are classified as under:

Desirable species
Perennial Rye grasses, Sceempter, Melle, Petra, Midas S.23 and S.321, Timothy S.50 and S.48, Cocksfoot S.143, Crested Dogstail, Wild White Clover, Dandelion, Ribgrass, Chicory, Yarrow, Burnet, Sainfoin.

Probably useful (turf species which are also palatable)
Tall Fescue Alta, Canadian Creeping Red Fescue, Smooth Stalked Meadow Grass, Rough Stalked Meadow Grass.

Best excluded
Perennial Rye grass S.24, Creeping Red Fescue, Brown Top, Meadow Foxtail, Red Clover.

Patella
(adjective, Patellar)
Patella is the sesamoid bone that lies at the front of the 'stifle joint', and is called the 'knee-cap'. It lies in the tendon of the large extensor muscles of the joint, just above and in front of the true femorotibial joint. It is roughly pyramidal in the horse, with the apex of the pyramid pointing downwards. It is dislocation of the patella that constitutes the condition known as 'slipped stifle'. Fractures can occur but are relatively uncommon. (See BONE.)

The patella is not present in amphibians, and many species of reptiles, but is well developed in birds and lizards.

Indications for surgery of the canine stifle are congenital medial luxation and rupture of the anterior cruciate ligament.

Congenital patellar luxation occurs also in cats, rendering them unable to walk normally or jump.

Patellar Luxation, Patellar Dislocation
Dislocation of the patella (patellar luxation) may occur as an inherited abnormality in certain breeds of dogs, e.g. AMERICAN COCKER SPANIELS, BOSTON TERRIERS, BOXERS, BULLDOGS, CAIRN TERRIERS, CHIHUAHUAS, WIRE-HAIRED FOX TERRIERS, FRENCH BULLDOGS, GRIFFON BRUXELLOIS, ITALIAN GREYHOUNDS, JACK RUSSELL TERRIERS, KING CHARLES SPANIELS, PEKINGESE, PHARAOH HOUNDS, LABRADOR RETRIEVERS, MALTESE, PAPILLONS, POMERANIANS, POODLES, SCOTTISH TERRIERS, SHARPEIS,YORKSHIRE TERRIERS.

Congenital patellar luxation occurs also in cats including the MAINE COON breed, rendering them unable to walk normally or jump. (See also SLIPPED STIFLE). Other species show it, including horses, ponies (relatively common in SHETLAND PONIES) and cattle.

Patent Ductus Arteriosus
An abnormality in which the ductus arteriosus, between the aorta and the pulmonary artery, fails to close at or shortly after birth. This condition has been recognised in the puppy, and gives rise to a characteristic murmur on auscultation; and also in cattle and cats. Several breeds of dog are prone to it including AMERICAN COCKER SPANIELS, GERMAN SHEPHERD DOGS, POMERANIANS, POODLES, ROUGH COLLIES, SHETLAND SHEEPDOGS. (See LIGAMENTUM ARTERIOSUM.)

Pathetic Nerve
The trochlear nerve. It is the 4th nerve arising from the brain and controlling the superior oblique muscle of the eye.

Pathogen
A disease-producing agent or organism.

Pathogenic
Disease-producing.

Pathognomonic
Pathognomonic is a term applied to those signs which are characteristic of a particular disease, and on whose presence or absence the diagnosis depends.

PCR
(See POLYMERASE CHAIN REACTION.)

PCV
Abbreviation for PACKED CELL VOLUME. (See under BLOOD - COMPOSITION; HAEMATOCRIT VALUE.)

PCV2
(See PORCINE CIRCOVIRUS TYPE II.)

PDD
(See PROVENTRICULAR DILATION DISEASE.)

PDSA
(See PEOPLE'S DISPENSARY FOR SICK ANIMALS.)

Peas, Mutter
(See LATHYRISM.)

'Peat Scours'
'Peat scours' is a name given in Australasia and Canada to MOLYBDENUM poisoning in grazing cattle. Excess molybdenum is found in several parts of the UK, in particular the 'teart pastures' of the Somerset levels. (See MOLYBDENUM.)

Pebble Plant
(See MESEMBRYANTHEMUM.)

VetBooks.ir

Peck Order, Pecking Order
This is the equivalent in poultry of the order of precedence described under BUNT ORDER.

PED
(See PORCINE EPIDEMIC DIARRHOEA.)

Pedal Bone
Pedal bone, or coffin bone, is the bone enclosed within the hoof of the horse, ruminants etc. It is also called the first phalanx.

Pediculosis
Pediculosis is infestation with lice.

Pekin Bantam Chickens
A true BANTAM CHICKEN breed, which does not also have a fowl of large size. It is shorter than the ordinary bantam and only 20 cm to 30 cm (8 in to 12 in) high. The legs and feet are covered with feathers. The colours include black, white, buff, lavender, mottled and red. The hens are quiet but the cockerels can be aggressive. The cock weighs 680 g (1.5 lb) and the hen 570 g (1.25 lb). They can become broody and are good sitters for other hens' eggs.

Pekingese
A toy dog originating from China. It has long straight hair, snub nose and pendulous ears. The eyes are protuberant and prone to dislocation if the animal is not handled correctly. They should never be lifted by the scruff of the neck for this reason. Its shape predisposes the breed to CLEFT PALATE, INGUINAL HERNIA, INTERVERTEBRAL DISC PROTRUSION, PERTHES DISEASE, and RETROGNATHIA (underdeveloped lower jaw). NICTITATING MEMBRANE GLAND PROLAPSE, DISTICHIASIS and PATELLAR LUXATION may be inherited. Because of its bulbous eyes, the breed is susceptible to CORNEAL ULCERATION. (See EYE, DISEASES AND INJURIES OF.)

Pelage
The collective name for the hairy coat of mammals be it hair, fur or wool over the whole body, limbs and head.

Pellagra
(See 'BLACK TONGUE'.)

Pellets
(See CUBES AND PELLETS.)

Pelodera Dermatitis
(See under HOOKWORM DERMATITIS.)

Pelvis
The pelvis is the posterior girdle of bones by which the two hind-limbs are attached to the rest of the skeleton. It is composed of two ilia, two pubes, and two ischia, united together by fusion into a basin-shaped whole (see BONE). Strictly speaking, it includes the sacrum and the coccygeal vertebrae. The two 'haunch bones' are the external angles of the ilia; the 'croup' is composed of the internal angles of these bones along with the spines of the sacrum; and the 'points of the buttocks' are the tuberosities of the two ischia. The pelvis is spoken of as having an 'inlet', formed by the brim of the pubes, and an 'outlet' posteriorly. In the living animal the outlet is occupied by the soft tissues forming the perineal region, except for the anus in the male and the anus and vulva in the female. The deep notch between the sacrum and the haunch bone is closed by the sacrosciatic ligaments, upon which lie the gluteal muscles which give the quarters their shape. The pelvis varies in the two sexes: in the female it is broader from side to side, and deeper from above downwards, than in the male; this difference being chiefly necessary to allow of the act of parturition.

The contents of the pelvis are the rectum and urinary bladder in both sexes (except in the dog, where the urinary bladder is abdominal in position). In the male there is, in addition, the prostate gland and the seminal vesicles around the neck of the bladder and the beginning of the urethra; while the female pelvis contains the vagina, uterus, their appendages and, perhaps, the ovaries.

Pemphigus
An autoimmune disease of dogs also seen in cats and horses. It can take various forms: in *Pemphigus vulgaris*, lesions affect the mucous membrane lining the mouth, and the junction with the lips, giving rise to ulcers. Sometimes the pads of the feet are affected. *P. erythematosis* is characterised by crusty lesions on and around the nose, and elsewhere on the face.

In *P. vegetans,* alopecia and pruritus follow pustules which ulcerate on the body and extremities.

P. foliaceus is common in cats, dogs and horses, resulting in loosening of the bonds between skin cells. This leads to pustules starting on the nose, around the eyes or on the ears but they then can spread to the body and legs.

Treatment is with corticosteroids; cytotoxic drugs are also used. Nicotinamide and OXYTETRACYCLINE can be effective, especially for GERMAN SHEPHERD DOGS with lesions of the nasal mucocutaneous junction. The prognosis in severe cases is not good, but sometimes the signs can be reduced.

Penenthamate
A penicillin ester, used as the hydriodide compound in intramammary preparations. It has a

similar activity to procaine penicillin but it might be more active against *Corynebacterium bovis*.

-penia

A suffix meaning too few, less than normal. (See LEUKOPENIA for an example.)

Penicillin

The first of the antibiotics, discovered by Sir Alexander Fleming in 1929. Benzyl penicillin (penicillin G) was the original preparation to be introduced for clinical use and remains widely effective against Gram-positive bacteria. It is the sodium or potassium salt of the antimicrobial acids produced when the moulds *Penicillium notatum* or *Chrysogenum* (or related species) are grown under suitable conditions.

Purified penicillin salts occur as a white crystalline powder, readily soluble in water.

Following injection into the animal body, penicillin is rapidly absorbed and diffused in the bloodstream throughout the body, being excreted by the kidneys. It is non-poisonous even in large doses (although allergic reactions are not uncommon) and is effective against:

Staphylococci, which causes local pyogenic inflammation as primary or secondary infections.
Haemolytic streptococci, which usually causes localised infections either primary or secondary.
Streptococcus equi, the cause of STRANGLES in horses.
S. agalactiae, causing mastitis in cattle.
Bacillus anthracis, the source of anthrax.
Clostridium chauvoei, causing blackleg (BLACK-QUARTER) in cattle.
Corynebacterium renale, causing PYELONEPHRITIS in cattle.
Erysipelothrix rhusiopathiae, causing SWINE ERYSIPELAS.
Actinomyces bovis, causing ACTINOMYCOSIS.
Leptospira canicola, causing LEPTOSPIROSIS in dogs.
Treponema cuniculi, the cause of 'RABBIT SYPHILIS'.

Penicillin is of value in the treatment of wounds and for the prevention of sepsis in surgery.

It is of great importance that penicillin should be used in full doses; otherwise there is a risk of strains of bacteria resistant to penicillin being developed. The appropriate dosage for systemic administration varies with the species being treated. All types of penicillin preparation may cause allergic reaction in some animals.

Types of penicillin *Benzylpenicillin (Penicillin G):* The original penicillin, and still useful. Active against most Gram-negative bacteria including *Staphylococcus aureus*, streptococci, *Actinomyces* spp., *Erisipelothrix* and *Baccilus* spp. and some Gram-negative organisms including *Clostridia* and some *Haemophilus*, *Pasteurella*, *Leptospira* and *Actinobacillus* spp. Inactive if administered by mouth. Rapid but short duration of activity by injection. Should not be given to gerbils, guinea pigs, hamsters or rabbits.

Benzathine Benzylpenicillin: Prolonged action after intramuscular injection.

Amoxicillin: Broad spectrum antibiotic, similar action to ampicillin; slightly less active but better absorbed when given orally. Should not be given to horses. The combination of amoxillin with clavulanic acid potentiates the action of the two substances by blocking the action of penicillinase.

Semi-Synthetic Penicillins *Ampicillin:* Broad spectrum antibiotic, active against most Gram-negative organisms; should be given on empty stomach.

Flucloxacillin: Active orally against β-lactamase (penicillinase)-producing staphylococci - the drug's only indication.

Phenoxymethyl penicillin (penicillin V): Similar bacterial action to benzylpenicillin; is less active, but stable to acids so is suitable for oral administration.

Procaine benzylpenicillin: Longer action after injection than benzypenicillin; may cause fever and abortion in sows affected with Erisepelothrix.

(See also CEPHALOSPORIN ANTIBIOTICS, TETRACYCLINES.)

Penicillin, Sensitivity to

People handling penicillin suffer a risk of sensitisation, shown by skin lesions. There is danger in the use of milk containing penicillin (e.g. milk from quarters of the udder treated for mastitis), especially in people sensitised to penicillin. Extremely severe skin lesions, and accompanying illness, have been caused in this way among farmers and others. (See also under MILK Antibiotics in milk.) Hypersensitivity to penicillins has been recorded also in cattle and other animals, including cats.

Penicillinase, Beta-Lactamase

A penicillin-destroying enzyme produced by certain bacteria, including strains of *E. coli*. Its activity is blocked by clavulanic acid which is added to some semi-synthetic penicillins to make them effective against such bacteria.

Penicillin in Milk

(See PENICILLIN, SENSITIVITY TO.)

Penile

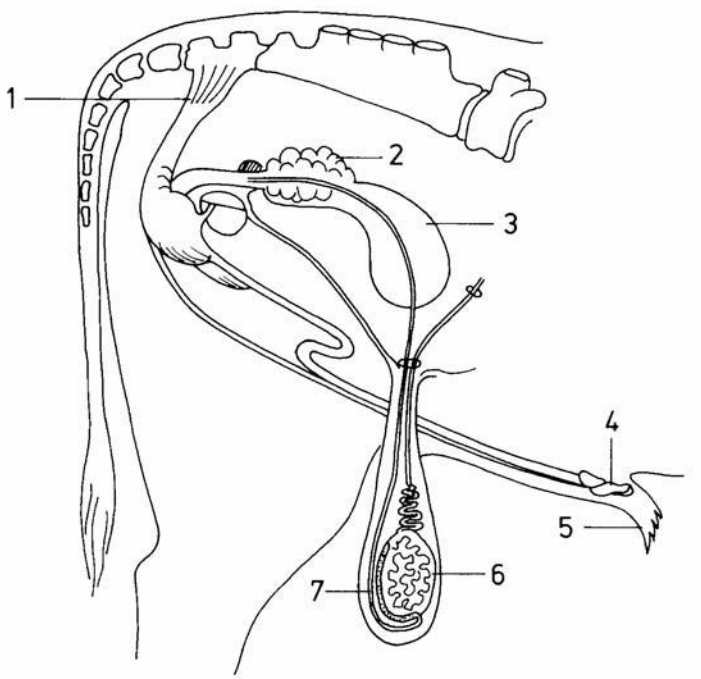
Related to, or of, the penis.

Penis

The male genital organ, The penis is attached by roots (crura) to the ischial arch of the pelvis. From the roots extends the body of the penis along the interior of which runs the urethra, for the passage of urine and semen. Erection of the penis depends upon the increased flow of blood into the spongy, erectile tissue in the body of the penis, and simultaneous decrease in relative outflow from the veins, partly as a result of contraction of the ischiocavernosus muscles. The bull, ram and boar each have a sigmoid or S-shaped curve in the penis. On erection this curve is straightened. The penis increases in length but not much in girth. In the stallion and dog, in which the penis is straight, erection brings an increase in girth to a greater extent. The os penis in the dog is a grooved bone within the glans penis, which is the terminal portion of the penis (except in the boar). The shape of the glans differs in the other species as regards shape. The penis of the cat is a frequent site of urethral obstruction owing to its very small diameter. Sand-like deposit, a calculus, plug of organic and crystalline deposit, or (very occasionally) a grass seed may cause blockage. In some cases manipulation of the penis may allow the passage of urine; otherwise the use of a catheter may be tried. The penis has no excretory function in the taxonomic orders Aves and Reptilia and is replaced by the PHALLUS in birds and by the HEMIPENIS in reptiles, except in CHELONIA in which the term penis is used.

(See UROLITHIASIS.)

Penis and Prepuce, Abnormalities and Lesions



These include the following conditions:

Necrosis of the prepuce has been recorded in pigs kept in poor hygienic conditions. There is no indication that the condition causes pain or distress.

Phimosis A narrowing of the orifice of the prepuce, preventing normal protrusion of the penis. Congenital phimosis is occasionally seen in dogs, cats, and horses. It can be corrected surgically.

Paraphimosis A condition in which the penis cannot be retracted into the prepuce. This is not uncommon in the dog, and is potentially serious unless quickly relieved, owing to interference with the circulation. As a first-aid measure, immerse or wash the penis with ice-cold water.

Prolapse of the penis due to paralysis is seen in bulls which have rabies, and also as a chronic condition in Zebu cattle (*Bos indicus*) and occasionally in breeds of UK origin.

Genitalia of the bull: 1, muscles which controls penis; 2, vesicles which store semen; 3, bladder; 4, penis; 5, sheath which covers penis; 6, testicle; 7, epididymis.

VetBooks.ir

Horses Prolapse of the penis may follow use of ACEPROMAZINE (to effect relaxation of the retractor muscles so that swabbing can be undertaken for contagious equine metritis). In six cases involving protrusion, oedema and paresis of the penis, four of the horses had received acepromazine with etorphine hydrochloride, and two had received the former drug along with others.

After such drugs have been used, it is important to check that retraction of the penis is taking place as the effects of medication wear off. If not, treatment should be started without delay.

Priapism A persistent erection of the penis unassociated with sexual stimulation. (See also PRIAPISM.)

Balanitis Inflammation of the glans penis – the cap-shaped spongy tissue at the end of the penis, normally covered by the foreskin.

Posthitis Inflammation of the prepuce.

Balanoposthitis A viral infection affecting both the penis and the prepuce. One example is an enzootic form, called 'pizzle rot' or 'sheath rot', of sheep (especially merinos) in Australia. *Corynebacterium renale* is the primary cause.

A herpesvirus also causes balanoposthitis in cattle and sheep.

An infectious balanoposthitis (also known as 'ulcerative dermatosis') of sheep may affect not only the penis, prepuce and vulva but also the face, feet and legs; this has to be differentiated from ORF. It occurs in Europe and South Africa. In lambs mortality may be up to 30 per cent.

Tumours of the penis include WARTS (papillomas) and also, in dogs, infective granulomas. (See VENEREAL TUMOURS.)

Traumatic lesions include injury to the penis from a kick by the cow or mare at service, or when a bull proves too heavy for a heifer. There is usually an accompanying haematoma. Trauma may also result in adhesions at the sigmoid flexure. In dogs a fracture of the os penis may occur as the result of being hit by a car.

Spiral deviation of the penis occurs in bulls. Service is prevented. (In the USA deviation of the penis is sometimes deliberately produced surgically in teaser bulls.)

Fur Ring A condition of the Chinchilla (*Chinchilla laniger*) in which a ring of fur around the penis leads to engorgement of the penis, similar to paraphimosis in other species.

Penitrem A

A mycotoxin. It was isolated from mouldy cream cheese from a refrigerator given to a dog which became very ill with ataxia, muscular tremors, and opisthotonus. The mould was identified as *Penicillium crustosum*.

Pentastomiasis

Infection with the nymphs of the pentastomid *Armillifer armillatus*, the adults of which infest snakes in Africa and Asia.

The disease has been recognised in man, dog and cat.

Signs Abdominal or thoracic oedema.

Infection occurs through drinking water contaminated by the eggs, or eating a snake.

Diagnosis In human medicine this is based on the radiographic appearance of calcified nymphs.

Pentobarbitone Sodium, Pentobarbital

(Sodium ethyl/methylbutyl barbiturate). A white crystalline powder, soluble in water, and used for its narcotic and anaesthetic effects.

First used as a general anaesthetic in veterinary surgery in America in 1931. A proprietary name is Nembutal.

Pentobarbitone has been used to produce anaesthesia in all the domestic animals including the fowl, but it is not recommended for horses, calves, or sheep. For anaesthesia in the dog and cat, however, pentobarbitone is very extensively employed, and is usually given by the intravenous route – a method which permits of varying depths of anaesthesia being obtained and the avoidance of overdosage. The drug may also be given by intraperitoneal injection or by mouth; narcosis being then slower in onset (eight to 20 minutes), and occasionally preceded by some degree of excitement, while the dose has to be an estimate calculated on the basis of bodyweight.

Deep anaesthesia with pentobarbitone may last for an hour, being followed by two to seven hours of narcosis. It has mainly been superseded by other general anaesthetics. (See ANAESTHESIA, GENERAL; EUTHANASIA.)

Pentosan Polyphosphate Sodium

An anti-inflammatory agent with an affinity for cartilage. It is given subcutaneously in the case of osteoarthritis and musculoskeletal problems in the dog.

Pentoses

Naturally-occurring sugars (monosaccharides) containing five carbon atoms; e.g. arabinose, ribose. (See HEXOSES.)

People's Dispensary for Sick Animals
Address: Whitechapel Way, Priorslee, Telford, Shropshire TF2 9PQ. Telephone: 01952 204713; website: www.pdsa.org.uk.

'Pepper and Salt Deposits'
A deposit seen on the skin, usually described in companion animals. It consist of skin debris and parasite, usually insect, faeces giving the effect.

Pepsin
Pepsin is an enzyme found in the gastric juice which digests proteins.

Peptides
Peptides are composed of two or more amino acids, and represent an intermediate stage in the digestion of protein.

Polypeptides are proteins composed of several amino acids linked by the peptide grouping CH–CO–NH–CH.

Synthetic polypeptides have potential uses as vaccines, e.g. against FOOT-AND-MOUTH DISEASE.

Peptide Tyrosine Tyrosine
(See PANCREATIC PEPTIDE YY_{3-36}.)

Peptide YY
(See PANCREATIC PEPTIDE YY_{3-36}.)

Peptococcus indolicus
A Gram-positive bacterium which is sometimes a complicating factor in CASEOUS LYMPHADENITIS of sheep and summer mastitis in cattle (see MASTITIS IN COWS, SUMMER MASTITIS).

Peracetic Acid
An organic compound used as a disinfectant and cleansing agent which removes the outer layers of micro-organisms. It can be used as a teat cluster flushing disinfectant following automatic removal, and a teat disinfectant.

Peracute
A condition is called peracute when it is very ACUTE and occurs within a short time period (few hours). (See also ACUTE, CHRONIC, SUBACUTE.)

Percheron Horses
These are classified as HEAVY HORSES and were originally bred in Belgium as draught horses. They normally stand 16 to 18 HANDS high. They are grey in colour and have clean (non-feathered) legs. They are the nearest modern breed of horse to resemble the medieval 'War Horse'.

Perforation
Perforation is one of the serious dangers attached to the presence of ulcerating conditions in the stomach and bowels. When a perforation of one of these hollow organs takes place in the peritoneal cavity, multitudes of bacteria, much ingesta, mucus and other noxious materials escape and set up PERITONITIS. The immediate signs are a collapse of the patient, with, later, collections of gas or fluids in the abdominal cavity. It is not uncommon to observe vomiting in the horse when the stomach ruptures and the contents escape into the abdominal cavity; this is one of the very rare times when the horse is seen to vomit, and it is accordingly very important.

Performance Lifetime Index
A measure of the genetic value of an animal. It involves measuring what is produced and how many years the animal has remained productive. It can assess why animals produce well but only remain in a herd a short time. Thus, in animals producing food the volume of milk produced or eggs produced are good indicators and for those used for breeding the number of calves, viable piglets or lambs is a useful guide. It can be used in most farm animals especially cattle, pigs, poultry and sheep. By varying the inputs it can be used for both males and females.

Performance Testing
A method of comparing strains or breeds of, e.g. beef cattle, by studying liveweight gains over a stated period with given rations. (See also PROGENY TESTING.)

Peri-
Peri- is a prefix meaning round, or about. Examples: PERICARDIUM; perianal abscess.

Perianal Fistula
(See ANUS - PERIANAL FISTULAE.)

Perianal Furunculosis
(See ANUS - PERIANAL FURUNCULOSIS.)

Perianal Glands
(See ANUS - ANAL GLANDS; CIRCUMANAL GLANDS.)

Pericardial
Related to, or of, the PERICARDIUM.

Pericardial Effusion
A condition seen in small animals; the clinical signs are muffled heart sounds and DYSPNOEA. An x-ray image of the chest will usually help diagnosis. An attempt should be made to withdraw fluid from the pericardium as this is one of the

manifestations of tuberculosis in these animals. (See also HEART DISEASES.)

Pericardiectomy
The surgical removal of the PERICARDIUM. (See also HEART DISEASES.)

Pericarditis
Inflammation of the pericardium. Traumatic pericarditis is common in cattle as a result of swallowing pieces of wire, nails, etc. (See also HEART DISEASES.)

Pericardium
Pericardium is the smooth lubricating membrane which surrounds the heart. (See also HEART DISEASES.)

Peridontitis
Reaction to dental plaque resulting in gingivitis and then inflammation of the deeper tissues. (See MOUTH, DISEASES OF.)

Perinatal Asphyxia Syndrome (PAS)
A condition in which the foal is born normal but becomes abnormal within 48 hours. It is usually the result of lack of oxygen (HYPOXIA) to the brain. There are many causes, often pregnancy and foaling problems are responsible. Supportive therapy is used with a good chance of recovery.

Perineum
Perineum is the region lying between the anus and the genital organs in the male, and lying between the anus and the mammary region in the female of the horse, ox, sheep, goat, and pig. In bitches and cats the female genital organs lie lower than in other animals, and in them the perineum lies between the anus and the vulva.

Rupture of the perineum sometimes occurs in the cow at calving, when the fetus over-distends the vulva. Suturing, under local anaesthesia, is usually required.

Periodic Ophthalmia
Specific ophthalmia, or 'moon blindness', is a condition of the eyes of horses, due to inflammation of the uveal tract (especially of the iris and ciliary body) which is characterised by a tendency to recur.

Causes It is a chronic immune-mediated eye disease. There is still doubt about specific antigens, but it is known that LEPTOSPIROSIS is one. Some two to eight months after acute leptospirosis, periodic ophthalmia appears in up to 45 per cent of the horses affected. Leptospires have been isolated from eye lesions over long periods.

Signs In the first stage a horse is found one morning with the eyelids on one side half-closed; tears run from the eye down the face, and any effort to examine the eye is resented. Bright light is avoided, and the eyeball appears sunken in the socket. This period of inflammation may last up to ten days, after which it gradually disappears and the eye returns to practically its normal appearance. However, repeated attacks are apt to occur: total blindness and/or lesions of the retina may follow. Periodic ophthalmia is common in Europe, the USA and Asia.

Treatment of periodic ophthalmia is directed to reducing inflammation with topical ocular preparations and sometimes systemic ANALGESICS. An optical implant impregnated with CYCLOSPORIN can reduce flare-ups.

Periodontal
(See TEETH, DISEASES OF.)

Perioperative
Relating to or around the operation period.

Periople
(See FOOT OF THE HORSE.)

Periosteal
Relating to the periosteum.

Periosteum
Periosteum is the membrane surrounding a bone. The growth of a bone in its thickness is due to the action of the cells of this membrane forming fibrous tissue in which lime salts are deposited. (See BONE.)

Periostitis
Periostitis means inflammation on the surface of a bone affecting the periosteum. (See BONE, DISEASES OF.)

Periparturient
Used to describe any condition occurring shortly before or shortly after birth.

Peripheral Tolerance
This is a mechanism by which young T cells are removed from the circulation by the thymus. Failure of this mechanism results in auto-immune disease.

Periphery
(adjective, Peripheral)

1. The outside or outer part or surface of an organ.
2. It is used in computing as a shortening of 'peripheral equipment', such as a keyboard, monitor, disk drive or printer.

Peristalsis
Peristalsis is the succession of involuntary muscular contractions which propel ingested food along the alimentary canal. (See INTESTINES.)

Peritoneum
The peritoneum is the membrane lining the abdominal (or peritoneal) cavity of mammals and the COELOM of birds and reptiles, and forming a covering for the organs contained in it. That part lining the walls of the cavity is called the 'parietal' peritoneum, and that part covering the viscera is known as the 'visceral' peritoneum. Between the two parts is a film of lubricating liquid.

Peritonitis
Inflammation of the PERITONEUM. It may be either localised or diffused.

Acute peritonitis

Causes The direct cause of acute peritonitis is nearly always the invasion of the membrane by micro-organisms. It occurs through a wound in the abdominal wall, in the stomach or intestines, uterus, bladder, etc., or through the spreading of inflammatory conditions from one or other of these parts. It may follow castration, when the infection gains entrance by the inguinal canal. Peritonitis may occur during the course of ANTHRAX, acute TUBERCULOSIS, etc.

Signs These include restlessness and signs of distress and pain. Horses and cattle usually remain standing, but the smaller animals lie almost continually. The temperature is raised by 5° C to 10° C (3° F to 6° F), and the pulse is quick, small, and wiry. Faeces and urine are usually retained and lead to further complication, and vomiting in dogs is common. Pressure over the sides of the abdomen is painful; the animal usually tenses the muscles of the abdomen, and may groan or grunt. As the disease progresses, fluid may be thrown out into the cavity in great quantities, leading to ASCITES. (See OEDEMA and PARACENTESIS.)

Treatment Operative treatment and drainage may be undertaken.

Antibiotics and/or sulfonamides may be given by injection. Hot fomentations to the abdomen relieve the acute pain. The prognosis is seldom good.

Chronic peritonitis

Causes Slowly-forming abscesses in the liver, tuberculous lesions in the peritoneal cavity, foreign bodies in the reticulum, etc.

Signs There may be slight attacks of pain at times, but very often it is only after death that the condition is discovered. Ascites and a gradual loss of condition may be seen.

Treatment This will vary according to the nature of the infection or of adhesions, but antibiotics are usually indicated.

Permethrin
A synthetic pyrethroid (derivative of pyrethrum) used as an insecticide in many companion animal and farm species. Excessive applications to cats can induce hyperaesthesia, with excitement, a staggering gait, muscular twitching, and occasional collapse. Treatment is by sedation or anaesthesia using preparations such as PROPOFOL, often combined with other anaesthetics. Muscle relaxation with METHOCARBAMOL may be helpful. (See INSECTICIDES; FLIES - FLY CONTROL MEASURES.)

Pernicious Anaemia
This anaemia is mainly seen in humans and is due to Vitamin B_{12} deficiency caused by a lack of cells lining the stomach wall which secrete intrinsic factor necessary for the absorption of the vitamin in the ileum. It is also used incorrectly for any other megaloblastic anaemia caused by Vitamin B_{12} deficiency. It was initially shown experimentally in dogs and in horses. (See EQUINE INFECTIOUS ANAEMIA – a condition in horses also known as PERNICIOUS EQUINE ANAEMIA.)

Pernicious Equine Anaemia
Another name for EQUINE INFECTIOUS ANAEMIA. An acute and chronic viral disease with intermittent fever, loss of weight, progressive weakness, OEDEMA, depression, intermittent and transitory or progressive ANAEMIA. There is HEPATITIS.

Peromelia
A congenital absence or deformity of the terminal part of a limb or limbs.

Peroneal
Relating to the fibula or the outer side of the leg or shank.

Perosis
(See under 'SLIPPED TENDON'.)

Perruque Antlers
Perruque antlers describes a defect in antler growth in red deer where the antlers form clumps close to the head. In severe cases, the animal has the appearance of wearing a judge's wig, hence the name.

VetBooks.ir

Persian Cats

This is a term used to describe long-haired cats. These cats are BRACHYCEPHALIC and this can make it difficult for the queen to bite through the umbilical cord when giving birth, resulting in umbilical hernia. Some are born with polycystic kidney disease (DNA test available) and the cysts enlarge causing kidney failure. HYPERTROPHIC CARDIOMYOPATHY and MANNOSIDOSIS (DNA tests available) are also present. Some breeds within this group, such as the Himalayan, are prone to hip dysplasia. (See under HERNIA - UMBILICAL HERNIA; KIDNEYS, DISEASES OF - POLYCYSTIC KIDNEY DISEASE.)

Persistent

A condition in which an embryonic development organ or entity does not reduce but remains until birth. It can happen with a variety of organs.

Persistent Hyperplastic Primary Vitreous

This results from the retention of parts of the fetal vascular supply to the lens of the eye, the tunica vasculosis lentis. It can result in a variable amount of vascular residue (opacity) on the posterior lens capsule to possible posterior cortical cataracts. Lens extraction is complicated by the blood vessel involvement. It is seen in all species; in dogs, it is relatively common in the DOBERMANN PINSCHER.

Persistent Pupillary Membrane

(See under PUPILLARY MEMBRANE, PERSISTENT.)

Persistent Right Aortic Arch

A developmental abnormality seen at birth, in which the persistent fourth right aortic arch causes constriction of the oesophagus. It can happen in all species and is recorded in cattle and dogs, particularly GERMAN SHEPHERD DOGS. Signs include regurgitation, DYSPHAGIA and inhalation pneumonia and BLOAT in ruminants.

Perspiration

The excretion of sweat on the skin from sudiferous glands (See SKIN). There are two types of gland: exocrine or unbranched, coiled glands which excrete onto the skin in response to nerve impulses; and apocrine glands which excrete onto the hair shaft in response to the action of ADRENALIN. Sweat is composed of water, SODIUM CHLORIDE and UREA. The rate of sweating varies from species to species, with the horse being the most profuse and dogs and small mammals the least. Sweating assists in controlling body temperature by cooling the skin. Sweat glands also produce PHEROMONES. (See SKIN - THE DERMIS (CORIUM), SWEAT.)

Perthes Disease

It is sometimes called Von Perthes disease or often Legg-Calvé-Perthes Disease of Legg-Calvés disease. It is a defect of the femoral head common in certain small breeds of dogs including MINIATURE SCHNAUZER DOG. (See LEGG-CALVÉ-PERTHES DISEASE.)

Pervious Urachus

Pervious Urachus is a failure on the part of the umbilicus to close at or before birth. In the condition, which is also popularly called 'leaky navel', there is a continual dribbling of urine and serum from the navel.

Before birth the urinary bladder is in direct communication with the fluid in the allantoic sac, and the fetal urine which is formed escapes into this sac, thus preventing over-distension of the bladder. Immediately before the young animal is born, this communication is narrowed down to only a very small passage, and at birth either it is already closed, or it has practically ceased to function as a means of escape for the urine. With the tying of the umbilical cord – or with the shrinkage that follows exposure of this structure to the air – the urachus, which hitherto has connected the bladder with the outside of the animal's body, becomes quite impervious in the normal animal, and the urine now escapes by the urethra or natural passage to the outside. In pervious urachus this closure does not take place, and there is a continual dribble from the region of the umbilicus. The fluid tends to blister the skin of the surrounding area, and causes considerable discomfort, besides being very unsightly. Surgical treatment is necessary.

Pessaries

Pessaries, or vaginal suppositories, are a means of administering drugs into the uterus. The medicaments are formulated in a base, traditionally of cocoa butter or gelatine, so that they may gradually liquefy and liberate their active substances. In some instances pessaries are made with dry powders of the active ingredients filled into gelatine capsules.

Peste Des Petits Ruminants (PPR)

A highly contagious disease of sheep and goats; similar to rinderpest, it causes high mortality. The cause is a paramyxovirus. It is a NOTIFIABLE DISEASE throughout the EU.

Signs A foul oculo-nasal discharge, diarrhoea, severe STOMATITIS and BRONCHOPNEUMONIA.

Prevention Vaccination can be used to assist in control in epidemics.

VetBooks.ir

Pesticides
Current pesticide testing determines whether or not pesticides kill beneficial insects. However it is unlikely to detect subtle changes in bee behaviour. Neonicotinoid pesticides, used to protect major crops, can be harmful to bees. Thus IMIDACLOPRID slowed spring population growth and reduced queen numbers. Thiamethoxam appeared to affect navigation ability of bees after foraging. (See also BEES.)

Pestivirus
(See BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE; 'BORDER DISEASE' OF SHEEP; SWINE FEVER; EQUINE VIRAL ARTERITIS.)

Pet Animals Act 1951
Pet Animals Act 1951 covers the licensing of pet shops, and the conditions under which animals are kept there and offered for sale.

Pet Bereavement Support Service
A counselling service for people whose pets have died is operated jointly by the animal charities Blue Cross and Society for Companion Animal Studies. The telephone helpline is open between 08.30 and 20.30 every day; the number is 0800 096 6606.

Petechiae
Petechiae are small spots on the surface of an organ or the skin, generally red or purple in colour and resembling flea-bites. They may be minute areas of inflammation or they may be small haemorrhages. (Petechial fever is another name for PURPURA HAEMORRHAGICA.)

Pet Foods
Pet foods come under the Feeding Stuffs (Sampling and Analysis) Regulations 1982. The Feeding Stuffs Regulations 2000 list the special diets which are permitted. Together, these regulations satisfy the requirements of the appropriate EU directives. (See illustration on next page, and see also DIET AND DIETETICS; DOGS' DIET; CAT FOODS, etc.)

Pethidine, Meperidine
An analgesic (pain reliever) used for dogs and cats. It may also be used in rabbits and rodents and for the relief of the pain of colic in horses. (See MEPERIDINE.)

Pet Insurance
This is often taken out by owners for companion animals such as dogs, cats, exotic animals and horses. In 2012, about 20 per cent of owners insured their pets. In 2013, in the UK there were over 420 policies involving about 18 to 19 underwriters, most or all of which have insurance interests.

Petit Basset Griffon Vendeen Dogs
A French breed bred to hunt hares in rough bramble-filled terrain. They are sturdy, short thick-boned legged dogs with a slightly long body. The coat is long, rough, and thick mainly coloured white with spots often of grey and white (grizzle), black, orange, lemon or sable. GLAUCOMA is common and officially tested for and recorded in British-bred animals.

Petlog
A UK national scheme for identifying pets by microchipping. The Petlog Reunification Service helps to trace lost microchipped animals and reunite them with their owners. Telephone: 0844 463 3999 at any time, if animal lost. Administration Office: Petlog, The Kennel Club, 4A Alton House, Gatehouse Way, Aylesbury, Bucks HP19 8XU. Telephone: 01296 337517; email: petlogadmin@thekennelclub.org.uk

Pet Ownership
In 2013, 41 per cent of UK households owned at least one dog and/or one cat, the same as in Europe but with France having 49 per cent pet ownership. The UK has 0.73 pets per household, and the USA 1.25.

Petri Dish
A shallow circular glass dish with lid in which bacteria are grown on a solid medium.

Pets, Children's and Exotic
For information on the breeding, care, diseases and treatment of mice, rats, rabbits, hamsters, guinea pigs, gerbils, reptiles, fish, birds, and monkeys, the reader is referred to the British Small Animal Veterinary Association's *Manual of the Care and Treatment of Children's and Exotic Pets*. (See also under CAGE AND AVIARY BIRDS, DISEASES OF; MONKEYS; HAMSTERS; GUINEA-PIG; AMERICAN BOX TORTOISES; TORTOISES; PIGS Foreign breeds; CHINCHILLAS; also ANAESTHESIA, GENERAL

PET Scan
The PET part is an acronym for Positron Emission Tomography. An injection of a radioactive tracer is administered, which is usually FLUDEOXYGLUCOSE, and the body treats it and metabolises it in the same way as GLUCOSE. The procedure allows evaluation as to how different parts of the body are dealing or not with glucose. The tracer releases particles known as positrons, which are antimatter. A positron is attracted to an electron and they then mutually destruct, giving off γ-waves, and it is these waves that are detected by the machine and a two-dimensional image of

VetBooks.ir

Pet food being prepared at the Waltham Centre for Pet Nutrition, research facility for a major pet-foods manufacturer. Products are developed and tested to ensure that dogs and cats obtain complete and balanced nutrition from these foods.

organs is produced. Some modern machines can undertake PET scans and CAT SCANS at the same time.

Pet Travel Scheme (PETS)

An arrangement by which cats, ferrets and dogs may travel to and from European Union countries, Norway, Australia, New Zealand, Japan, and certain islands in the Atlantic and the Caribbean without having to go into quarantine. This was made possible under the Pet Travel Scheme (Pilot Arrangements) Order 1999. Amended regulations came into operation on 1 January 2012 from the EU and about 50 other countries. Strict conditions apply: the animals must have been vaccinated against DISTEMPER and RABIES after being identity microchipped, the last vaccination being at least 21 days before import. The animal must have an official EU Passport, or an official veterinary health certificate from a veterinary surgeon certifying the microchip presence and the dates of vaccination. Where an animal is imported from 'non-approved' countries then the animal must be blood tested 30 days after final vaccination for RABIES and shown to be adequately protected. From these countries the official veterinary certificate must include the result of the rabies blood test titre. In addition import is not allowed until three months after the blood sample has been taken.

Prior to arrival in Britain, all animals must have been wormed, especially against the tapeworm *Echinococcus multilocularis,* and have been treated for the presence of ticks. Animals must be treated for E. multilocularis by a veterinary surgeon 24 to 120 hours (one to five days, but ideally within 48 hours) before they enter Britain or another country with the EU derogation (UK, Ireland, Finland, Malta). Failure to observe those requirements will lead to the animal being quarantined. From 2000 to 2011, 864,707 animals had travelled to the UK under this Scheme without being quarantined. In 2003 alone, there were 48,329 dogs and 5838 cats. In 2011, the Scheme catered for 85,774 dogs, 8,279 cats and 68 ferrets.

Companies operating the scheme have to provide trained staff to deal with checking animals and make available adequate facilities for handling them.

Details are available from Animal Health, Pet Travel Scheme (PETS) Section, Government Offices, Beeches Road, Chelmsford CM1 2RU. The PETS Helpline, telephone: 0870 2411710; fax: 01245 351 162; email: quarantine@defra.gsi.

gov.uk or from the DEFRA website at www.defra.gov.uk/wildlife/pets/pets/travel/pets/index.htm. (See also RABIES; RABIES (CONTROL) ORDER 1974; THE RABIES (IMPORTATION OF DOGS, CATS AND OTHER MAMMALS) ORDER 1974.)

Peyer's Patches

Peyer's patches are lymph follicles on the small intestine; they appear as raised oval areas in mucous and submucous areas. In sheep they have a function analogous to that of the bursa of Fabricius in birds. An investigation of jejunal Peyer's patches (JPP) and ileocaecal Peyer's patches (IPP) showed that, in JPPs, there are big interfollicular T-cell areas, but IPPs contained mainly B-lymphocytes. Germinal centres of JPPs had about 40 per cent IgM positive cells and, in IPPs, about 80 per cent of these cells were present. Peyer's patches contribute to gut-associated lymphoid tissue (GALT). (See also under INTESTINES.)

PGE

(See PARASITIC DISEASE, NATURE OF; PARASITIC GASTROENTERITIS OF CATTLE; PARASITIC GASTROENTERITIS OF GOATS; PARASITIC GASTROENTERITIS OF SHEEP.)

pH

A symbol (derived from the term 'puissance d'Hydrogène') used to express acidity or alkalinity – pH7 being neutral, a higher figure being alkaline and a lower figure being acid.

Phacoemulsification

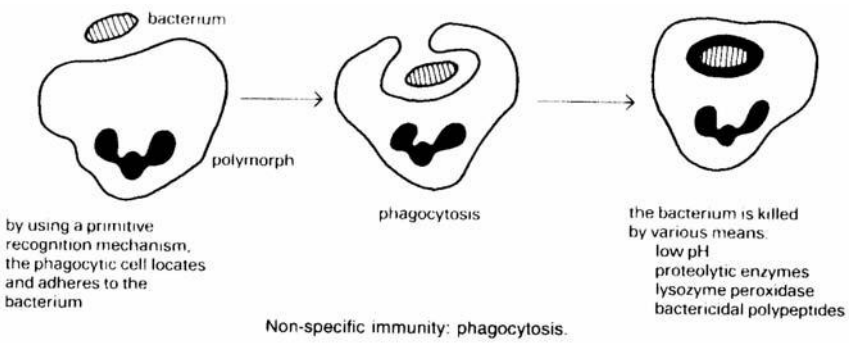
A high-frequency ultrasonic process used for emulsifying a lens affected by cataract, irrigating with fluid and extracting it from the eye. (See also CATARACT; FLURBIPROFEN; KETOROLAC.)

Phage

(See BACTERIOPHAGES.)

Phagocytosis

Phagocytosis is the process by which the attacks of bacteria upon the living body are repelled and the bacteria destroyed through the activity of the white blood cells other than lymphocytes and reticuloendothelial cells. (See HISTIOCYTES.) Bacteria coated with antibodies are phagocytosed more efficiently. (See BLOOD; IMMUNE RESPONSE; INFECTION - BLOOD CELLS WHICH COUNTER INFECTION; ABSCESS; INFLAMMATION.)



Many bacteria may be able to survive within phagocytes in mammary tissue, where staphylococci are protected from the lethal action of most antibiotics used in treating bovine mastitis. The situation may then arise where the staphylococci live longer than the phagocytes, so that when the latter die and disintegrate, the staphylococci are released, with potential for further mastitis-production.

Phalanx

Phalanx is the name given to each of the main bones below the metacarpal and metatarsal regions. They vary with the species: there are three in each limb in the horse, six in the cow, 12 in the pig, and 14 in the dog. In general each of the digits possesses three phalanges, but the first digit in each foot of the dog has only two (as in the thumb and great toe of man). The horse has now only one functional digit left in each of its limbs.

'Phalaris Staggers'

A condition seen in Australia and New Zealand among cattle and sheep grazing on pasture dominated by *Phalaris tuberosa*. Cattle may show stiffness of the hocks and dragging of the hind-legs. Similar signs are shown in sheep, with the addition of excitability, muscular tremors and head nodding in the early stages. Phalaris is believed to contain a specific nervous-system poison which is normally destroyed in the digestive passage of the animal; but, where there is a deficiency in cobalt, the destruction of the poison is impeded and the signs occur. Provision of oral cobalt seems to stimulate the growth of organisms in the digestive system which destroy the toxin.

Non-specific immunity: phagocytosis.

VetBooks.ir

Phallus
The male sexual organ of birds; it is carried internally in the CLOACA. It is subject to PROLAPSE especially in drakes. The treatment is usually AMPUTATION, as the organ is used only for sexual activity and, unlike in mammals, it has no excretory function. (See PENIS.)

Phantom Pregnancy
(See PSEUDO-PREGNANCY; also 'CLOUDBURST'.)

Pharaoh Hound Dogs
The national hound of Malta. The dog has a fine red coat, large erect ears and weighs 18 kg to 27 kg (40 lb to 60 lb); its height is 52.5 cm to 62.5 cm (21 in to 25 in) at the withers. Life expectancy is 12 to 15 years. HIP DYSPLASIA and PATELLAR LUXATION can occur as well as some eye defects. Its appearance is of a large CIRNECO DELL'ETNA.

Pharmacodynamics
The study of the action of drugs within the body.

Pharmacokinetics
The study of the movement of drugs within the body, including absorption, distribution, and excretion. (For an example, see LUNGS – Functions)

Pharmacology
The science of drugs, and especially of their actions in the body.

Pharmacopœia
Pharmacopœia is an official publication dealing with the recognised drugs and giving their doses, preparations, sources, and tests. Most countries have a pharmacopœia of their own; that of Britain is known as the *Pharmacopœia Britannica*, usually called the British Pharmacopoeia or 'BP'; the *Pharmacopoeia Europa* (denoted by 'Ph Eur' after the name). The European Pharmacopoeia now produces monographs which are used within the UK and Europe.

In the USA the official publication is the *United States Pharmacopeia*, often called the 'USAP'.

The *British Pharmacopœia* (*Veterinary*), published by the British Pharmacopoeia Commission, provides standards for drugs and medicines for veterinary use.

Pharyngeal Paralysis in Horses
Due to a central or local nervous damage, it results in collapse, obstruction or malfunction of the pharynx. It causes DYSPHAGIA and there may be return of food to the mouth and nose. Treatment includes NSAIDs and ANTIBIOTICS in case of INHALATION PNEUMONIA. When present with GUTTURAL POUCH MYCOSIS, most horses died.

Pharyngitis
Pharyngitis means inflammation of the pharynx. It often accompanies catarrhal inflammation in adjoining areas, viral infections, and tonsillitis.

Pharynx
The pharynx is an irregularly funnel-shaped passage situated at the back of the mouth, common to both the respiratory and the digestive passages. It acts as the crossroads between these systems. Into its upper part open the two 'posterior nares', by which air enters and leaves the nasal passages during respiration. Below is the opening from the mouth, known as the 'fauces'; while lower still is the entrance to the larynx – the 'glottis'. Situated most posteriorly is the beginning of the oesophagus, and on either side are the openings of the Eustachian tubes, communicating with the middle ear. (See EAR.)

The walls of the pharynx are composed of muscles which are the active agents of swallowing, along with a sheet of fibrous tissue known as the pharyngeal aponeurosis. On the inside they are lined with mucous membrane which is continuous with that of the several cavities which open into it.

Pharyngeal injuries In a study of 65 dogs treated for penetrating wounds of the pharynx, the following findings were noted. Recent wounds resulted in dysphagia, pain, pyrexia and local cellulitis; longstanding wounds led to discharging sinuses of the head, neck or cranial thoracic region. Pieces of wood were removed from 37 dogs, and they recovered. No foreign body was found in 18 dogs whose clinical signs resolved after treatment of the wounds. Four dogs died shortly after the injury from major oesophageal tears which resulted in mediastinal contamination. In six dogs the discharging sinuses persisted, although no foreign body was recovered at surgery.

PHE
Abbreviation of proliferative haemorrhagic enteropathy. (See HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Pheasants
They are members of the Order *Galliformes* and include many species. In the UK, the most common is used as game (*Phasianus colchicus*) and others are ornamental. They show marked sexual DIMORPHISM. (See GAME BIRDS, MORTALITY.)

Phenobarbitone Sodium, Phenobarbital
A sedative; used in dogs and cats for the treatment of EPILEPSY. In large doses it is used for euthanasia; administered intravenously, it produces smooth and rapid loss of consciousness.

VetBooks.ir

Phenol, Carbolic Acid

A tar derivative, related to the cresols and, like them, used in DISINFECTANT preparations, but not suitable (1) where animals may come into contact with them, as absorption through the skin – leading to poisoning – readily occurs, and (2) in the proximity of milk. (See MILK - CHLOROPHENOL TAINT.)

First-aid consists in the administration of milk and raw white of egg. The skin (in cases where the phenol or cresol compounds have come into contact with it) should be washed with soap and water.

Phenolphthalein

Phenolphthalein is a substance used as an indicator in the testing of urine, gastric juice, etc., being colourless in an acid and a brilliant red in an alkaline medium. It is also sometimes given to dogs as a purgative.

Phenolsulphone-phthalein has been used as a test for the excretory powers of the kidneys; a known amount is injected into a muscle and the urine is tested by comparison of its colour with that of known standards during the next few hours. Phenoltetrachlor-phthalein is a coal-tar derivative used to estimate the functional power of the liver.

Phenol Poisoning

In man, phenol is a corrosive poison when swallowed, giving rise to shock, convulsions and death

Cats especially may be fatally poisoned as a result of absorption of phenol compounds through the skin.

Phenothiazine

A pale greenish-grey powder which darkens on exposure to light and is practically insoluble in water. In the body it is oxidised to colourless compounds which are excreted in the urine, and on exposure to air are converted to a red dye.

Phenothiazine is an anthelmintic, at one time widely used in farm animals against a variety of parasitic roundworms; but it has been superseded by more modern drugs. (See WORMS, FARM TREATMENT AGAINST.)

Phenotype

In heredity this refers to all the individuals showing the same characters. The term can also mean the individual resulting from the reaction between genotype and environment.

Phenylalanine

One of the essential amino acids which is involved in the maintenance of neurotransmitters, especially DOPAMINE. Most animals can metabolise phenylalanine to tyrosine, however, in excess it can suppress appetite.

Phenylbutazone, Butazolidine; Bute

An NSAID analgesic for the relief of pain associated with inflammation of joints and muscles. It acts as an analgesic by reducing the synthesis of prostaglandins. Phenylbutazone can be given orally or intravenously. Withdrawal of the drug before a horse competes in international events is necessary. As the drug can be detected at very low levels, the withdrawal period can be lengthy.

Any use of the product in horses and ponies must be recorded on the HORSE PASSPORT and the animal cannot be used for meat for human consumption.

Phenylephrine

A topical adrenergic drug predominantly used in the investigation and diagnosis of HORNER'S SYNDROME. Resolution of signs with one drop of 0.5 per cent phenylephrine within 10 minutes suggests a third order nerve lesion, while resolution in about 20 minutes suggests a second order nerve lesion. It is also used as a decongestant in the form of nasal drops for dogs, cats and chelonians. (See MYDRIASIS.)

Phenylpropanolamine

A sympathomimetic drug which acts on the smooth muscle of the internal urethral sphincter. Its use is indicated in the management of the incontinent bitch, when the cause is incapacity of the urethral sphincter.

Phenytoin Sodium

An anti-convulsant drug formerly used in the treatment of epilepsy, but now of only historical interest as it has such a short HALF-LIFE that the need for frequent dosage precludes its use.

Pheromone

A volatile chemical substance produced and released by specialised glands (usually in the skin) of an animal which is detected by another individual via the vomeronasal (Jacobson's) organ. They affect the behaviour or physiology of another of the same species. Pheromones have a potent effect on the animal detecting them. The most obvious example in companion animals is the distance over which a male dog can detect a bitch in heat.

The normal mating process in pigs is much influenced by pheromones; the sexes must be able to smell each other before being introduced.

In some cases, the substance has a different effect. In pregnant mice the odour of a strange male will cause fetal resorption. Some pheromone

VetBooks.ir

preparations are available commercially. Feline pheromone is sold as a spray to stop urine-spraying, scratching of furniture, for calming a cat during transport, and to counteract stress. A canine pheromone product is claimed to calm anxious dogs. (See JACOBSON'S ORGAN.)

Philtrum
The junction between the two sides of the upper lip and/or nose/nostrils. Its development varies between species, being very pronounced in the rabbit, hare, dog, cat and horse, but less so in ruminants.

Phimosis
A narrowing of the prepucial orifice, preventing normal protrusion of the penis. (See under PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Phlebitis
Inflammation of a vein. Most cases seen in animals arise following intravenous injections or catheters, or inflammation of the umbilical vein. (See OMPHALOPHLEBITIS.)

Phocidae
(noun, Phocid; adjective, Phocine)
The Family name for the true SEALS or earless SEALS. (See also PINNEPEDIA.)

Phocine Distemper
This is the name given to distemper in members of the family *Phocidae* – mainly seals. The cause is a MORBILLIVIRUS. Outbreaks caused a high death-rate among seals in European waters in 1988; the disease returned with equally devastating effect in 2002. Seals have been vaccinated against distemper, but handling wild animals can cause severe stress which can itself upset the immune mechanism. There is also the problem of the substantial layer of subcutaneous fat in seals: injection into fat will not provoke an immune response. There is evidence that the virus has also caused outbreaks of DISTEMPER in farmed mink and in dogs.

Pholedrine Sulphate
A drug which raises the blood pressure, and is used in cases of heart failure after pneumonia or bronchitis and shock.

Phosgene
This gas, first produced experimentally by John Davy in 1812 by the combination of carbon monoxide with chlorine in the presence of sunlight, has the formula $COCl_2$. Phosgene has a characteristic smell of musty hay, and is 10 times more toxic than chlorine. The gas in the presence of water is converted into carbon dioxide and hydrochloric acid, and it is the latter which damages the lung tissues, giving rise to pulmonary oedema. Horses usually die between the seventh and 24th hour following exposure to the gas. Birds are highly susceptible. The gas may be liberated from chloroform, carbon tetrachloride, and paint-strippers in the presence of heat. Still-births and heavy piglet losses followed the feeding in the USA of mouldy, weevily grain which had been fumigated with a mixture containing carbon tetrachloride.

Phosmet
An organophosphorus liquid parasiticide.

Phosphates
Phosphates are salts of PHOSPHORIC ACID, and as this substance is contained in many articles of food, in bone, the nuclei of cells, as well as in the nervous system, quantities are continually excreted in the urine.

Phosphofructokinase Deficiency
Also known as glycogen storage disease type VII or Tarui's disease. It is due to autosomal recessive inheritance, the condition causes muscle pain, MYOGLOBINURIA and later HAEMOLYTIC ANAEMIA. It impairs the ability of certain cells such as erythrocytes and rhabdomyocytes to use carbohydrates such as glucose and has a direct effect on glycolysis. It is seen in AMERICAN COCKER SPANIELS and COCKER SPANIELS, and is due to autosomal recessive inheritance.

Phosphorescence
Phosphorescence of meat is a luminous condition due to the organism *Photobacterium phosphorescens*. The meat is apparently unchanged during the daytime, but in the dark it glows with a yellowish light. Fish, especially herring, show this condition normally, but sausages, pork and occasionally beef may also exhibit the phenomenon.

Phosphoric Acid
An acid formed from PHOSPHORUS. It forms part of ORGANOPHOSPHORUS COMPOUNDS.

Phosphorus (P)
This forms an important element of the minerals within the diet, being required for bone formation, milk production and normal reproduction. It occurs in the body as the salt calcium phosphate and it is a major component of BONE.

Phosphorus itself is not used in medicine, but is usually given in the form of one or other of the glycerophosphates, or hypophosphites of sodium, potassium, calcium, magnesium, or iron. Preparations are used with calcium and dextrose in the treatment of MILK FEVER.

Phosphorus Deficiency
This is seen in RICKETS; 'MILK LAMENESS'; POST-PARTURIENT HAEMOGLOBINURIA; and may complicate MILK FEVER. (See also INFERTILITY.)

Phosphorus Poisoning
Phosphorus poisoning may occur in the dog and cat, either through puppies eating matches, or from animals gaining access to rat poison made with phosphorus.

Signs When an animal has been poisoned by phosphorus there is acute abdominal pain, vomiting, intense thirst, diarrhoea and great dullness. The material vomited may be green in colour and is often luminous in the darkness. Collapse rapidly follows, and the animal dies in a few hours. Where less has been taken, death may not occur for some days.

First-aid An emetic should be given at once, as soon as the signs appear. Washing-soda crystals (sodium carbonate), salt (sodium chloride) or mustard placed at the back of the tongue are effective emetics. Sulphate of copper (bluestone), in solution, may be given: this induces vomiting, gets rid of the majority of the phosphorus, and renders inert what remains. In 15 minutes another dose dissolved in water as before should be given, and this should be repeated every quarter of an hour till four doses have been given. In all cases, white of egg, milk, oils, and fatty substances must be avoided; these dissolve the phosphorus and render it able to be absorbed with greater rapidity. (See also ORGANOPHOSPHORUS POISONING, which arises from contaminations with certain farm chemicals.)

Photosensitisation
(See LIGHT SENSITISATION.)

Phrenic Nerve
This arises from the fifth, sixth and seventh cervical spinal nerves, passes through the thoracic cavity, and ramifies in the muscular part of the diaphragm.

Phthiriasis
Infestation with lice of the genus *Phthirus*.

Phthirus pubis
(See CRAB LICE.)

Phycomycosis
A group of fungal infections by species of *Absidia*, *Mucor*, *Rhizopus*, etc., which affects the lymph nodes and may give rise to loss of weight and tumour-like (granulomatous) swellings. It may affect the lungs and intestines. A monkey died from systemic phycomycosis in the UK after loss of appetite, depression and laboured breathing. (See also MONKEYS, DISEASES OF.)

Phylloerythrin
A rose-red PORPHYRIN pigment formed in the rumen from chlorophyll by bacterial digestion. Some is absorbed and excreted in the bile, but when the liver is damaged in any way the phylloerythrin may reach the peripheral circulation and give rise to LIGHT SENSITISATION.

Phylum
A division in the plant or animal kingdom where the members are considered to have a common ancestry.

Physiological Saline
(See NORMAL SALINE.)

Physiology
The science of how organisms function and of their component tissues and organs.

Physiotherapy
In the UK, some veterinary practices use the services of qualified physiotherapists for the treatment of selected cases of disease in animals. There may be beneficial results with OSTEOARTHRITIS, orthopaedic conditions and soft tissue injuries.

Physis
A synonym for EPIPHYSIS (see also BONE, DISEASES OF).

Physitis
Inflammation or disease of the growth plate. (See EPIPHYSITIS.

Physostigmine
Physostigmine is an anticholinesterase. Eye drops containing physostigmine sulphate are used to contract the pupil and lessen intra-ocular pressure. It is prepared from the ripe seeds of *Physostigma venenosum*, a tree from West Africa.

Phytanic Acid
A by-product of chlorophyll breakdown.

Phytin
A substance present in oatmeal, MAIZE meal (and in other cereals) that binds to calcium, making it unavailable to animals. As a result, calcification of bone is disturbed and RICKETS may result. Phytase is added to many diets to break down phytin and remove this risk.

Phytochemicals
These are substances produced by plants. Many plants contain within them chemicals to deter

VetBooks.ir

their predation or eating by HERBIVOROUS or OMNIVOROUS animals, man, fungi, insects. Some of these substances can result in POISONING but many have medicinal properties. (See also HERBALISM.)

Phytoestrogens

These are natural substances found in some plants (CLOVER, IRISES, SOYA BEANS) that can act like OESTROGENS in animals. They include ISOFLAVONES and COUMESTANS.

Pia Mater

Pia mater is the membrane that closely invests the brain and spinal cord. (See BRAIN; SPINAL CORD.)

Pica

Depraved appetite. It is often the result of a deficiency in the diet such as lack of fibre or salt, or inadequate trace elements such as phosphorus or copper. (For causes, see under APPETITE.)

Picornavirus

A member of the Picornaviridae family which includes apthovirus, responsible for foot-and-mouth disease; rhinovirus, responsible for respiratory diseases in cattle and sheep; and enterovirus, which causes poliomyelitis in pigs and chickens (see FELINE CALICIVIRUS; VIRUSES).

Picrotoxin

Formerly used in veterinary medicine principally as an antidote to barbiturate poisoning. It has a similar action to STRYCHNINE (it is a GABA antagonist) and is now regarded as a poison.

Piebald

A coat colour usually used when referring to horses involving a mainly white coat with large irregular patches of black. (See also SKEWBALD.)

Piedmontese Cattle

They were originally bred in Piedmont area of North West Italy; the herd book was opened 1877. Adult cattle are grey-white in colour but the calves are born brown. They are used for meat and cheese: the meat is low in calories, has a reduced fat content and a high percentage of omega 3 fatty acids. They contain the gene for inactive myostatin which increases muscularity.

Piétrain

This Belgian breed of pig dates from about 1920, but the Breed Society was formed in the 1950s. There is uncertainty as to the origins of the Piétrain, but it is thought that it stems from old native stock crossed with English breeds such as the BERKSHIRE, TAMWORTH and WESSEX SADDLEBACK, and with the French breed Bayeux. There is still some lack of uniformity within the breed, but a constant feature is the extreme development of the hams – perhaps the result of a mutation such as is believed to have occurred in a strain of Devon cattle.

The Piétrain is white with large black spots. It is a pork pig which gives high killing-out and lean-meat percentages, but it is slow growing and has, in comparison with LARGE WHITES and LANDRACE, a somewhat high food conversion ratio.

The boars attain a weight of between 250 kg and 295 kg (550 lb and 650 lb), sows 272 kg (600 lb). The sows are usually quiet and docile. Litter-size is smaller than that expected in the UK. Pale-muscle disease and heart failure are by no means rare in this breed, of which there are now many in the UK. (See PORCINE STRESS SYNDROME.) There is some evidence that a Piétrain boar will reduce losses from PMWS. (See POST-WEANING MULTISYSTEMIC WASTING SYNDROME.)

Pig, External Parasites of the

Half the bacon pigs examined at an abattoir were found to have external parasites – mange mites, lice, or forage mites; and a survey made at the department of veterinary medicine, University of Edinburgh, suggested that 20 per cent of pedigree pigs and piggeries in Britain are infested with sarcoptic mange mites.

The itchiness and scurfiness of many infested pigs are attributed to the results of dry feeding or of a zinc deficiency, but pig breeders would be wise not to be in too much of a hurry to make this assumption.

A proper investigation by a veterinary surgeon would not merely pay for itself, but could effect a big saving; for mange can have an important effect upon food conversion ratios. Moreover, mange can actually kill piglets – and lead to stunting of others which do not succumb.

It is recommended that, once buildings have been cleared of the infestation, each new intake of pigs should be treated with an ectoparasiticide. (See also IVERMECTIN.)

Pig Carcases, Rejection of

Analysis of the causes of rejection of carcases and viscera among 1.3 million pigs slaughtered in seven abattoirs showed that 2,556 (0.2 per cent) whole carcases and parts of 25,583 (2.0 per cent) carcases were rejected. The principal causes of rejection of whole carcases were pneumonia, pleurisy, peritonitis and fever; for parts of carcases, abscesses and arthritis. The main reasons for rejection of liver, heart and lungs were 'MILK-SPOT LIVER', PERICARDITIS and PNEUMONIA, respectively. The variation between abattoirs in the amount of meat and viscera rejected was very large and economically significant.

VetBooks.ir

Pigeon Pox

A highly contagious viral disease with high morbidity but low mortality. Visible signs are sores around the mouth and eyes. It is caused by a paramoxyvirus and controlled by routine vaccination. Birds over five weeks old are vaccinated, all birds in a loft being vaccinated at the same time. Thereafter, the birds are vaccinated annually, between 30 September and 31 December – that is, out of the racing season. The vaccine is administered by removing six to eight feathers and brushing the vaccine onto the skin so that it enters the plucked follicles. The manufacturer's directions must be followed.

Pigeons

Pigeons in cities may constitute a hazard to public health, since many are infected with ORNITHOSIS. Some harbour salmonellae, and *Cryptococcus neoformans* has been isolated from pigeon droppings. Grain soaked in the narcotic ALPHACHLORALOSE has been successfully tried as bait; loss of consciousness begins 10 minutes or so after eating the bait.

Dieldrin is highly poisonous to pigeons. (See also under GAME BIRDS, MORTALITY.)

Racing pigeons in Europe have suffered outbreaks of a highly contagious viral disease causing high morbidity but low mortality. The virus belongs to the avian PARAMYXOVIRUS serogroup 1. The clinical signs include watery droppings, POLYDIPSIA and neurologic signs ranging from ataxia and tremor of the head and neck, to TORTICOLLIS varying from slight head tilt to carriage of the head upside down. The most important differential diagnosis is SALMONELLOSIS. Adult pigeons should be vaccinated after moulting and before breeding and young pigeons should be vaccinated four weeks before racing.

Live Newcastle disease vaccine stimulates a rapid, but short-lived, immunity.

Ornithosis occurs in young racing pigeons, the signs including diarrhoea, conjunctivitis and nasal discharge. (See CHLAMYDOPHILA.)

Pigeon pox is associated with vesicles around the beak and eyes, and with hard growths – which, if on the feet, may cause lameness.

'Canker' may give rise to a 70 per cent mortality; it is caused by *Trichomonas gallinae* which affects the liver and alimentary canal.

Salmonellosis is often fatal in recently hatched birds, and in adults may cause diarrhoea, distressed breathing, swollen joints, lameness, dropped wing and loss of weight.

Parasitic worms, especially capillaria, may cause huddling, loss of weight and anaemia.

Pigeons imported into the UK must be vaccinated against paramyxoviruses within 24 hours of their arrival. Four weeks later they must receive a second dose of vaccine and remain in quarantine for a further week.

Pig Influenza

(See SWINE INFLUENZA.)

Piglet Anaemia

A common cause of pre-weaning losses among housed pigs.

Cause The disease is associated with a deficiency of iron, and is aggravated by cold and damp. (A deficiency of copper and cobalt may sometimes also occur.)

Signs Dullness, a pale whitish skin, scouring and sometimes exaggerated heartbeats.

Treatment Turn sow and litter out to grass. Give an iron and copper preparation sold for the purpose.

Prevention If outdoor rearing is not desired, give a suitable iron preparation (with cobalt and copper, preferably) at seven days of age. (A solution made by dissolving 25 g (2 oz) of commercial iron pyro-phosphate in 500 ml (1 pint) of water is effective; a quarter of a teaspoonful being given daily for four or five days.) Place a fresh turf in the farrowing house. Acute iron poisoning, often leading to death within 24 hours, sometimes follows the injection or oral dosing of normally used iron preparations. To prevent this it is advisable to wait until the piglets are a week old, when this danger is reduced; it is also wise to ensure that gilts' rations contain adequate vitamin E.

The intramuscular injections of iron dextran to prevent piglet anaemia are sometimes followed by ham abscesses – the result of broken-off needles or failure to clean the skin adequately before making the injection. Unweaned piglets eat a significant amount of their dam's dung, and if the sow's diet is supplemented with 2,000 mg iron per kg dry matter, it is possible to prevent piglet anaemia; the dung will then contain enough iron to protect the piglets.

Supplements of calcium carbonate fed to fattening pigs from weaning onwards can cause iron deficiency, shown by reduction in blood haemoglobin concentrations and rates of liveweight gain. This effect is especially marked in litters with low weaning weights, probably because their reserves of iron are generally lower. Iron injections or dosing at weaning will overcome these harmful effects.

A secondary anaemia, due to blood-sucking lice, must be borne in mind.

Piglet Mortality

Causes: AUJESZKY'S DISEASE, 'Baby Pig' Disease, PIGLET ANAEMIA, HAEMOLYTIC DISEASE, *E. Coli*, STREPTOCOCCAL MENINGITIS, SWINE

VetBooks.ir

ERYSIPELAS, SWINE FEVER, ENZOOTIC PNEUMONIA OF PIGS, GLÄSSER'S DISEASE, TALFAN DISEASE, ATROPHIC RHINITIS and TRANSMISSIBLE GASTROENTERITIS OF PIGS (TGE); also overlying by the sow. (See also under ILEUM for another form of enteritis and BOWEL, OEDEMA OF THE; DYSENTERY; GASTRIC ULCERS; MUCORMYCOSIS; LISTERIOSIS; HEART DISEASES Pericarditis; DERMATOSIS VEGETANS; SPLAYLEG, CONGENITAL.) *Chlamydia psittaci* is another cause of piglet mortality. A list of diseases which affects pigs usually after weaning is given under PIGS, DISEASES OF.

Piglets, Artificial Rearing

Cows' COLOSTRUM makes a satisfactory substitute for sows' colostrum, and may be frozen and later thawed when required. Pigs' serum as an addition enhances the value of cows' colostrum.

Pig Management and Disease

From a veterinary viewpoint, outdoor pig rearing has advantages: namely, fresh air, exercise, and the availability of grass (and soil) which can minimise any deficiencies of vitamins or trace elements. (The outdoor piglet will not need iron injections to avert anaemia, but may still need a vitamin A supplement in autumn and winter.)

The disadvantages are that, especially in the bleaker parts of the country, piglets in arks on grassland may not thrive during the winter; also, where sows and their litters share an enclosure, there may be some savaging by sows of other sows' piglets. The system is suitable only where there is light soil on free-draining land.

Straw-bale 'houses' have much to be said for them. They provide excellent insulation and hence warmth, and can be burnt after use – which obviates the need for disinfection.

Fattening pigs, if properly fed indoors, make better liveweight gains than those outside. They are, however, utterly dependent upon the feed provided, having no opportunity to graze or scavenge. Should the feed be deficient in trace elements or vitamins, their health will suffer.

Pregnant sows thrive best when allowed free access to grassland and the opportunity for exercise, but see PADDOCKS for the danger of contamination of pasture by parasitic worm larvae, unless precautions are taken.

Housing Pig housing, varying from simple wooden huts and arks to costly and elaborate controlled-environment buildings, naturally has an important bearing on health. The type and quality of building materials can be as important as the design of the building. Abrasive concrete can lead to injuries and abscesses, resulting in lameness. (See CONCRETE.)

Straw bedding is the ideal from a health angle. It can keep the pigs warmer, improve liveweight gains, obviate boredom (a possible cause of tail-biting), and reduce stress. (See BEDDING AND BEDDING MATERIALS.)

Recommended temperatures for pigs are given under HOUSING OF ANIMALS. With controlled-environment buildings, precautions must be taken against the effects of power-cuts: it is useful to have a tractor-pto generator for such emergencies. These may arise during both winter and summer, and be due not to a power-cut but to fuses blowing in the building itself. In one case, fuses blew during a thunderstorm, and fail-safe ventilators failed to operate, with the result that 500 pigs inside that building died of heat-stroke — DEFRA veterinary investigation service report.

As pigs are particularly susceptible to the effects of water deprivation, precautions must be taken to ensure that water pipes do not freeze, and that the levers of automatic drinkers are not too stiff for piglets to manage. (See under WATER AND WATERING OF ANIMALS for other dangers.)

Feeding stalls prevent greedy and aggressive sows from obtaining more than their fair share of feed, leaving others undernourished. However, confinement of sows in stalls (other than for feeding only) deprives the animals of any opportunity for the slightest exercise (not allowed in the UK), and they are unable to move away to escape any cold draughts and stress results. (See THIN SOW SYNDROME.)

Stress (which reduces bodily resistance to infection) may also occur at times when pigs are moved from one building to another, or when litters are first mixed. Accordingly, the use of farrowing-to-finish pens has been advocated.

However, relatively few fatteners breed their own pigs. Bought-in pigs are best kept away from other stock on the farm for three or four weeks. Young pigs are said to do better at this period if they are kept as far away from their dung as possible, and this is one reason why slatted floors and floor feeding rarely work at this stage.

A popular way of achieving good accommodation at this time is to provide a simple covered straw yard allowing about 3 m^2 (10 sq ft) per pig of total area preferably with part of the area 'kennelled' to give a warm sleeping area. If the latter is raised and dark it will usually be kept clean, and the dung placed in the lighter and lower strawed area. Suitable-sized groups are of 25 to 30 weaners and a lean-to yard will be as cheap a method of housing as any, particularly with ad lib feeding from large hoppers.

For the farmer who cannot use straw or other bedding, there are a number of designs of kennel-type pens with covered or uncovered yards where

VetBooks.ir

the muck can be readily cleared away, with tractor or squeegee, or with a hose to wash it down a drain. An essential of this system is to have pigs in small and separated groups perhaps no more than 20 to a pen.

After the conditioning period, the usual practice is to finish the pigs under more intensive conditions. This often involves keeping pigs in litter-less pens, and there is little doubt that this is the type of environment that can be conducive to tail-biting and cannibalism.

Ventilation – at pig level – becomes all the more important in such circumstances. Railed or Weldmesh pen fronts or sides are often preferred as they allow a much better circulation of air in a low-roofed building in particular. Their advantages do not stop there. Many farmers find that it is difficult to get the younger pig dunging in the passage rather than in the pen: a sure help is a gate of Weldmesh or of bars, as a new group will appear to follow the habits of its older companions on the other side of the gate.

It is good practice to have separate sections or units which can be cleaned and disinfected between batches.

The age for weaning piglets is usually five to seven weeks, but later in organic systems. Where for any reason the sow is not wanted for breeding again immediately, the period of suckling may be extended by an additional week or two. In countries with a severe winter climate, where only spring litters are satisfactory and where consequently only one litter per year is bred, the last course is that normally followed. (For early weaning, see under WEANING.)

It is not normally advisable to put pigs into the finishing house until they are at least 32 kg in weight, and most feeders continue the weaner-pool system until this weight is reached.

Feeding Many unsatisfactory results are directly attributable to badly balanced rations. (See CONCENTRATES.)

The growing pig needs a diet that provides the amino acids required to build body proteins as well as vitamins. These (particularly A, D and E) are best added as a special preparation according to the manufacturers' recommendations. (See ADDITIVES; RATIONS FOR LIVESTOCK; COPPER; SOWS' MILK.)

Floor feeding has been shown to have a link with vices. If pens are dirty and the food goes on top of this muck, a scouring, uncomfortable pig can be the result – and it does not seem to take long for the other pigs to set about the weakened individual. Also if ventilation is bad, the dust from meal fed on the floor can appear to induce coughing and fractiousness.

A virtually automatic system of liquid feeding via pipelines is not uncommon in large, modern piggeries. Dry meal may be delivered from hoppers in pre-arranged quantities and at set intervals by means of a time-switch. It has been shown that dry-fed pigs take 10 days longer to reach bacon-weight and 90 g (0.2 1b) more food for each 450 g (1 lb) liveweight gain, as compared with wet feeding.

Good results have been obtained by feeding moist barley from a Harvestore tower silo.

One method is for weaners to be brought into the fattening house at eight weeks old, and there they have free access to meal from self-feeders. At 45 kg (100 lb) liveweight, the ad lib feeding ceases, and the pigs are trough-fed daily. Water is run into the trough (from a conveniently placed tap) and the meal is placed on top, being mixed with the water by the pigs themselves. They are given as much as they will clean up in 20 minutes, subject to a limit of 3 kg (7 lb) per head per day. (See RATIONS FOR LIVESTOCK.)

Aspects of pig husbandry having a bearing on health and disease problems, and of economic importance to the farmer, are given under the following headings: ADDITIVES; ARTIFICIAL INSEMINATION; BEDDING AND BEDDING MATERIALS; BUNT ORDER; CASTRATION; CONTROLLED BREEDING; CONTROLLED ENVIRONMENT HOUSING; COPPER; COPPER, POISONING BY; CREEP-FEEDING; DIET AND DIETETICS; DISINFECTANTS; DRENCHING; DRESSED SEED CORN; DRIED GRASS; FARROWING CRATES; FARROWING RATES; FLIES Fly control measures; GENETICS, HEREDITY AND BREEDING; HEAT-STROKE; HOUSING OF ANIMALS; INFERTILITY; INJECTIONS; INTENSIVE LIVESTOCK PRODUCTION; LAMENESS; LIGHTING OF ANIMAL HOUSING; MEAL-FEEDING IN PIGGERIES; MUMMIFICATION OF FETUS; NIPPLES; NITRITE POISONING; NOTIFIABLE DISEASES; OESTRUS; OVERLYING; PARASITES; PIGLET ANAEMIA; PIGLET MORTALITY; POISONING; RATIONS FOR LIVESTOCK; ROUNDHOUSE; SALT POISONING; SENNA; SLURRY; SOW STALLS; SOWS' MILK; STILLBORN PIGS; STRESS; SWILL; TAIL-BITING; THIN SOW SYNDROME; TRACE ELEMENTS; TROPICS, LIVESTOCK PRODUCTION IN THE; VENTILATION; VITAMINS; WATER AND WATERING OF ANIMALS; WEANING; WHEY; WORMS, FARM TREATMENT AGAINST.

Pig-Meal, Surplus

Pig breeders who rear cattle and sheep should be wary of feeding surplus pig-meal to those animals unless it is definitely known that the meal does **not** contain a copper supplement. Sheep are very easily poisoned by repeated dosage of a copper supplement well tolerated by pigs, and the death of

a heifer was reported after five months of supplementary feeding on pig-meal. Conversely, poultry meal medicated with NITROPHENIDE against COCCIDIOSIS should never be fed to pigs. It has caused paralysis.

Pigmentation, Loss of

This mostly affects Siamese cats. Eyelids, foot-pads, etc., are altered, with resultant exclusion from cat shows. The causes are various, including hereditable factors. It also occurs in POT-BELLIED PIGS.

Pigment Deposition in the Eye, Abnormal

(See ABNORMAL PIGMENT DEPOSITION IN THE EYE.)

Pig Pox

(See under POX.)

Pigs

As seen by research workers, pigs are the fastest growing of the domestic animals, prone to heart troubles and disease of the arteries, and greatly affected in body by mental stress.

Domesticated pigs are believed to be the descendants of the native European wild pig (*Sus scrofa*), with probably an admixture of the blood of the closely related Asiatic species (*S. vitatus*).

During the 18th and early 19th centuries there were introduced into Britain considerable numbers of pigs belonging to a markedly different type, which originated at a very early date in China and Southwest Asia. This type, variously known as the Siamese or Chinese, and given the specific designation of *S. indicus*; was of smaller size than the native stock; and was short-legged and round-bodied, with a short dished snout and a coat of soft hair. Its most marked economic characteristics were early maturity and a tendency towards rapid fattening. At the same time it was both less hardy and less prolific than the native type. The Chinese type was not long preserved in a pure state in Britain, but was widely employed for crossing with the native sorts, and it seems certain that all of our modern breeds have been influenced to a greater or lesser extent by the infusion of this Eastern blood. The influence is most clearly to be seen in the smaller and earlier maturing breeds such as the MIDDLE WHITE and the BERKSHIRE, while it is least apparent in breeds such as the TAMWORTH and WESSEX SADDLEBACK.

British breeds of pigs These include 9 main breeds:

White breeds
LARGE WHITE
MIDDLE WHITE
WELSH
BRITISH LANDRACE

Black, black-and-white breeds LARGE BLACK
WESSEX SADDLEBACK
GLOUCESTER OLD SPOTS

Red breeds OXFORD SANDY-AND-BLACK
RED WATTLE
BERKSHIRE
TAMWORTH

Most favoured crosses Large White × Landrace; Large White or Landrace × LA/LW; Duroc × LW/LA.

Chinese Meishan pigs can rear an average of 14 to 16 piglets, compared with 10 to 12 from Western breeds. Meishans reach sexual maturity when three months old.

Foreign breeds Pigs imported into the UK for commercial use and breeding trials, crossing purposes, etc., include DUROC PIGS, HAMPSHIRE, LACOMBE, PIÉTRAIN and POLAND CHINA.

The VIETNAMESE POT-BELLIED PIGS and the KUNEKUNE are popular as pets, and have been imported for that purpose. They are subject to the Pigs (Records, Identification and Movement) Order 2008.

Leading hybrids include the Camborough female and the Cotswold.

Breeding (See GENETICS, HERITAGE AND BREEDING - HERITABILITY OF CERTAIN TRAITS.)

Boars may be used for breeding at from seven to nine months according to size and development. Oestrus occurs in females that are in good thriving condition, at all seasons of the year, except when the animal is pregnant or nursing. The period of gestation is about 16 weeks; the time allowed for nursing varies from seven to 12 weeks, and oestrus generally recurs within 10 days, and very commonly on the third or fourth day, after the litter is weaned. The whole breeding cycle is thus completed in 24 to 28 weeks, and it is possible to arrange for sows to produce two litters a year regularly throughout their breeding life. Some pig farmers, by means of early weaning, managed to obtain three litters in little over a year; but early weaning, and so-called 'piglet batteries', are sometimes accompanied by unacceptable losses. The normal breeding life is five or six years, but exceptionally good breeders are sometimes kept much longer, and 12 years or more is not unknown.

VetBooks.ir

Pigs, Diseases of

(See AGALACTIA; ANAEMIA; ANTHRAX; AUJESZKY'S DISEASE; CLOSTRIDIAL ENTERITIS; ENCEPHALOMYELITIS, VIRAL, OF PIGS; ENZOOTIC PNEUMONIA OF PIGS; EPERYTHROZOON PARVUM; GASTRIC ULCERS; HAEMOLYTIC DISEASE; EPERYTHROZOON PARVUM; HEAT-STROKE; LEPTOSPIROSIS; LISTERIOSIS; MANGE; MASTITIS; MENINGOENCEPHALITIS; 'MULBERRY HEART'; NECROTIC ENTERITIS; BOWEL, OEDEMA OF THE; PERICARDITIS; PORCINE DERMATITIS AND NEPHROPATHY SYNDROME, PORCINE CORONAVIRUS INFECTION; POST-PARTURIENT FEVER OF SOWS, POST-WEANING MULTISYSTEMIC WASTING SYNDROME; PYELONEPHRITIS; RHEUMATISM; RHINITIS, ATROPHIC; SALMONELLOSIS; SWINE DYSENTERY; SWINE ERYSIPELAS; SWINE FEVER; SWINE FEVER, AFRICAN; SWINE INFLUENZA; TAIL-BITING; TALFAN DISEASE; TESCHEN DISEASE; TOXOPLASMOSIS; TRANSMISSIBLE GASTROENTERITIS OF PIGS; TRICHINOSIS; TUBERCULOSIS. See also BACK MUSCLE NECROSIS; 'BLUE-EAR' DISEASE OF PIGS; FOOT-ROT OF PIGS; GLÄSSER'S DISEASE; 'GREASY PIG DISEASE'; HAEMORRHAGIC GASTROENTERITIS OF PIGS; LOUPING-ILL; OESOPHAGOSTOMIOSIS; PITYRIASIS; PNEUMONIA; PORCINE INTESTINAL ADENOMATOSIS; PORCINE STREPTOCOCCAL MENINGITIS; PORCINE ULCERATIVE SPIROCHAETOSIS; SWINE VESICULAR DISEASE; VOMITING AND WASTING SYNDROME; WORMS, FARM TREATMENT AGAINST and headings under PORCINE.

For causes of death among unweaned pigs, see list of diseases, etc., given under PIGLET MORTALITY. (See also PIG CARCASES, REJECTION OF.)

Pigs, names given according to age, sex, etc.

The naming of pigs at various times in their life, and according to their age, sex, etc., varies in different areas; the following gives the most usual names:

Store pig – a pig between the time of weaning and being fattened.

Hog (barrow in the USA) – a male pig after being castrated.

Stag, steg, or seg – a male castrated late in life.

Gilt or yelt – a female intended for breeding purposes, and up to the time that she has her 1st litter.

Boar, bran, or hogg – an uncastrated male.

Sow – a breeding female after the 1st litter.

Pigs, Sale of

In the UK this is subject to the Pigs (Records, Identification and Movement) Order 2008. Pigs moved on to a premises must not be subject to further transport to other premises for 21 days, except for slaughter. The farmer is responsible for the necessary certification.

Pigs, Sedation of

Sedation is useful to prevent fighting after the mixture of litters or re-grouping of pigs; to 'cure' fighting after it has broken out; to make the aggressive sow accept her litter; to facilitate castration, nose-ringing, detusking, etc. Among drugs used for this purpose is AZAPERONE, which is administered by intramuscular injection.

Precaution There is a risk of damaging the sciatic nerve when making intramuscular injections into the hind-legs of pigs; it is therefore advisable to inject into the neck muscles, just behind the ear.

Case histories Within one to eight weeks of an injection of an antibiotic into the ham of one hind-leg of 180 four-week-old piglets, 150 had developed paralysis of that leg. In another group of 380 five-week-old piglets, 30 per cent had become paralysed within 10 days, and 30 per cent had died from complications such as septicaemia and pneumonia – 'probably due to necrosis of the foot'.

Pigs, transmissible diseases of

Occupational hazards of people handling pigs include: erysipeloid (the human form of swine erysipelas infection); PORCINE STREPTOCOCCAL MENINGITIS; SWINE VESICULAR DISEASE, which has been transmitted to laboratory workers, but there appear to be few, if any, reports of farm workers becoming ill; and LEPTOSPIROSIS.

Pigs, Transport of

The use of containers for the transport of pigs can reduce the risk of infection being carried on to a purchaser's farm. One crate can hold a complete litter group, and keep the pigs from coming into contact with the sides and floor of the lorry – which are often not properly cleaned and which can seldom or never be sterilised. Pigs can suffer travel sickness. The minimum space allowances for transporting pigs can be found in the current legislation.

Pilobolus

A fungus often present in bovine faeces on pasture, it acts as a disperser of lungworm larvae, by means of a 'rocket-like' effect caused when the fungal spores are dispersed.

Pilocarpine

A cholinergic alkaloid used in ophthalmic treatments to constrict the pupil and to reduce intraocular pressure in cases of GLAUCOMA. It has now been superseded by more modern agents such as

carbonic anhydrase inhibitors and prostaglandin analogues. (See MIOSIS, MIOTICS.)

Pilus
(plural, Pili)
A pilus is a filament attached to the surface of a bacterium. It is another name for bacterial FIMBRIAE. For sex pilus, see under PLASMIDS.

Pimobendan
A medicine used in dogs to treat chronic CONGESTIVE HEART FAILURE and ENDOCARDITIS. It causes the heart to beat more strongly and the blood vessels to dilate. It can be used with FRUSEMIDE but the increase in cardiac contractility is reduced by the presence of the calcium antagonist verapamil and the β-antagonist propanolol. It has been successfully used to delay the onset of dilated CARDIOMYOPATHY in DOBERMANNS and other large breeds. (See under HEART DISEASES.)

Pin Bone, Tuber Ischii
The rearmost (caudal) projection on the floor of the pelvis.

Pineal Body
Pineal body is a small structure situated in a deep recess of the mid-brain. It occupies a position similar to the third eye in certain reptiles. The pineal body is often regarded as an endocrine gland, concerned with growth. It is the source of MELATONIN, and it has an inhibitory action on the gonads.

'Pining', Pine
A term formerly used to describe any progressive loss of condition in sheep, but nowadays – together with 'vinquish' – usually reserved for copper or cobalt deficiency. This occurs in many parts of the world, is known as bush sickness in New Zealand, and has been reported in areas of Scotland, Northumberland, Devon and North Wales, where tracts of land are cobalt deficient. (See under COPPER and COBALT.)

'Pink-Eye'
'Pink-eye' is the colloquial name for infectious keratitis of cattle caused by *Moraxella (Haemophilus) bovis*; and also for EQUINE VIRAL ARTERITIS. (See EYE, DISEASES AND INJURIES OF.)

'Pink Tooth'
The colloquial name for congenital PORPHYRIA in South Africa.

Pinna
The major part of the external ear, supported by the conchal cartilage.

Pinnepedia
(noun, Pinneped)
Carnivorous mammals (pinnepeds) of the Suborder *Pinnipedia* (derived from the Latin pinna [wing or fin] and ped [foot]. They are a diverse group of semiaquatic mammals including eared seals (furred seals, Sea Lions), and earless SEALS [PHOCIDAE], Walruses, etc.

Piperazine Compounds
Piperazine compounds are used in the treatment of roundworm infestations in dogs and cats; also in pigs, poultry and horses. They are of low toxicity and can be given in wet or dry food.

Piperonyl Butoxide
A chemical synergistic with pyrethroid compounds, with which it is found in several ectoparasiticides.

Pirlimycin
An antibiotic used to treat mastitis caused by Gram-positive organisms. It is used in intramammary preparations.

Piroplasmosis
(See CANINE BABESIOSIS.)

Piroplasms
Piroplasms are protozoon parasites of the red-blood cells and the cause of numerous tick-transmitted diseases. They include *Babesia* and *Theileria*. (See BABESIOSIS.)

Piscivorous
Fish-eating.

Pitangueiras Cattle
A breed of cattle; RED POLL and Guzera (itself originally a Red Poll Brahman) developed in Brazil with Red Poll semen from the UK.

Pit Bull Terriers
A very strong muscled dog, bred for fighting. They are a type of dog rather than a breed. The possession and breeding of the breed is banned in the UK, under the Dangerous Dogs Act 1991.

Pitch Poisoning
This has occurred with fatal results in pigs after eating clay pigeons, and after contact with tarred walls and floors of pig pens. The signs are inappetence, depression, weakness, jaundice, and anaemia.

Pitohui Birds
An orange and black songbird, of attractive appearance but possessing a venom powerful enough to kill a mouse within minutes. An inhabitant of New Guinea, this bird has a sharp beak and claws. The venom is present in the bird's

VetBooks.ir

feathers, skin, and flesh. The birds sometimes attack people.

Pituitary Dwarfism

An uncommon inherited condition in dogs caused by cyst formation in the PITUITARY GLAND. It shows after the third month of life. The puppy coat is retained and there may be bilateral ALOPECIA on the trunk. There is proportional DWARFISM and the life expectancy is reduced, death usually occurring within a year.

Pituitary Gland

The pituitary gland is a small oval body up to 2.5 cm (1 in) in diameter, attached to the base of the brain and situated in a depression in the upper surface of the sphenoid bone called the *Sella turcica*. The gland is connected to the hypothalamus.

The anterior lobe produces several hormones. One of these, the growth hormone somatotrophin (STH), has an important effect on protein metabolism. Lack of this hormone causes or contributes to dwarfism. STH controls body growth, including fetal growth in pregnant females.

Adrenocorticotrophin (ACTH) stimulates the cortex of the adrenal gland. Thyroid-stimulating hormone (TSH) stimulates the thyroid.

Pituitary gonad-stimulating hormones include luteinising hormone (LH), follicle-stimulating hormone (FSH), and prolactin which is associated with lactation. (For the functions of LH and FSH see under LUTEINISING HORMONE and FOLLICLE STIMULATING HORMONE, respectively.)

When hypertrophied in the young, the gland causes gigantism, in which a great increase in size occurs. Hypertrophy or increased function in adults results in acromegaly, in which there is a sudden growth of extremities of the body. If it atrophies, growth ceases, and a condition of infantilism results. In this there is a pronounced lack of development of ovaries and testes and of secondary sex characters, together with deposition of fat, and a general sluggishness and lack of development. In the male there is a tendency towards reversion to female characteristics, but the opposite effect in the female is not observed. Anterior lobe extract is used to correct such atrophic conditions. (See also TWINNING, ARTIFICIAL.)

The posterior lobe secretes two important hormones:

1. vasopressin, which is also known as the antidiuretic hormone (ADH), being concerned with water loss from the body; lack of ADH gives rise to diabetes insipidus;
2. oxytocin acts on the muscular wall of the uterus causing contraction, e.g. during birth; it also acts on the mammary gland and is sometimes known as the 'let-down hormone' in connection with the release of milk.

Pituitary tumours In a series of eight dogs, some tumours were found to be carcinomas but more were adenomas.

Signs Lethargy, pacing, circling, head-pressing, and partial paralysis affecting all four limbs.

Death occurred in from two weeks to 13 months. Tumours are also common in aged rats.

Pituitary Pars Intermedia Dysfunction (PPID)

(See CUSHING'S SYNDROME.)

Pituitrin

An extract prepared from the posterior lobe of the pituitary gland, and containing two distinct fractions: one affecting the blood vessels and the other, the uterine muscle. These fractions are named the 'pressor' and 'oxytocic' principles, respectively. In human and veterinary medicine the purified oxytocin fractions are prepared as a separate product. (See HORMONES; ENDOCRINE GLANDS; OXYTOCIN.)

Pityosporon spp.

(See MALASSEZIA.)

Pityriasis

Pityriasis is a bran-like (dandruff) eruption 3 cm to 4 cm in diameter that appears on the surface of the skin. In animals, it is found only in pigs; the cause is not known. *Pityriasis rosea* is quite common and high levels have been seen in offspring from some LANDRACE boars. Lesions resemble ringworm, are red, and last about 10 weeks.

Pitysporon

A genus of yeast-like fungi. Now called MALASSEZIA.

'Pizzle Rot'

A disease of the prepuce and penis (BALANOPOSTHITIS); it is very uncommon in the UK, being mainly seen in castrated male MERINO SHEEP in Australia. The condition is caused by *Corynebacterium renale* and occurs when there is lush grass causing the urine to become alkaline. The prepuce and penis become scabby, ulcerated, swollen and inflamed; it is painful, and urine normally dribbles out of the prepuce. It is known as enzootic balanoposthitis. Affected ewes develop a vulvitis. (See under BALANITIS.)

Placenta

The placenta (afterbirth) is the organ of pregnancy by which the fetus is nourished while in the uterus.

VetBooks.ir

Food and oxygen are supplied to the fetus and carbon dioxide and waste products are removed from it and enter the dam's circulatory system for eventual excretion. The placenta develops after IMPLANTATION and is expelled after PARTURITION.

Structure It is composed of three fetal membranes:

1. The chorion, which is the outermost, is a strong fibrous membrane, the outer surface of which is closely moulded to the inner surface of the uterus. The chorion has villi, which are vascular projections inserted into the crypts of the uterine mucous membrane.
2. The allantois is the middle membrane. It develops early in embryonic life as an outgrowth from the hind-gut, and insinuates itself between the other two membranes. That part of the allantois remaining inside the abdominal cavity of the fetus forms the urinary bladder in after-life, and, until the time of birth, is in direct communication with the extra-fetal portion by means of the urachus – that part passing through the umbilicus. Fluid secreted by the kidneys of the fetus and passing to the urinary bladder gains exit to the allantoic cavity, which is outside the fetus, until just before the time of birth, when the passage is closed.
3. The amnion, which is continuous with the skin at the umbilicus (navel), and completely encloses the fetus but is separated from actual contact with it by the amniotic fluid, or the 'liquor of the amnion', which in the hunter type mare measures about 5 l or 6 l (9 to 10 pints).

This 'liquor amnii' forms a kind of hydrostatic bed in which the fetus floats, and serves to protect it from injury, shocks, extremes of temperature, allows free though limited movements, and guards the uterus of the dam from the spasmodic fetal convulsions which, late in pregnancy, are often vigorous and even violent.

At birth the placenta helps to dilate the cervical canal of the uterus and the posterior genital passages, and later protrudes from the vulva where it forms part of the 'waterbag', and, on bursting, lubricates the maternal passages. (See PARTURITION.)

The membranes should be discharged from the uterus with or soon after the young animal, but it is not uncommon to find their expulsion delayed for a variable time, depending upon the species and the individual. Immediately after the birth of the young animal the uterus contracts to a size smaller than when pregnant, with the result that the attachment between fetal envelopes and maternal uterus is severed to a greater or lesser extent. Afterpains follow, similar to those of normal labour, but less severe, with the object of expelling the membranes.

In the mare, attachment is scattered and slight; the afterbirth separates rapidly and is soon expelled; indeed, not infrequently the foal is born still enveloped in, or attached to, its membranes. These appear as a complicated mass of pinkish-grey tissue, plentifully supplied with blood, and often possessing little bladder-like pockets of amniotic or allantoic fluid.

If, in six hours, the placenta has not been discharged naturally, measures should be taken to effect its prompt removal, for the mare is very susceptible to metritis.

In the cow, where the attachment is cotyledonary, the fetal membranes may be expelled at any time during the first 6 hours after calving, or not for one or two days, without any serious consequences. Retention occurs frequently.

In those animals which normally produce multiple offspring at a birth – ewe, sow, bitch and cat – as each fetus is born the corresponding membranous envelope either accompanies or else immediately follows it. The exception to this otherwise almost invariable rule is in the case of the last fetus to be born, which occupied the extremity of one or other horn of the uterus; the envelopes of this, the youngest member of the family, are sometimes retained, and may occasion a mild or severe metritis, until such time as they are expelled. (See UTERUS, DISEASES OF.)

The bitch, cat, sow, cow and even the mare eat the membranes.

Retained placenta is one of the undesirable sequels of parturition. Retention of the fetal membranes is commonest in the cow. Normally, the membranes should be expelled in from half an hour to four or five hours after the birth of the calf, but owing to the intricate cotyledonary attachment in cattle, they are often retained for long periods. (See PARTURITION.)

Signs A portion of the fetal membranes hangs from the lips of the vulva attached to what remains inside the cavity of the uterus. The exposed portion may measure only a few inches, or be a large mass reaching to the cow's hocks. In some cases there is no membrane visible externally, but there is an odour of decomposition evident.

During the first day after calving the membranes in an ordinary uncomplicated case are fresh, slimy, and pinkish in colour. There is no objectionable smell, and the cow is not distressed. After the second day the external portions undergo decomposition; the colour becomes greyish; an offensive chocolate-brown-coloured discharge makes its

VetBooks.ir

appearance and soils the hindquarters and tail of the cow. She stands with her back arched, frequently switches her tail and paddles with the hind-feet.

Masses of semi-dissolved membrane, looking like pieces of wet cobweb, are passed out at intervals, and can be found behind the cow along with quantities of greyish foul-smelling discharge; the mucous membrane of the vagina is inflamed, and the cow resents having her hindquarters examined.

It is certainly not advisable that a mass of decomposing fleshy material should be allowed to hang from a cow's uterus for a longer time than is absolutely necessary, but too hasty attempts at removal may be followed by infertility or even death.

In modern practice, hormone injections (PROSTAGLANDINS) have largely displaced manual removal, with its attendant risks. Manual removal consists of introducing the hand and arm, protected in sterile disposable plastic sleeve-length gloves; if these are not available, the hand and arm must be cleansed as far as possible by thorough washing in an antiseptic solution, and a subsequent rinsing in strong salt and water. The membranes should not be removed until they can be displaced without difficulty, and without distress to the cow. Each cotyledon is grasped as it is reached, and the adherent membrane is peeled off from its surface with the fingers and thumb. At the same time gentle traction should be exerted upon the protruded membranes from the outside.

After removal it may be advisable to flush out the uterus with a suitable antiseptic solution, and to give prophylactic antibiotics (see UTERUS, DISEASES OF - THE COW).

In the sow and bitch the membranes that are liable to be retained are those belonging to the fetus that is born last, which occupied the extremity of one or other of the horns of the uterus, but the condition is rare in each of these animals.

It is most advisable that owners of animals which have retained their afterbirth after parturition should seek veterinary advice.

Plague

A disease epidemic accompanied by high mortality. (See CATTLE PLAGUE; AVIAN INFLUENZA (FOWL PLAGUE); BUBONIC PLAGUE.)

Plantain, *Plantago lanceolata*

A relatively recent crop in Britain, although more grown in the USA and Australia, mainly used for sheep. It grows well in a variety of soils except deep sands or waterlogged soils and ceases growing in most British winters. It increases supply of some minerals, especially COBALT, COPPER and SELENIUM and it reduces the impact of helminths. (See ROUNDWORMS - CATTLE, SHEEP AND GOATS.)

Plantar

At the back of the hind-limb.

Plantar Cushion

Plantar cushion is the dense fibro-fatty rubber-like structure which lies immediately above the frog in the foot of the horse, and is one of its most important anti-concussion or shock-absorbing mechanisms. (See FOOT OF THE HORSE.)

Plant Juice

At grass-drying plants, when mechanically de-watering forage before drying, a rich green juice is expressed. The juice represents a source of protein concentrate comparable with fish-meal in value.

From six tons of fresh material, such as lucerne or grass, 2.5 tons of this plant juice is squeezed out. However, using plant juice presents some problems, as it is very unstable, due to enzyme action. It must be heated to about 85° C (185° F) to stabilise the protein, and some chemical preservative is also added.

The easiest way to use the juice is to include it in liquid pig feed.

Plasma

Plasma is the fluid portion of the blood. It can be produced by centrifugation to separate the red cells. Fresh plasma should be produced within eight hours of donation and is then usually frozen for storage. (See also LACTESCENT SERUM.)

Plasma Cells

Also called PLASMACYTES (or plasmocytes). Larger than lymphocytes, with dark-staining granules in the nucleus, plasma cells are found in the lymph nodes, and are concerned with antibody production. (See diagram under LYMPHOCYTE.)

Plasmacytes, Plasmocytes

Also called PLASMA CELLS. A single cell involved in the synthesis, storage and release of antibodies.

Plasma Substitutes

(See DEXTRAN; GELATIN, SUCCINYLATED.)

Plasmids

Plasmids are genetic structures which many species of bacteria possess in addition to their chromosomes, and which, like the chromosomes, determine the inheritance of various properties. Since plasmids are not essential to cell growth, the cell may gain or lose them without lethal effect. Some plasmids can unite with chromosomes: these are

called episomes. All episomes are plasmids but not all plasmids are episomes.

Plasmids have been defined as 'circular lengths of DNA which behave as viruses with a restricted range of host bacteria, and which are replicated in step with the organism'. (See also GENETIC ENGINEERING.)

Infectious (self-transmissible) plasmids are found in Gram-negative rods. In addition to genes coding for specific properties (e.g. R-determinants coding for antibiotic resistance), these plasmids also possess other genes which code for the production of sex pili by which conjugation with a recipient cell is made possible. Non-transmissible plasmids, also found in Gram-negative rods, lack the genes necessary for self-transfer; for these plasmids to be transferred the cell must first be infected with a sex-factor from another cell.

In Gram-positive organisms, plasmids may be transduced from one cell to another by bacteriophages.

Plasmin

This is an enzyme from PLASMINOGEN which breaks down FIBRIN clots.

Plasminogen

It is the precursor of PLASMIN and is found in plasma. It can be converted by activators found in blood, most tissues, vessel walls and body fluids. It is also called PROFIBRINOLYSIN.

Plasmodium gallinaceum

A parasite which causes malaria in the domestic fowl.

P. durae causes death in turkey poults.

'MALARIA OF BIRDS' is a group of almost worldwide infections which include *Haemoproteus* and *Leucocytozoon* as well as *Plasmodium*.

Plaster Casts

(See SPLINTING MATERIALS.)

Plastic Bags or Sheeting

Cattle have died following ingestion of plastic bags discarded on grazing land. In some instances the material is digested and does not cause an obstruction.

Plastic 'Bones'

A fractured scaphoid in the right hind-leg of a racing greyhound has been successfully replaced by a plastic replica of a scaphoid bone. For a further use of plastics, see under HOOF REPAIR WITH PLASTICS.

Plate Culture

The growing of bacteria in a medium contained in a Petri dish, a covered, shallow, circular glass dish which gives a large surface area.

Platelets, Thrombocytes

Platelets (Thrombocytes) are described under BLOOD.

Plating

Plating is the cultivation of bacteria on flat plates (Petri dishes) containing nutrient material. The term is also applied in surgery to the method of securing union of fractured bones by screwing to the sides of the fragments narrow metal plates which hold them firmly together whilst union is taking place.

Pleomorphic

The description of an organism, such a micro-organism, which can assume various forms.

Pleomorphism

The assumption of different forms by the same organism, usually a micro-organism.

Pleura

Pleura is the membrane which covers the external surfaces of the lungs and lines the inside of the chest walls. (See LUNGS.)

Pleural Cavity

In normal healthy animals this is merely a potential cavity, since between the pleura lining the chest and the pleura covering the lungs there is usually a thin film of fluid. Surface tension holds the one surface to the other.

Pleurisy, Pleuritis

Inflammation of the PLEURA, which may occur as a complication of pneumonia, of 'shipping fever' in cattle, and in cases of tuberculosis and other infections; occasionally from a chest wound.

Friction between the inflamed surfaces gives rise to pain each time the animal breathes, and the breathing is changed in character – i.e. there is minimal movement of the chest walls, and extra effort by the abdominal muscles, which appear to be doing all the work. The line of the rib cartilages often stands out prominently, giving rise to what has been called the 'pleuritic ridge'. Other signs include fever, dullness, and what is often described as a 'hacking' cough; sometimes a rasping sound due to friction may be heard.

After 12 to 48 hours the painful stage of pleurisy may be followed by an effusion of fluid. Removal of this fluid becomes necessary if respiration is seriously impaired by it.

Sometimes the fluid is purulent, a condition known as 'empyema'. Sometimes there is very little effusion, and the condition remains one of 'dry pleurisy'.

A complication of pleurisy is that adhesions sometimes occur, and persist, between the parietal

and visceral pleura. (See also PLEURODYNIA; PLEURO-PNEUMONIA.)

Treatment Pleurisy is one of those conditions in which professional advice is highly desirable in the early stages, and reliance should not be placed on first-aid. It may be necessary to withdraw fluid from the chest, to administer an appropriate antibiotic; and it is important to establish the presence or absence of tuberculosis. (See also NURSING OF SICK ANIMALS.)

Pleurodynia
Pleurodynia means a painful condition of the chest wall. It is a sign of PLEURISY; it may be due to fractures of the ribs; it is sometimes seen in tumours affecting the chest wall, and it is commonly recognised by pressing the fingers into the spaces between the ribs.

Pleuro-Pneumonia
Pleuro-pneumonia is a combination of PLEURISY with a PNEUMONIA. Acute pneumonia is often accompanied by some amount of pleurisy, which is largely responsible for the painfulness which accompanies pneumonia. (See also CONTAGIOUS BOVINE PLEURO-PNEUMONIA.)

Plexus
Plexus is a network of nerves or vessels, e.g. the brachial and sacral plexuses of nerves and the choroid plexus of veins within the brain.

Plumage
The feather covering of a bird.

Plumbism
Plumbism is another name for chronic lead poisoning. (See LEAD POISONING.)

Pluriparous, Multiparous
Relating to a female who has produced more than one viable offspring or more than one litter.

PML
Pharmacy and merchants' list: under the Medicines Act 1968 a category of veterinary medicines which was sold to the public only through pharmacies; and to farmers or others 'maintaining animals in the course of their business' through pharmacies or agricultural merchants. Horse and pony owners were able to obtain PML horse wormers from pharmacies, agricultural merchants or registered saddlers. Under the Veterinary Medicines Regulations most of these medicines are recategorised as POM-VPS (Prescription-Only Medicine – Veterinarian, Pharmacist, Suitably Qualified Person.

PMS
Pregnant mare's serum, a source of gonadotrophin.

PMWS
(See POST-WEANING MULTISYSTEMIC WASTING SYNDROME.)

Pneumatised Bones
These occur in birds, where they supply additional space for the respiratory system. The air-filled cavity of a pneumatised bone communicates with an AIR SAC. Pneumatised bones include the humeri and femora and others which vary between species.

Pneumocystis Pneumonia
Pneumocystis pneumonia, one of the most serious diseases of human AIDS patients, has been found in dogs, cats, rodents, and primates.

Pneumogastric nerve
Another name for the VAGUS nerve.

Pneumomediastinum
The presence of air in the MEDIASTINUM, following damage to the lung alveolar tissue near its root. Other causes the trauma may be more serious, e.g. escape of air from a damaged trachea or rupture of the oesophagus. A swelling on a dog's whole face and neck due to subcutaneous EMPHYSEMA may follow pneumomediastinum, the air tracking upwards. It may take weeks before the swelling totally disappears, but the condition is seldom serious unless the trachea or oesophagus are damaged.

Pneumomycosis
A fungal infection of the lungs.

Pneumonia
Pneumonia may be defined as inflammation of lung tissue.

Pneumonias have been classified in various ways, e.g. according to the area or tissue involved, or according to lesions, or causes.

Lobar pneumonia is that in which a whole lobe is involved; in lobular pneumonia the inflammation is less localised and more patchy. Bronchopneumonia is that in which the inflammation is concentrated in and around the bronchioles leading from the bronchi. Pleuro-pneumonia, as the name suggests, involves the pleural membranes as well as the lung itself. Interstitial pneumonia affects the fibrous supporting tissue of the lung rather than the parenchyma though consolidation of the latter can then occur. (See also LUNGS, DISEASES OF for lesions.)

Pneumonia, which can be acute or chronic, may – as mentioned above – also be classified according to causes, e.g. viral, mycoplasmal, bacterial,

VetBooks.ir

mycotic, parasitic and non-infective. It must be borne in mind, however, that infections may be mixed and changing. (See RESPIRATORY DISEASE IN PIGS for an explanatory diagram.)

Pneumonia may arise from a primary viral infection, with complications caused by secondary bacterial invaders, as in canine distemper. Some viruses and bacteria depend upon each other, as explained under SYNERGISM. The infection may be a very mixed one, e.g. in ENZOOTIC PNEUMONIA OF PIGS. Bacterial pneumonia may be acute, e.g. KLEBSIELLA infection, or of a chronic suppurative type, e.g. TUBERCULOSIS.

The main effect of pneumonia, whether through the presence of exudate in the bronchioles and alveoli, or destruction of areas of lung by abscess formation or consolidation or hepatisation, is that the normal exchange of carbon dioxide for oxygen is impaired and impeded. The animal has to struggle for breath to obtain sufficient oxygen.

Signs With less oxygen available to the red blood cells (and hence to the organs and tissues) at the normal respiratory rate, the animal accordingly needs to breathe faster. This increased respiratory rate (tachypnoea) is therefore a main sign. The breathing may also become laboured and painful (dyspnoea). Fever is usually present, with accompanying dullness and loss of appetite (but see under CALF PNEUMONIA for an exception to this). There is often a cough, though this is not an invariable or attention-catching sign.

Viral pneumonia In cattle, most cases of viral pneumonia, uncomplicated by secondary bacterial infection, show areas of collapse in the lungs, emphysema of the apical lobes, some in the cardiac lobes but little in the diaphragmatic lobes, with little or no exudate. An acute pneumonia may develop in some cases of infectious bovine rhinotracheitis. (See RHINOTRACHEITIS, INFECTIOUS BOVINE.) Bovine syncytial virus is another important pathogen, causing coughing, oedema of the lungs, consolidation and emphysema. (See also CALF PNEUMONIA.) In horses, pneumonia in young foals may be caused by equine herpesvirus 1. (See also SWINE PLAGUE.)

Mycoplasmal pneumonia An example of this is fully described under CONTAGIOUS BOVINE PLEURO-PNEUMONIA – a disease not normally present in the UK. *Mycoplasma bovis* and *M. dispar* are primary pathogens in the UK. The latter may cause CALF PNEUMONIA of a mild type except for the harsh cough. (See also under MYCOPLASMA.)

Bacterial pneumonia Bacterial toxins may have an important additional effect in this. In cattle, *Pasteurella haemolytica* can be a primary cause of pneumonia, typically producing much exudate as well as a secondary invader. In horses *Corynebacterium equi* causes a suppurative bronchopneumonia in foals, and in adult horses a suppurative pneumonia may also occur during the course of strangles.

Streptococcus pneumoniae and *Staphylococcus aureus* are other important secondary invaders of damaged lungs.

Parasitic pneumonia This may be an extension of PARASITIC BRONCHITIS in calves, caused by the lungworm *Dictyocaulus viviparus*. Autopsy findings include dark red consolidation of some lung lobes. In pigs, lungworms (*Metastrongylus*) are also a cause of pneumonia.

Mycotic (fungal) pneumonia is caused by *Aspergillus* species, and also by *Candida albicans.* (See MONILIASIS.) The latter may be associated with oedema of the lungs, in both mammals and birds, and may follow the use of certain antibiotics. (See also PHYCOMYCOSIS.)

Allergic pneumonia (See 'FARMER'S LUNG' which affects cattle also.)

Non-infective pneumonia can result from the action of certain poisons, e.g. PARAQUAT, ANTU and phenolic sheep dips (see DIPS AND DIPPING), as well as from aspiration pneumonia. The latter may result from milk 'going the wrong way' in bucket-fed calves, and also from medicines administered to animals by stomach tube passed in error into the trachea instead of the oesophagus (fortunately a rare occurrence!). Aspiration of vomit is another example.

Non-infective pneumonia quickly becomes infective, as micro-organisms take advantage of the inflamed mucous membranes. The animal becomes suddenly dull, uninterested in food, feverish, and may show signs of chest pain. Death can be expected within 72 hours, and autopsy findings may include areas of necrosis and abscess formation.

Treatment of pneumonia Separate affected animals, provide good-quality feed in a well-ventilated environment, free from draughts, and good bedding. Appropriate antibiotics, sulfa drugs, and trimethoprim may all be of service. Heart stimulants, the administration of oxygen, and possibly diuretics in the case of oedema, may be indicated. Anti-inflammatory drugs, e.g. FLUNIXIN MEGLUMINE, may help in the acute stage. The one golden rule in the treatment of pneumonia in all animals is: 'Do not drench.' Medicines should be administered by injection, in

the food, or perhaps as an electuary. (See also NURSING OF SICK ANIMALS.)

Pneumonia in Calves

(See CALF PNEUMONIA.)

Pneumonia in Cats

Bronchopneumonia can be a complication of feline viral rhinotracheitis in young cats.

In older cats tuberculosis is still sometimes a cause of disease of the lungs, though with nearly all milk now pasteurised in EU countries, feline TB is no longer at all common. It can, however, result from a cat eating TB-infected prey.

A granulomatous pneumonia is caused, rarely, by *Corynebacterium equi*. Theoretically, a stable cat would be more prone to it.

Pneumonia in Horses

In a USA study, anaerobic bacteria were isolated from pleural fluid or tracheobronchial aspirates obtained from 21 of 46 horses with bronchopneumonia. *Bacteroides oralis* and *B. melaninogenicus* were the species most commonly isolated (nine and five horses, respectively). Other *Bacteroides* species were cultured from 12 animals and *Clostridium* species from eight. A putrid odour was associated with the pleural fluid and/or breath of nearly two-thirds of the horses from which anaerobes were isolated. The prognosis was significantly poorer in cases with anaerobic infections; 14 of the 21 horses involved either died or were euthanased. (See also under FOALS, DISEASES OF.)

Another cause is *Corynebacterium equi*, which can also infect cats.

Pneumonia in Pigs

Actinobacillus (Haemophilus) pleuropneumoniae is a major cause of pneumonia in pigs. (See RESPIRATORY DISEASE IN PIGS.)

For the most common form of pneumonia in pigs, see under ENZOOTIC PNEUMONIA OF PIGS. (See also SWINE PLAGUE.)

Pneumonia in Sheep

In Britain, pneumonia caused by *Mannheimia haemolytica* has become more frequent. This organism commonly lives in normal sheep, and causes disease only when the animal's resistance is weakened by bad weather, transport from one farm to another, movement from a poor to a richer pasture, or perhaps by a virus. In some outbreaks, where the disease takes an acute form, a sheep which seemed healthy enough in the evening may be found dead in the morning. Usually, however, the shepherd sees depressed-looking animals with drooping ears, breathing rather quickly and having a discharge from eyes and nostrils, and a cough. Death often occurs within a day or two. The last sheep to be involved in the outbreak tend to linger for several weeks, looking very tucked-up in the meantime, with a cough and fast breathing. Vaccines are available for prevention.

Another cause of pneumonia in sheep is *Chlamydia psittaci*. (See also HAEMORRHAGIC SEPTICAEMIA, which occurs in the tropics; PARAINFLUENZA 3 VIRUS; MAEDI/VISNA.)

Pneumothorax

Pneumothorax is a condition in which air has gained access to the pleural cavity through a wound in the chest wall. (See LUNGS, DISEASES OF.)

Pneumothorax is not uncommon in the dog which has fallen out of a window, or been run over or hit by a car. Distressed breathing and cyanosis are, following an accident, suggestive of pneumothorax.

Mild cases may be accompanied by mild signs, and spontaneous recovery may occur. Severe cases may die. Treatment includes aspiration of the air from the pleural cavity. (See also LUNGS, DISEASES OF - COLLAPSE OF THE LUNG.)

Simple pneumothorax In such cases, the condition may be caused by sudden non-penetrating trauma to the chest wall which momentarily raises the intrathoracic pressure. If this occurs against a closed glottis, then alveolar tissue may rupture. In many cases the leak will be small, but in others, sufficient air will enter the pleural cavity to cause marked dyspnoea.

Pneumothorax may be seen in rabbits that have survived an attack from a cat or dog and sustained a puncture injury to the chest.

Open pneumothorax is caused by a penetrating wound of the chest wall, resulting in an immediate and total collapse of the lung. Air can be heard entering the chest wound at each respiratory effort. There is severe dyspnoea.

Tension pneumothorax may develop following an open pneumothorax, or when a small bronchus ruptures, and air accumulates in the pleural space during inspiration but is not expelled during expiration. The mediastinum is apt to be displaced from the midline, partially collapsing the remaining functional lung.

Pneumovirus

A cause of rhinotracheitis in turkeys and chickens. An ELISA test is available for diagnosis.

'Poaching'

Land becoming muddy and broken up by the feet of animals. Especially soil with a high proportion

VetBooks.ir

of heavy clay (i.e. heavy land), and with high stocking rates, wet weather can bring serious poaching problems. (See DAIRY HERD MANAGEMENT.) At gateways, deep mud (in winter often at near-freezing temperatures) can lead to foul-in-the-foot and mastitis.

Pododermatitis

(See FOUL-IN-THE-FOOT.)

Pododermatitis in Poultry

A problem that can result from wet litter and ammonia production.

Pododermatitis in Rabbits, 'Sore Hocks'

A chronic DERMATITIS of rabbits with ulceration of the back of the hocks and occasionally on the front of the knees. It is common and seen in commercial and pet rabbits. Factors include improper flooring, OBESITY, ARTHRITIS and other conditions, and insufficient fur on the feet. It is very difficult to treat and often any underlying cause should be addressed. Otherwise, ANTIBIOTICS, painkillers, anti-inflammatories, artificial skin and bandaging have all been used.

Poikilocyte

Poikilocyte is a malformed red blood cell found in the blood in various types of anaemia.

Poikilothermic

Commonly called 'cold-blooded'. The rate of metabolism of such an animal varies with its environmental temperature although some internal heat can be produced (see below).

Poikilothermy

The situation in which an animal's temperature and metabolism varies with and reflects its environment. Some internal production of heat is possible. (See also ECTOTHERMY and ENDOTHERMY.)

Pointer

A medium-sized, slim dog with long neck and pointed tail; used as a gun dog. ENTROPION and ununited ANCONEAL PROCESS and SPINAL MUSCULAR ATROPHY are inheritable, as may be CALCINOSIS CIRCUMSCRIPTA.

Poisoning

Most cases result from the poison being swallowed. In a few instances poison may be taken in through a wound of the skin, or even through the unbroken skin, e.g. phenol preparations. Malicious poisoning is most frequently carried out against dogs and cats, although horses and ruminants are also targeted.

The use of poison to control vermin – rabbits, foxes, rats, mice, etc. – is a hazard, for when the poisoned bait is accessible to domesticated animals, cases of poisoning may result. It should be remembered that the exposure of such poison above ground constitutes an offence.

The constituents of common and commercial rat-poisons are mentioned under RODENTS - RODENTICIDES.

Many cases of poisoning result from the careless use of sheep-dips, paints, weed-killers and insecticides, which, in powder, paste, or solution, are left about in places to which animals have access. Cattle are notoriously inquisitive, and will lick at anything they find, sometimes with fatal consequences.

It is perhaps not widely enough realised that cattle seem to like the taste of lead paint – one heifer helped herself to a whole pint of it – and that very small quantities spattered on the ground can kill several beasts. Even the contents of old, discarded paint tins can be lethal. In one instance, children found such tins and scraped out the residue on to pasture, killing five yearlings. In another instance, cattle licked out old paint tins on a rubbish dump in a pit to which they found their way. A recently painted fence is also a danger.

Parrots allowed freedom in old domestic houses often chew the woodwork. If this has been painted many years ago when paints contained more lead than those produced today, even if it were under several coats of more modern paints, signs of lead poisoning might be observed.

Thirsty cattle will drink almost anything: diesel oil and a copper-containing spray liquid have each caused death in these circumstances. SALT POISONING is certainly no myth, and pigs should never be kept short of drinking water.

Some insecticides, such as TEPP and Parathion, are totally unsuitable for use on livestock. Fatal poisoning of a herd of cattle sprayed with TEPP has been reported from Texas. Many old containers of banned organochloride compounds have survived national bans and occasionally poisoning cases are seen. (See HERBICIDES; WEEDKILLERS.)

Near factories and chemical works, grass, etc., may become impregnated with fluorine compounds, copper, lead or other metals, and lead to chronic poisoning of any animals grazing nearby. The same thing applies in orchards after spraying of fruit-trees. Pasture may be contaminated by spray-drift or dusting operations, particularly from the air, and the chemicals used may cause poisoning. This applies also to other treated green crops which animals may eat. DDT and BHC and other insecticides (used in home and garden) of the CHLORINATED HYDROCARBON group may poison birds, cats and dogs. (See also ORGANOPHOSPHORUS POISONING; FARM CHEMICALS; FLUOROSIS.)

VetBooks.ir

The use of pitch (the poisonous ingredient of clay-pigeons) or coal tar on the walls and floors of piggeries is a cause of poisoning. Some wood preservatives cause hyperkeratosis.

Poisoning may result from indiscretion on the part of owners or attendants in the use of patent or other animal medicines, or from the administration to animals of tablets, etc. intended for human use, e.g. paracetamol, caffeine.

Dogs and cats may also be poisoned by gaining access to unsecured medicines (pills, tablets, etc.) intended for human use. IBUPROFEN (Nurofen) is particularly palatable and attractive to dogs but it is very toxic in this species and must not be given as home medication to a dog 'off colour'. Other NSAID derivatives are more suitable. For home and garden hazards to pet animals (including cage birds), see under CARBON MONOXIDE; 'FRYING PAN' DEATHS; ANTIFREEZE; CREOSOTE; LEAD POISONING; METALDEHYDE POISONING; BHC POISONING; BENZOIC ACID POISONING; WARFARIN; DDT; HOUSE PLANTS; HOUSE DECORATING, POISONING; 'NEW WIRE DISEASE'. If one considers dogs out for walks, one should add DIELDRIN; PARAQUAT; FARM CHEMICALS. Dogs are susceptible to theobromine and caffeine in chocolate, on which they can easily overdose. Foods sweetened with the sugar substitute xylitol, to which dogs are highly susceptible, can cause a drop in blood sugar levels.

Cats: all parts of the lily are highly toxic. Cats may brush against the flowers and be poisoned by licking the pollen off them; acute and fatal poisoning may result.

As regards dog and cat foods, poisoning has resulted from biscuit meal made from corn dressed with dieldrin, from stored food contaminated by rats' urine containing warfarin, from aflatoxins, and from horse-meat containing barbiturates or choral hydrate. In the cat, food containing benzoic acid as a preservative has caused poisoning.

Fodder poisoning Excess of fodder beet may cause scouring in both pigs and cattle, and the after-effects may be serious. In sows just farrowed, the milk supply may almost disappear. Beet tops have caused the deaths of cattle when given unwilted, and even when wilted they should be strictly rationed. Kale and rape poisoning can occur in cattle and sheep; these must be used sparingly and not constitute an animal's sole diet, and hay in particular is necessary in addition. Deaths have occurred in horses and cattle restricted to rye-grass pasture. Sheep have been fatally poisoned by feeding them surplus pig-meal containing a copper supplement; a heifer likewise. Pigs have been poisoned by giving them medicated meal intended for poultry and containing nitrophenide against coccidiosis. Medicated feeds are by no means always interchangeable between different species of livestock, since there are genetic differences between them as regards susceptibility to poisoning, depending in part upon possession or absence of some enzyme which can readily detoxify the poison. (See GROUNDNUT MEAL.)

The use of surplus seed corn for pig-feeding has led to fatal poisoning – the mercury dressing having been overlooked! (See DIELDRIN for poisoning from seed dressings, and FLOOR SWEEPINGS; also MONENSIN SODIUM.)

Hay contaminated with foxgloves or ragwort is a source of fatal poisoning. Silage contaminated with ragwort has similarly caused death. Silage contaminated with hexoestrol has caused abortion. (See under HORMONES IN MEAT PRODUCTION.)

Poisonous plants growing in pastures, in swampy or marshy places, in the bottoms of hedges, on waste land and in shrubberies and gardens, are other very common sources of poisoning. In the early spring, when grass is scarce, and when herbivorous animals are let out for the first time after wintering indoors, the tender succulent growths attract them, often with serious consequences. Similar results may be seen during a very dry summer when grass is parched. Ragwort and bracken are the most common causes of plant poisoning in cattle; in sheep, bracken can cause night blindness and neoplasia as well as true poisoning. (See BRACKEN POISONING.)

Clippings from shrubs, especially from yew, rhododendrons, aconite, boxwood, lupins, laurel, laburnum, etc., should never be thrown 'over the hedge', because in some of these the toxic substances are most active when the clippings have begun to wither, and animals are very prone to eat them in this condition. It is a safe rule to regard all garden trimmings as unsafe for animals, with the exception of vegetables, such as cabbages and turnips. (See under ACONITE; BITTERSWEET POISONING; FOXGLOVE POISONING; HEMLOCK POISONING; LABURNUM POISONING; POTATO POISONING; RAGWORT POISONING; WATER-DROPWORT; YEW POISONING; 'LOCO WEED', etc.)

Tortoises (*Testudo* spp.) allowed uncontrolled freedom in gardens can show signs of poisoning - brassicas are goitrogenic and buttercups are eaten to excess they can cause liver disease.

Signs The signs of each of the more common poisonous agents are given under their respective headings.

It must be emphasised that the signs of some illnesses are the same as those of some poisons, and vice versa. For example, not only vomiting and diarrhoea but also cramp, fever, rapid breathing, convulsions, hysteria, jaundice, salivation,

VetBooks.ir

blindness and deafness are common to both. A professional diagnosis is therefore important.

Irritant poisons produce acute abdominal pain, vomiting (when possible), purging, rapidly developing general collapse, and often unconsciousness, perhaps preceded by convulsions. Poisoning of dogs by cannabis discarded by their owners has been recorded.

Narcotics produce excitement at first, unsteady movements, interference with sight; and later, stupor and unconsciousness appear; coma, with or without spasmodic or convulsive movements, supervenes, and death occurs in many cases.

Narcotic irritants produce signs of irritation in the first place, and later, delirium, convulsions and coma.

As a general rule poisoning should be suspected when an animal becomes suddenly ill, soon after feeding; when put out to pasture for the first time in the season after dipping; or when a change of food has recently taken place. Newly purchased animal feeds may be followed by an outbreak of illness, and such results point to the inclusion of some harmful substance. Fungal poisoning may occur as a result of mouldy barley, etc.

First-aid In suggesting simple first-aid measures, it should be emphasised that they necessarily differ from – and are likely to be less effective than – those the veterinary surgeon will take. It should be realised, too, that against some poisons there are no effective antidotes.

Where it is suspected that poisoning has arisen from use of some proprietary product, take the container (or the label from it) to your veterinarian (or write down the name of the manufacturer and product) so that he or she may ascertain the chemical ingredients and, if necessary, consult the manufacturer as to the recommended antidote.

If it is suspected that poisoning may have resulted from a skin dressing, wash this off with warm soapy water and rinse well to prevent further absorption. (See CARBOLIC ACID POISONING.)

Where a poison is believed to have been taken by mouth, give an emetic. However, emetics should be avoided if strong acids or alkalis are involved.

Emetics which may be safely used are: for pigs, a dessertspoonful of mustard in a cupful of water; for dogs, a strong salt solution (ordinary household salt), or a crystal of washing soda; for cats, the latter.

To hinder absorption in the horse, ox, or sheep, strong black tea or coffee which has been boiled may be given. These, all of which contain tannic acid or tannates, are useful against vegetable poisons.

To counteract the effects of irritants, use demulcents (olive oil, milk, milk and eggs, or liquid paraffin). Yellow phosphorus is an exception to this rule; oily substances favour its absorption and must be avoided; copper sulphate should be given instead. Against narcotics, stimulants are needed, e.g. strong coffee or black tea, given by the mouth as a first-aid measure.

Advice on poisons In the UK, veterinary surgeons may obtain information and advice concerning poisonous compounds, and their antidotes, if any, from the Veterinary Poisons Information Service, Mary Sheridan House, Guy's Hospital, London SE1 9RT. The telephone number for this subscription service for veterinary professionals is 0207 188 0200. E-mail for non-urgent administrative enquiries is vpis@gstt.nhs.uk

Confirmation of poisoning No matter how strong circumstantial evidence seems to be, it is always essential that a post-mortem examination be made, and that necessary samples of the stomach contents, portions of the liver and perhaps other organs, should be removed in the presence of an independent witness and submitted to a qualitative and quantitative chemical examination by an analyst, before a suspected case of poisoning can be considered proved beyond doubt. The necessity for this procedure is obvious when legal proceedings are contemplated.

Poisoning by Salmonella

(See SALMONELLOSIS.)

Poisonous

Pertaining to, or having the potential to, poison. (See also TOXIC, TOXINS, TOXOID, VENOM.)

Poland Chickens

A fancy breed originating from Poland. The cocks weigh 2.7 kg (6 lb) and hens 2 kg (4.5 lb). Eggs are white. These birds are bearded and coloured golden, silver, white and buff laced, and non-bearded white crested black, white crested blue, black crested white, golden, silver, white and buff laced.

Poland China

A breed of pig from Ohio, USA. Colouring is black with six white points (feet, tip of nose and tail). Rapid growth and good meat production are characteristics of the breed.

Pole Syringes

These are used for injecting animals that are wild or fractious. They allow an INTRAMUSCULAR injection to be given for sedation, anaesthetic or therapeutic purposes.

Polioencephalomalacia

(See CEREBROCORTICAL NECROSIS.)

Poliomyelitis of Pigs
This disease is distinct from that of human beings and is possibly identical with TALFAN DISEASE.

Poll
1. (Noun) The region lying between the ears and a little behind them.
2. (Verb) To remove the horns of cattle or other horned animals.

Pollakuria
The abnormal frequent passage of urine.

Polled
Inherited hornlessness of an animal belonging to a normally horned breed, e.g. HEREFORD CATTLE. (See SCUR.)

Polled Dorset Sheep
(Poll Dorset Sheep)

A white sheep, medium-sized developed in Australia. They are not closely related to the DORSET DOWN SHEEP but there is also a DORSET HORN variety. The rams weigh 100 kg to 125 kg (225 lb to 275 lb) and the ewes weigh 70 kg to 90 kg (150 lb to 200 lb) with a fleece of 2 kg to 3.5 kg (5 lb to 9 lb). Their good body and well muscled conformation has made them one of the most popular terminal sires in Australia and their use in producing the White Suffolk breed. They have an extended breeding season and so can produce 1.5 to two litters a year. Lambing in March/April; mate May; lamb autumn. The inherited condition of GLOBOID CELL LEUKODYSTROPHY occurs in the breed.

(See DORSET HORN SHEEP.)

Pollen
Pollen is the male fertilising element of flowering plants. It is incriminated in the aetiology of ATOPIC DERMATITIS and other allergic diseases of animals.

Pollen of oilseed rape has been linked to CHRONIC OBSTRUCTIVE PULMONARY DISEASE seen in horses at pasture, but it is now considered to be a major factor.

'Poll Evil'
'Poll Evil' is an old, colloquial name sometimes incorrectly applied to any swelling in the POLL region, but which should be reserved for a sinus following infection of some of the deeper tissues and giving rise to pus-formation. It may result from an injury which displaces a chip of bone from the atlas. Apart from this, and its situation, 'poll evil' resembles fistulous withers.

Causes Self-inflicted injuries such as striking the poll against the top of a doorway, or falling backwards with the poll striking the ground; blows, such as from a whip-handle; bridle pressure.

Fusiformis necrophorus has been associated with some cases and may have gained entrance through damaged skin. It has been suggested that some cases may arise through infection without injury. *Brucella abortus* and the worm *Onchocerca reticulata* have each been found, and the former is now known to account for some cases of fistulous withers.

Signs A painful swelling on one or both sides with, after a time, the appearance of one or more orifices exuding pus. The animal resents the part being touched and, if the *ligamentum nuchae* is involved, avoids downward movement of the head.

First-aid measures include the use of a poultice and the placing of food at a level which the animal can reach without pain.

Treatment may involve the enlargement of any openings to allow free drainage. Antibiotics may be used to overcome the infection.

Polo Ponies
These animals are called ponies, although they are normally over 14.2 HANDS in height. They are well-behaved animals trained for use in playing polo. The sport is very tiring and so each rider will normally have access to several animals during a single game.

Poloxalone
An anti-frothing agent used in the treatment of frothy BLOAT in ruminants. It acts by reducing the surface tension on the ruminal fluid releasing gas that can then be expelled by the animal. It is either drenched or added to the feed at times of risk.

Polyarthritis
Inflammation of several joints occurring simultaneously, as in JOINT-ILL. In pigs a common cause is *Erysipelothrix rhusiopathiae*; streptococci and staphylococci may also be involved. The disease is seen also in lambs, calves, and foals. A similar condition is seen in dogs as part of the SYSTEMIC LUPUS ERYTHEMATOSIS syndrome.

Polycerate
Multi-horned. It is seen particularly in the Jacob breed of sheep which can have two, four or six horns.

Polycystic Disease in Cats
(See KIDNEYS, DISEASES OF.)

Polycythaemia
A marked increase in the number of red blood cells. This disorder is seen, rarely, in dogs and cats.

VetBooks.ir

Polydactyly
A congenital defect in which an animal has one or more extra digits. Cattle, horses (rarely), dogs and cats may be affected; the fore-feet only or the hind-feet only may be involved. It occurs quite commonly in some cat breeds (Manx and Maine-Coon) where it is thought to be due to an autosomal recessive trait.

Polydipsia
Polydipsia is excessive thirst, which is seen as excessive water intake.

Polyfolliculitis
A condition reported in captive birds in which many feathers are produced simultaneously from one follicle. The cause of the condition is not known, and there does not appear to be any effective treatment although plucking all the feather stubs from the follicle may result in a beneficial atrophy of the follicle, or even the growth of a single replacement feather.

Polygenic Inheritance
A characteristic or trait in an animal which is inherited as a result of the interaction and cumulative effects of several, or many genes. It does not follow the Mendelian dominant-recessive principle of inheritance.

Polymelia
A developmental disorder resulting in an extra limb or limbs.

Polymerase Chain Reaction (PCR)
A laboratory procedure wherein part of natural DNA can be replicated, and therefore enlarged, to be more easily identified and examined. Used as a diagnostic test for the detection of micro-organisms in diseased tissues. Also used to amplify remnants of tissue cells – e.g. in DNA isolation. (See also REAL-TIME POLYMERASE CHAIN REACTION; REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION.)

Polymers
These are compounds comprising of a number of simpler molecules and they usually have a high molecular weight.

Polymixin B Sulphate
This is an antibiotic which has a wide range of activity against Gram-positive and Gram-negative organisms (including *Pseudomonas aeruginosa* and *Neisseria* spp.) It must be used with care as it is more toxic than many other antibiotics and is mainly used as a topical application.

Polymorph
Polymorph is a name applied to certain white cells of the blood which have a nucleus of varied shape. (See BLOOD; HETEROPHIL.)

Polyneuritis
Polyneuritis means an inflammation of nerves or their sheaths occurring in different parts of the body at the same time. (See NEURITIS.)

Polyneuropathy
A disease that involves several nerves.

Polyoestrous
Polyoestrous animals are those which have several oestrus cycles per year – the converse being monoestrous.

Polyostotic
Affecting several bones.

Polyostotic Fibrous Dysplasia
Abnormal localised overgrowths of fibrous tissue in several bones: bone cysts. The condition is seen in DOBERMANN PINSCHER DOGS.

Polyp
Polyp is a tumour which is attached by a stalk to the surface from which it grows. The term only applies to the shape of the growth and has nothing to do with its structure or to its nature. Most polyps are benign, but some may become malignant. They are generally of fibrous tissue in the centre covered with the type of local epithelium. In animals, the common situations where they are found are: in the nostrils; in the vagina, where they sometimes interfere with successful copulation; and in the interior of the bladder. They are also fairly commonly encountered in the ears of cats.

Polyphagia
Excessive ingestion of food. While it is a common attribute of animals, it can in companion animals lead to obesity, and mask metabolic disease. It is also a sign of HYPERTHYROIDISM in cats and in some cases of DIABETES MELLITUS in dogs and cats.

Polyploidy
The presence of multiples of the haploid number of chromosomes greater than the diploid number, e.g. triploidy, tetraploidy.

Polyradiculoneuritis, Idiopathic
A disease of dogs, and occasionally cats, affecting nerves.

Signs Weakness of the hind-legs, followed by paralysis of them within a few days. The fore-legs

then become involved. Hyperaesthesia of all legs occurs. Body temperature remains normal.

Muscle wasting occurs. Recovery is gradual. In one case a puppy was able to walk again after four weeks; but complete recovery took over six months.

Polysaccharides

These are carbohydrates usually consisting of simple SACCHARIDES (MONOSACCHARIDES). (See SUGAR.)

Polysaccharide Storage Myopathy (PSSM)

A common and arguably under-recognised cause of EXERTIONAL RHABDOMYOLYSIS or 'SET-FAST'. There is an abnormal accumulation within skeletal muscle. It is common in QUARTER HORSES, DRAUGHT HORSES and WARM BLOOD HORSES. Most horses affected have a mutation in the GLYCOGEN Synthase 1 which results from it being enzyme (AMYLASE) resistant POLYSACCHARIDE. Signs are usually precipitated by exercise often after a period of rest and can recur. The signs are sometimes not seen; when present they include poor performance, gait abnormalities, muscle stiffness and MYOPATHY. Both plasma CREATINE KINASE and ASPARTATE TRANSFERASE rise. Treatment can include NSAIDs, ACEPROMAZINE and CORTICOSTEROIDS. Concentrate feeding should be stopped and exercise started as soon as possible possibly placing in a small paddock. Prevention is by attention to diet and relating it to exercise.

P

Polyserositis

Concurrent inflammation of several of the serosal membranes (PERICARDIUM, PERITONEUM, PLEURA). It occurs in all species. The inflammation is usually fluid-based initially but may later contain FIBRIN. It occurs in some pig diseases such as HAEMOPHILUS PARASUIS.

Polytetrafluoroethylene, Teflon

(See 'FRYING PAN' DEATHS; 'KITCHEN DEATHS'; TEFLON.)

Polytocous

Producing several offspring at birth, i.e. a litter.

Polyuria

Polyuria is a condition in which a much greater amount of urine is passed than is usual.

Polyuria is also a sign of DIABETES INSIPIDUS and DIABETES MELLITUS, and it occurs in certain forms of inflammation of the kidneys, especially in the early stages of pyelonephritis affecting cows after calving, when infection has travelled into the bladder, up the ureters, and so into the kidney. Polyuria is encountered in cage birds especially psittacines and is often confused with diarrhoea. The causes may be DIABETES MELLITUS or RENAL disease or it simply may be psychogenic in origin. (See INCONTINENCE; KIDNEYS, DISEASES OF; URINE; STRESS.)

Polyvalent Vaccine

One prepared from cultures of several strains of the same bacterial or viral species or from different species. A single polyvalent vaccine can now protect against as many as 8 diseases.

Polyvinyl Pyrrolidine Iodine

A formulation used as an antiseptic spray for minor wounds and abrasions in horses. It has also been used as an antiseptic hand wash prior to surgery.

Pom

(See PRESCRIPTION-ONLY MEDICINES.)

Pomeranian

A small alert dog with tail carried over the back, pointed ears and prominent eyes. PATELLAR LUXATION is inheritable and PATENT DUCTUS ARTERIOSUS may be present.

Ponds

Salmonella typhimurium was isolated from marl ponds on a farm where the dairy herd had a reduced milk yield, fever and dysentery. Fencing off the ponds to prevent access by the cattle stopped the outbreak immediately. (See also LEECHES, ALGAE POISONING, COCCIDIOSIS, JOHNE'S DISEASE, BOTULISM.)

Ponies

Breeds of horse whose height does not exceed 14.2 HANDS, which is the defined height of a pony. These are described under various breed names. (See under HORSES, FEEDING OF; MOORLAND PONIES; MOUNTAIN PONIES.)

Pons, Pons Varolii

Pons (Pons Varolii) is the so-called 'bridge of the brain'. It is situated at the base of the brain in front of the medulla, and behind the cerebral peduncles, and appears as a bulbous swelling not unlike a small curved artichoke. It is mainly composed of strands of fibres which link up different parts of the brain.

Poodle

A breed of dog originating in Germany (in spite of being known as a French poodle) where it was used as a gun dog for retrieving game, especially that which had fallen in water. The characteristic clip of its curly black coat was designed to

VetBooks.ir

streamline the dog as it swam. The topknot of the head and the tip of the tail were to show the hunter the position of the dog in the water; the hair left round the leg joints was to protect them against underwater objects they might strike.

There are three types: STANDARD, miniature and toy. The standard was the original and is less liable to defects than the others. The miniature poodle is one of the longest living purebred dogs at 14.2 years. Toy and miniature poodles are prone to LEGG-CALVÉ-PERTHES DISEASE, PATENT DUCTUS ARTERIOSUS, and PROGRESSIVE RETINAL ATROPHY. DISTICHIASIS may be inherited. CLEFT PALATE is found in toys. Miniature poodles are prone to EPILEPSY, EPIPHYSEAL DYSPLASIA, PATELLAR LUXATION and GLAUCOMA. In the standard poodle hereditary CATARACT may be found but the mechanism of inheritance is unknown; DEGENERATIVE MYELOPATHY also occurs. In the miniature poodle OPTIC NERVE HYPOPLASIA and DWARFISM are recorded. (See EYE, DISEASES AND INJURIES OF.)

POOS
An acronym for Pre-Ovulatory Ovarian Stasis. (See also EGG-BOUND; VITELLOGENESIS.)

Popliteal
Popliteal refers to a region that lies behind the stifle joint, and to the vessels, lymph glands, nerves, etc., lying in this region. It is protected laterally by the biceps femoris, posteriorly by the semitendinosus and the gastrocnemius, and internally by the gracilis and semitendinosus tendon; consequently it is seldom that its vessels or nerves are injured.

Porcine
Related to the pig.

Porcine Circovirus Type II (PCV2)
A virus first seen in the UK in 1999 and causing PORCINE DERMATITIS AND NEPHROPATHY SYNDROME and POST-WEANING MULTISYSTEMIC WASTING SYNDROME.

Porcine Colonic Spirochaetosis
A disease caused by *Brachyspira pilosicoli*. The organism is found widely in animals including humans, dogs and wild birds. Sign usually occur about 10–14 days after mixing of young weaned pigs from different sources and of varying health status. It is seen as persistent diarrhoea with decreased performance and a lack of uniform weight gain. There may be other factors predisposing to disease, including other pathogens, dietary and/or environmental conditions. Antimicrobials such as TIAMULIN, VALNEMULIN, LINCOMYCIN and DIMETRIDAZOLE are used in treatment.

Porcine Coronavirus Infection (PRC)
This is enzootic in the UK and in some other EU countries. The virus has a close antigenic relationship with transmissible gastroenteritis virus and is a cause of a non-severe pneumonia. (See under RESPIRATORY DISEASE IN PIGS.)

Porcine Cytomegalovirus (PCMV)
Porcine cytomegalovirus (PCMV) is a name for inclusion-body rhinitis virus, which can produce rhinitis and pneumonia in pigs.

Porcine Dermatitis and Nephropathy Syndrome (PDNS)
A condition of young pigs (10 to 16 weeks) in which red-brown circular lesions and haemorrhages appear under the skin of the ears, face, flanks and limbs. Temperature may not always rise. Often only a few animals are affected but most of those die, sometimes suddenly after lesions develop but usually within about three days. The lesions may be caused by an antigen-antibody reaction; porcine intestinal circovirus type 2 has been isolated from cases. This sign is usually seen before the more common POST-WEANING MULTISYSTEMIC WASTING SYNDROME. The condition was first identified in Chile in 1976 and in England in 1987. Circovirus 2 vaccines are available.

Porcine Encephalomyelitis
Also called TALFAN DISEASE and TESCHEN DISEASE.

Porcine Enterovirus England/72
Porcine Enterovirus England/72 is the cause of SWINE VESICULAR DISEASE.

Porcine Epidemic Diarrhoea (PED)
A CORONAVIRUS disease of pigs seen worldwide. It causes an explosive outbreak of diarrhoea in weaned non-immune pigs (Type 1) or in all ages (Type 2). There is vomiting, diarrhoea and inappetance, with acute signs lasting three days and illness for about seven to 10 days. Mortality is usually low. A new strain has appeared in North America with a high mortality in piglets. A vaccine has been developed in the USA.

Porcine Influenza
(See SWINE INFLUENZA.)

Porcine Intestinal Adenomatosis (PIA)
Porcine Intestinal Adenomatosis (PIA) is the most common form of proliferative enteropathy, a serious economic problem for pig farmers. The signs include poor growth and chronic diarrhoea or acute haemorrhagic diarrhoea, sometimes with

VetBooks.ir

perforation of the intestine, and death. Growing and finishing pigs are usually affected, although it can occur in adult pigs. Many cases may not be noticed, and failure to make satisfactory weight gains may be the only indication of the disease. The cause is the bacterium *Lawsonia intracellularis*.

Salinomycin or zinc bacitracin in the feed have been reported to improve weight gain and general condition.

(See also Proliferative haemorrhagic enteropathy *under* HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Porcine Intestinal Spirochaetosis

(See PORCINE COLONIC SPIROCHAETOSIS.)

Porcine Parvovirus (PPV)

This can be a cause of fetal death and mummification, if infection occurs during the first half of the gestation period. An inactivated vaccine is available.

Porcine Periweaning Failure-to-Thrive Syndrome

A clinical syndrome affecting piglets two or three weeks after weaning. The syndrome includes anorexia, lethargy and progressive debilitation in the absence of any recognisable infectious, managemental, nutritional or environmental causes to explain the signs.

Porcine Reproductive Respiratory Syndrome (PRRS)

(See 'BLUE-EAR' DISEASE OF PIGS.)

Porcine Respiratory Coronavirus Infection (PRCV)

(See under RESPIRATORY DISEASE IN PIGS.)

Porcine Respiratory Disease Complex (PRDC)

This is a highly complex syndrome of growing pigs involving respiratory signs, poor growth rates and sometimes deaths. It involves multiple infectious agents and interaction between pigs, these infectious agents, social and physical environment, nutrition and stockmanship. The environment includes neighbouring farms, ventilation, temperature (especially fluctuations), humidity, aerial pollutants, space and group size (>200), mixed age groups in same air space, direct contact between different ages, competition, stress, management, genetics, nutrition (deficiencies), poor hygiene, poor recognition of disease, mycotoxin and other disease problems (alimentary problems, skin conditions, parasites including ASCARIS SUUM, METASTRONGYLUS - METASTRONGYLUS APRI). Infectious agents are many including PORCINE REPRODUCTIVE RESPIRATORY SYNDROME, PORCINE CIRCOVIRUS TYPE II, SWINE INFLUENZA, PORCINE RESPIRATORY CORONAVIRUS INFECTION, MYCOPLASMA HYOPNEUMONIAE (SWINE ENZOOTIC PNEUMONIA), ACTINOBACILLUS PLEUROPNEUMONIAE, BORDETELLA BRONCHISEPTICA, HAEMOPHILUS PARASUIS, PASTEURELLA MULTOCIDA, STREPTOCOCCUS SUIS and *Trueperella pyogenes*. (See also PASTEURELLOSIS IN PIGS; RESPIRATORY DISEASE IN PIGS.)

Porcine Streptococcal Meningitis

This was first recognised in fattening pigs in the UK in 1975 (though in unweaned pigs in 1954).

Streptococcus suis type I causes meningitis as a complication of septicaemia in the unweaned piglet. Signs include fever, loss of appetite, a tendency for the piglets to bury themselves in the litter, stiffness and an unsteady gait. The ears may be drawn back and held close to the side of the head. An inability to rise and paddling movements of the hind-legs precede death in many instances. Some pigs recover; others die from septicaemia associated with arthritis or pneumonia.

Streptococcus suis type II affected pigs mainly in the age bracket four to eight weeks, but pigs up to 16 weeks can be involved.

The death of a large pig in excellent condition is often the first sign of the disease. If signs are observed, they are similar to those already described for the unweaned pig. In untreated cases the illness is usually brief and fatal.

This streptococcal meningitis is 'primarily associated with the mixing and moving of young weaned pigs', and may affect from less than 1 per cent to over 50 per cent of pigs, depending on management factors, etc. Poor ventilation favours a higher incidence, which is seen more in imperfectly managed controlled-environment buildings than in old or converted fattening houses.

Control measures Vaccination has not been very successful. Control measures can be aimed at either eradicating the infection on the farm or, if this is considered impracticable, minimising losses. If weaners are being bought from different suppliers, it may be possible to discover which is the source of infection. On some farms, buildings could be emptied, disinfected, and restocked – avoiding buying from anyone known or suspected of having the disease on the premises. If carrier sows can be identified, they should be culled.

Penicillin or broad spectrum antibiotics may be used for treatment.

Public health People working with pigs should be aware of the risk to them, even though it is a small one.

VetBooks.ir

Streptococcus suis type II was isolated from a case of meningitis in an abattoir worker by the public health laboratory, Cambridge. Seven of 10 cases of streptococcal meningitis occurring in the Netherlands were associated with infection with the porcine streptococcus group R. The other three isolates were similar but lacked the R antigen. All streptococci fell into the bacterial species provisionally named *S. subacidus*. Nine of the 10 patients had contact with pigs, while the other person liked to eat raw meat. One of the affected people died of the disease.

Porcine Stress Syndrome (PSS)

A group of signs, due to a single gene, occurring in some breeds of pigs, notably Dutch Piétrain, Belgian Landrace, German Landrace, and French Piétrain. Under stress, death from heart failure may occur suddenly. The syndrome is associated with pale watery meat (pale soft exudative muscle (PSE)). The anaesthetic halothane can be used for on-farm testing of pigs to discover whether they are susceptible. A selective breeding programme has eliminated this gene from some strains of pig.

Porcine Ulcerative Spirochaetosis

An infection believed to be present in the UK, and reported also in the USA, Australia and New Zealand. Experimentally, injection of the spirochaetes has led to foot-rot, scirrhous cord, and ulceration of the skin.

Porcupine Quills

In some areas of the USA and Canada, dogs require treatment as a result of rash encounters with porcupines. The North American porcupine uses its tail as a means of defence, leaving behind numerous quills; while if the dog attempts to bite a porcupine, the result may be a mouthful of quills, which stick in the tongue and cheeks.

In the UK, free-living porcupines (Asiatic and African species) in both Devon and Staffordshire are, like mink and coypu, escapers, and have bred since gaining their freedom.

Removal of quills is a very painful process, for they are barbed. Nevertheless it should be attempted as deep penetration may occur with possible fatal injury involving internal organs. However, it should be completed under a general anaesthetic by a veterinary surgeon.

If there is delay, some quills will have disappeared from sight and, as they are not revealed by X-rays, no veterinary surgeon could guarantee 100 per cent removal. Some quills may work themselves out through the skin in due course. One dog died after penetration of the pericardium by quills.

Porker

In Britain, porkers weigh 40 kg to 67 kg (90 lb to 190 lb) (liveweight). Baconers are 101 kg (220 lb). 'Heavy hog' weight is 102 kg (225 lb) and above.

Porphyria

A condition in which porphyrins accumulate in the tissues or are excreted in the urine. The clinical signs vary in different species but include discoloration of bone, teeth and urine, and photosensitivity. The condition may be inherited or acquired. (See BONE, DISEASES OF, and HEXACHLOROBENZENE; also under ALUMINIUM TOXICITY with reference to the rat.)

Porphyrin

A collection of compounds, usually containing iron, that are the residues from the respiratory pigments of plants and animals. When combined with iron they form HAEMS.

Portal Vein

Portal vein carries to the liver the blood that has been circulating in the stomach, intestines, pancreas and spleen. It is unique among the large veins of the body in that on entering the liver it breaks up into a capillary network, instead of passing its blood into one of the larger veins to be carried back to the heart. It is formed by the confluence of the anterior and posterior mesenteric with the splenic vein in the horse, and by the union of the gastric and mesenteric radicles in the ox; from a point behind the pancreas and below the vena cava, it runs forwards, downwards, and a little to the right, to reach the porta of the liver. Here it divides and subdivides in the manner usual with an artery. (See LIVER for further course, and DIGESTION, ABSORPTION AND ASSIMILATION.)

Portosystemic Shunt

An abnormality of the blood circulation system, resulting in blood from the heart bypassing the liver and entering the general circulation. The condition has been seen in cats, dogs and a foal. It is relatively common in some dog breeds, including IRISH WOLFHOUNDS.

Portuguese Water Spaniel Dogs

Individuals may develop an atypical dilated myocardiopathy (heart muscle disease) at between two and 32 weeks old; affected pups become dyspnoeic and die. Seen in the USA and probably elsewhere. (See HEART DISEASES.) PROGRESSIVE RETINAL ATROPHY and GM_1 GANGLIOSIDOSIS (DNA tests available) may be inherited as a recessive trait. (See EYE, DISEASES AND INJURIES OF.)

VetBooks.ir

Positron
A positively charged subatomic particle. The antiparticle of a positron is an ELECTRON.

Positron Emission Tomography
(See PET SCAN.)

Posological
Relating to dosage.

Posthitis
Inflammation of the prepuce. (See PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Post-Mortem Examination
Examination of the body, or parts, after death. (See under AUTOPSY.)

Post-Partum
Following parturition.

Post-Parturient Fever of Sows
Post-parturient fever of sows occurs, as a rule, two or three days after a normal farrowing. The animal goes off her food, is slightly feverish, and apt to resent suckling by her piglets. The udder is hard, the hardness beginning at the rear and extending forward. A watery or white discharge from the vagina is not invariably present. The uterus may not be involved at all. Treatment by antibiotics is successful if begun early. (See also UTERUS, DISEASES OF.)

Post-Parturient Haemoglobinuria
This disease is seen in high-yielding dairy cows in North America, two to four weeks after calving. A deficiency of phosphorus in the diet and/or consumption of rations containing cruciferous plants or beet products are among the causes. Mortality may reach 50 per cent. In New Zealand it is associated with copper deficiency, and mortality is low.

Signs These are sudden in onset and include red-coloured urine, loss of appetite, and weakness. Faeces are firm. Breathing may be laboured. Death may occur within a few days.

Treatment A suitable phosphate preparation intravenously, or bone-meal by mouth. Blood transfusion may be indicated in severe cases. (See also under KALE.)

Postvaccinal Sarcoma in Cats
(See FELINE POSTVACCINAL SARCOMA.)

Post-Weaning Multisystemic Wasting Syndrome (PMWS)
A condition in young pigs in which there is failure to thrive. It was first recorded in Canada in 1991 and appeared in Britain in 1999. There are probably several factors involved in the disease but a major component would appear to be PORCINE CIRCOVIRUS TYPE II infection. Often PORCINE DERMATITIS AND NEPHROPATHY SYNDROME occurs before this. Risk factors increasing severity of PMWS include rearing growers indoors, requiring a higher number of veterinary visits per year, having poorly isolated hospital pens, buying replacement boars and seropositive for *Mycoplasma hyopneumoniae*. Factors which reduced the risk of PMWS include low stocking density for growers, adjusting diets at least three times between weaning and 14 weeks of age, and requiring all visitors to be at least two days pig free. The disease is seen in pigs six to 14 weeks old; signs are variable and slow in onset. There is wasting and depression; affected pigs often look pale or jaundiced and have diarrhoea; conjunctivitis may be seen as well as respiratory signs. Sometimes sudden death is the only sign. Morbidity is 3 to 50 per cent and up to 80 per cent of affected animals die. It is seen more often in wet, mild conditions, may be triggered by stress, and may be complicated by other infections. Attention to such factors assists in reducing the problem. Circovirus 2 vaccines are available and work well in controlling this severe economic disease.

Potash Fertilisers
Potash (potassium) fertilisers are best not applied to pasture land in the spring shortly before grazing, owing to the increased risk of HYPOMAGNESAEMIA.

Potassium (K)
Potassium is a metal which, on account of its great affinity for other substances, is not found in a pure state in nature.

Potassium is a mineral element essential for the body. It helps to control the osmotic pressure of the fluid within cells. Its content in body fluids is controlled by the kidneys. (See also under ALDOSTERONE and PURGATION.)

Potassium salts are used in human and animal medicine, but as their action depends in general not upon the metallic radicle, but upon the particular acid with which each is combined, their uses vary greatly and are described elsewhere. Thus, for the action and uses of potassium iodide, see IODIDES.

All salts of potassium are supposed to have a depressing action on the nervous system and on the heart, but in ordinary doses this effect is so slight as to be of no practical importance. The corresponding sodium salts can be used if preferred. For intravenous injections, however, potassium salts must not be used as they are liable to be rapidly fatal; sodium salts must be used instead.

VetBooks.ir

Potassium deficiency shows as an acute onset of weakness, loss of weight, a reluctance to walk, a stiff stilted gait; the necks are bent downwards, and palpation is painful.

Treatment Lactated Ringer's solution supplemented with potassium chloride by intravenous or subcutaneous injection; with further K supplementation by oral fluids.

Potassium Bromide

A treatment, often used as for idiopathic EPILEPSY, that does not have any toxic effects on the liver. It should only be used following veterinary prescription.

Potassium Diformate

A patented salt of formic acid sold under the name 'FORMI'. It is approved for use in certain animal feeds and has antimicrobial properties. It is not destroyed by stomach acid and exerts antimicrobial activity in the small intestine. Added to the diet of pregnant sows, it improves performance allowing more milk production, better litter growth and less backfat loss in the sow at weaning.

Potato Poisoning

Both the haulms and the tops contain varying quantities of solanine, an alkaloid, which is present to a dangerous extent in green and sprouting potatoes. The haulms are most dangerous just after flowering. When boiled, the alkaloid is dissolved out in the water, and does no harm.

There is some evidence that solanine alkaloids can cause deformities in litters of piglets born to sows fed on green or sprouting potatoes.

Rotting or mouldy potatoes have also caused poisoning.

Signs Pigs have shown loss of appetite, dullness, exhaustion, watery diarrhoea, low temperature and coma.

Cases on the continent of Europe have exhibited peculiar skin lesions. They occurred after the green haulms had been eaten by cattle, and consisted of eczematous ulcerated areas occurring on the scrotum of the male and the udder of the female. In addition, there were ulcers in the mouths of some animals, and blisters about the hindlimbs which suggested foot-and-mouth disease, except that considerable quantities of pus were produced.

The most constant signs appear to be loss of appetite, prostration or interference with movement, a weak pulse, and a low or subnormal temperature.

Sweet potato (*Ipomea batatas*) poisoning may cause acute respiratory distress in cattle fed mouldy tubers – the fungus (*Fusarium solani*) causing toxin production by the potato itself. Six cows died from this cause on an East Anglian farm in 2007.

Pot-Bellied Pigs

The breed is a domesticated pig originating in Vietnam. They are often kept in children's farms and as pets. All the laws and rules governing farm pigs also apply to them. The breed is often about the size of a medium to large sized dog. They are very variable in size, from 8 kg to 136 kg (20 lb to 300 lb). While most have a pot belly and a dipped back, not all do. They can be distinguished easily from other domestic pigs by their size, pricked-up ears and straight tails. The pigs tend to become fat; rolls of fat occur over the eyes, which are hard to see, and the belly touches the ground both indicate the pigs are overweight. They are able to mate with normal domestic pigs and wild boars. They are often kept as pets and the hooves quite frequently require trimming. Melanotic tumours are quite common, which causes depigmentation.

Potentiate

To increase the effectiveness of two drugs which have a synergistic effect by administering them together.

Potomac Horse Fever

This occurs in the USA, and has a seasonal incidence (May to October).

Cause *Ehrlichia sennetsu* or *E. risticii*.

Signs In addition to fever there may be acute diarrhoea, sometimes abortion, leukopenia. The clinical signs are said to be similar to those of EQUINE INFECTIOUS ANAEMIA.

The vectors are mainly black flies of *Simulium* species.

The infection has been detected in farm cats.

POTZ

(See PREFERRED OPTIMUM TEMPERATURE ZONE.)

Poult

A young turkey or pheasant.

Poult Enteritis and Mortality Syndrome (PEMS)

A complex viral infection of young turkeys involving a coronavirus, an astrovirus, several groups of rotavirus and other viral agents. The multiviral nature of the infection causes high mortality (up to 80 per cent). The litter gives off a sickly-sweet odour. The syndrome has a detrimental effect on the immune system.

Poultices and Fomentations

Poultices and fomentations are traditionally used in all stages of inflammation to soothe pain and,

VetBooks.ir

when pus is forming, to hasten the formation of an abscess.

Poultices include a mixture of kaolin and glycerin, made into a paste, incorporated with an antiseptic and applied hot upon a piece of gauze or cotton-wool to the part.

Hot fomentations are usually made by cooling boiling water down to a temperature that can be easily borne by the attendant's bare elbow, wringing a piece of flannel or blanket out of the water, and applying it to the part.

Poultry and Poultry Keeping

These have, so far as large-scale production is concerned, undergone great changes in recent decades. Many of the older breeds and strains of poultry have given way to more efficient hybrids – a form of genetic selection, in effect. Increasingly, intensive production of layers or broilers in controlled-environment houses has been practised. Formulation of poultry foods for optimum production has advanced, too, and well-balanced proprietary compounds are extensively used.

Backyard Chickens/Hens These are a very common companion animal that is found in urban and country areas including schools and also they produce eggs. (See also BACKYARD CHICKENS.)

Large-scale production Information will be found under CONTROLLED ENVIRONMENT HOUSING; HOUSING OF ANIMALS; BROILERS; INTENSIVE LIVESTOCK PRODUCTION; BATTERY SYSTEM; NIGHT LIGHTING; CANNIBALISM; DEEP LITTER FOR POULTRY; EGG YIELD.

Hen yards are nowadays preferred to large pens for birds kept intensively, and are often adapted from old bullock yards. Protection from cold winds and rain is necessary. The high cost of straw is sometimes a disadvantage.

Free range The keeping of poultry in open fields, where they can move freely and supplement their rations by foraging is once again popular. Cabins, to which the hens have free access, are provided for shelter. 'Free range' eggs attract a premium price.

Housing Competitive broiler and egg production has led to the use of specially constructed, controlled-environment buildings in which temperature, ventilation, etc., are maintained at optimum levels. The main features are described under CONTROLLED ENVIRONMENT HOUSING and HOUSING OF ANIMALS.

What follows relates to non-intensive housing where high capital expenditure is not possible or desirable.

Height A very high house is apt to be cold and draughty, while a very low one is difficult to ventilate and troublesome to clean. From 200 cm to 215 cm (6 ft 6 in to 7 ft) at the highest point to 175 cm to 195 cm (4 ft 6 in or 5 ft) at the lowest should be allowed.

Ventilation There must be good top ventilation. The amount to be given depends a good deal upon the situation and exposure. Houses of the open-fronted type may prove to be too draughty for exposed wind-swept districts. For such places a pitched roof is rather to be preferred to a lean-to. Dampness in a house may be due to faulty ventilation.

Light The maximum amount of light and sunshine should be aimed at. Fowls will not shelter during the day in a dark house. Additional windows should be placed a few centimetres/inches above the level of the floor, if possible at the east and west sides. This means that the floor will always be light, and the birds will always be encouraged to scratch for grain buried in the litter. (See also NIGHT LIGHTING.)

Litter The floor should be covered to a depth of 30 cm (1 ft) or more with clean dry litter, such as straw. Litter has to be kept friable (i.e. not compacted or wet) at all times is a legislative requirement. (See DEEP LITTER FOR CATTLE; DEEP LITTER FOR POULTRY.)

Perches These should measure 5 cm^2 (2 in by 2 in) and have the edges on the upper surface smoothed off. They should be all on one level about 75 cm (2 ft 6 in) from the floor, and made to drop into sockets. About 15 cm or 20 cm (6 in or 8 in) below the perches should be placed a removable dropping board. This keeps the floor clean and prevents upward draughts. They must be

cleaned regularly, and lightly sprinkled with sand or peat moss litter.

Nests are best placed on the same sides as the windows, so that the light does not shine directly into them.

Houses should be regularly cleaned and sprayed with disinfectant from time to time.

Runs Fresh clean ground is very necessary. If birds remain too long in one place the ground becomes foul, and the egg-yield and the birds' health soon suffer. Where space permits (as on farms) the birds may be kept on free range in portable houses. When the ground round the house becomes dirty, the house may be removed to another place. In this way the fowls always have clean land.

Hatching and rearing The time to begin hatching depends on the breed, the strain, and the poultry-keeper's requirements. Quick-maturing breeds, such as LEGHORN, ANCONA, and good laying strains of WHITE WYANDOTTES, RHODE ISLAND REDS, and LIGHT SUSSEX, will, if properly fed and managed, lay at 5 or 5½ months, so that if pullets are wanted to lay in October, chickens should be hatched in March or April. It is generally considered that birds hatched early in the year have more natural vitality and mature more rapidly than those hatched later. Against this must be the fact that in very cold weather and in exposed districts the percentage of fertility may be low in the first two months of the year, and there may be heavy mortality in the rearing of the chickens unless adequate protection can be given. June or even July chicks may be brought on to lay if they are well fed. As soon as the days begin to get short, these late-hatched chicks should be fed by lamplight, otherwise they are not getting sufficient food to make their full growth. Where only a few chickens are to be raised, or where very special eggs are to be set, the hen is to be preferred to the incubator.

Silkies make excellent sitters and mothers. They are small eaters, their eggs are of fair size, they lay a small batch, and then go broody almost irrespective of the season. A silkie hen can cover from six to eight ordinary eggs.

Brooders Bottled gas is much used for heating brooders. Infra-red heating, especially the dull-emitter kind, is popular where reliable electricity supplies are available, and enables the chicks to be readily observed.

Rearing houses These should be well ventilated but free from floor draughts, well lit by windows, and spacious enough. Allow 15 cm² (6 sq in) per chick up to a month old.

Drinking water must be constantly available. (See under CHICKS.)

Trough space About 2 m (6 ft) of trough space per 100 chicks should be provided until the birds are three weeks old; 3 m (10 ft) per 100 chicks at from three to six weeks old; 3.5 m (12 ft) at from six to 12 weeks old; 5 m (16 ft) at from 12 to 16 weeks old, and 6 m (20 ft) thereafter. With linear troughs 2.5 cm (1 in) per hen is required and with circular troughs 1 cm (0.4 in) per hen. These are set out as minimum requirements under law.

Bought-in stock If buyers insist on 'Accredited' stock, they can be almost certain of avoiding trouble from pullorum disease (bacillary white diarrhoea) and from fowl typhoid.

When chicks are bought as day-olds, mortality should not exceed 3 per cent by the third week. Losses exceeding 5 per cent indicate the need for an investigation; and several dead chicks should be sent to a laboratory for a post-mortem examination.

Chick feeding There is no longer support for the old idea that chicks must not be fed for the first 48 hours. It is better to feed day-olds on arrival (otherwise they pick at their bedding) and to allow them ample cold water. Feeding appliances must be of a good design and not placed in a dark spot where chicks may fail to find them.

Proprietary crumbs, or mash or meal, may be fed. Limestone grit and oyster shell should **not** be given with these. (See under GRIT FOR POULTRY.) Day-olds do not need this unless they are to be fed on grain or to be put on grass when very young. Grain should not be fed ad lib, but rather as a twice-daily scratch feed, until chicks are a month old.

Dirt, dampness, and overcrowding are the chickens' worst enemies. Coops and brooders should be moved constantly, so that the chickens have fresh clean ground to run on. After the birds have been removed from the rearing ground, the land should be dressed with burnt lime at the rate of 2,030 kg (40 cwt) to the acre. The cockerels should be separated from the pullets as soon as it is possible to differentiate them. The pullets need plenty of space both in their houses and in their runs. It is best to get them into their winter quarters by August or September and not move them again, as changes of all kinds are apt to check laying. As a preventive of soft-shelled eggs, 2 per cent steamed bone-flour or bone-meal may be added to the mash. Pullets should begin to lay in October or November if hatched in good time. Trap-nesting should be adopted wherever it is

VetBooks.ir

possible, as it is important to find out the winter records of the pullets. A good winter record (for 4 months) is from 30 to 40 eggs, but birds of good strain, properly managed and fed, will produce up to 70 or 80 eggs. A good flock average for the year is 180, but there are, of course, instances of birds producing up to 300 eggs in their first year.

Feeding Where fowls have access to good grass runs, and especially where these contain a fair proportion of clover, they can themselves correct any faults in a badly balanced ration, but birds on earth runs, or kept purely on the intensive system, are entirely at the mercy of the poultry-keepers, and their diet must be carefully considered. An excess or deficiency of any one substance in the ration may cause derangement of the digestive system of the bird, and so may affect egg-production. Birds, especially those kept in confinement, often suffer from a deficiency of some sort. Modern carefully formulated proprietary foods have been developed to obviate all known deficiencies in housed birds.

The amount which a fowl will eat must depend on the breed, the condition of the bird, whether she is laying or not, and the conditions under which she is kept. The bird's appetite is the best guide, but a rough rule is to allow about 60 g (2 oz) of grain and 60 g to 70 g (2 oz to 2½ oz) of mash per bird per day. For a grain food, a mixture of two parts oats and one part cracked maize may be recommended. The grain should be lightly buried in the litter, so that the birds have to work for it. The mash may be fed either wet once a day, or dry in hoppers, so that the fowls can help themselves.

Poultry-Keepers

The occupational hazards of people looking after poultry include: allergy to the northern chicken mite (see MITES, PARASITIC); conjunctivitis and/or an influenza-like illness from NEWCASTLE DISEASE virus. See also VENT GLEET; AVIAN TUBERCULOSIS; SALMONELLOSIS.

Poultry Litter

Where there is access of poultry waste bedding, livestock diseases such as BOTULISM and SALMONELLOSIS can occur. It is banned from use as a bedding material under the Animal By-Products (Enforcement) (England) Regulations 2011 and similar legislation in Scotland and Wales. Used bedding without carcases in it is best spread on arable land, and immediately ploughed in. It must be kept away from livestock before spreading. Incineration is also an option.

Poultry Waste, Dried

This has been fed to beef cattle as part of their diet, especially in the USA, but not in the EU. The product is very variable in its content – droppings being the main ingredient; litter, feathers, broken eggs may also be present. From a veterinary point of view there may be dangers – high levels of copper or arsenic, for example, used in broiler diets; also high calcium carbonate levels. Crude protein content may vary from 15 to 35 per cent, crude fibre 12 to 35 per cent.

Feeding beef cattle with large quantities of this waste product has, in Israel, caused sudden deaths from heart failure. It was found that the broilers had been receiving a coccidiostat, either maduramycin or salinomycin. It has been said that 'Some ionophores are well recognised as having a cardiotoxic potential in certain species'.

Ensiled poultry litter, fed to cattle, proved to be a source of *Clostridium botulinum*, and caused botulism.

Producers intentionally or inadvertently feeding poultry carcase material to livestock on their premises commit an offence under the Disease of Animals (Waste Food) Order 1973.

The World Health Organisation has pointed out that the feeding of poultry manure introduces the risk that people may acquire zoonoses, such as salmonellosis from cattle products, and that there is a danger of drugs and other chemicals fed to poultry accumulating as residues in cattle.

Pour-on

It is often used as a noun to describe medicines applied to the skin of the animal that may then spread over the surface of the animal or be absorbed (SYSTEMIC) and enter the body and act on various organs including the gut. Some preparations are used to provide TOPICAL APPLICATIONS to prevent or treat skin parasites. Most preparations are INSECTICIDES, ENDECTOCIDES or ANTHELMINTICS.

Povidone Iodine

A compound produced by a reaction of IODINE with the polymer povidone; it is used as a topical antiseptic. There are many different formulations: tinctures, solutions and scrubs, the last being used as a pre-surgical hygiene.

Powder Down

A specialised contour feather, continuously shed from the skin, which covers the larger outer feathers and is often seen coating the beak. It is considered to be an adjunct to hygiene, especially in fish-eating birds, which find it easier to preen after a feed (the scales of the fish would otherwise coat the feathers and be difficult to remove). Production of powder down is affected by certain diseases, notably PSITTACINE BEAK AND FEATHER DISEASE in which one of the clinical signs is a shiny, powder-free beak.

VetBooks.ir

Pox

The best known pox diseases, caused by orthopox viruses, are cowpox (vaccinia) and smallpox (variola). The latter disease was eradicated on a worldwide basis, the World Health Organisation announced, in 1980. However, the other pox diseases are transmissible to human beings.

Some of the pox diseases are mild, whereas in others there may be a high fever, and even a high mortality.

These pox diseases are all contagious, and characterised by skin lesions. Typically they begin with small red spots followed by papules. Exudate causes these to become vesicles, and pus forms, so that the vesicles become pustules. These either burst or become desiccated, and the larger ones may leave a pock mark which can be a deep lesion with permanent scarring.

Mucous membranes may be affected as well as skin. (In horses lesions may occur in the mouth; and in canaries lesions may be found only in the trachea.)

Public health Human cases of cowpox are reported only rarely, and may be severe. However, mild or subclinical infections may occur, and the possibility of person-to-person infection has been suggested.

Cowpox is now a rare disease in the UK. In the days of hand milking it was spread from cow to cow by that means (and also sometimes by milkers recently vaccinated against smallpox). Lesions appear on the teats and skin of the udder mainly, but the lips and perineal region may be affected too. Cowpox is usually a mild disease, with slight fever, reduced appetite and milk yield. Cowpox is transmissible to people, horses, dogs, sheep and goats. lt was diagnosed in cats for the first time in the UK in 1978, but see 'Cat-pox' below, as a different virus may be involved.

Pseudo-cowpox (parapox) is a common disease of cattle, and affects man also. The papules tend to be larger than with cowpox. A mild disease.

Cat-pox An infection of domestic cats and of some wild Felidae in captivity. It was first reported in the United Kingdom in 1970, but it has now been reported in other countries. It used to be known as 'cowpox in cats', but the cow's involvement is questionable and there is a greater likelihood that the infection comes from some small wild animal (probably a rodent).

The pock may appear at the site of a bite, and several cases have occurred in cats known to be keen hunters. The siting of pocks on the lips or at the base of the claws further supports the idea that the infection comes from cats' prey.

Previously it was thought that cat-pox was not transmissible from cat to cat, but evidence from the Netherlands indicates that it can be, and that cat-to-human infection may also occur.

Cat-pox appears to be patchy in its geographical distribution, and not common.

Lesions in the cat vary from no more than a scabby condition along the back, in mild cases, to small red glistening areas of skin covered by scabs. White pus may be present. The paws become ulcerated in some cases; also lips and eyelids.

Buffalo-pox is a mild disease but one of economic importance. Similar to cowpox, it is caused by an orthopox virus distinct from vaccinia virus. (The latter can also cause pox in buffaloes.)

Camel-pox is usually a mild disease, except in young camels in which a generalised form may prove fatal. Facial oedema and lip lesions occur in adult camels.

Sheep-pox This is the most serious of the poxes affecting farm or domestic animals. Infection can occur through inhalation, direct contact, and probably the bites of insects.

Signs include high fever, perhaps dyspnoea, salivation as a result of mouth lesions, a discharge from eyes and nose. Skin lesions follow in a day or two, and may cause intense irritation or pain, leading to self-mutilation. Areas of skin may slough off, leaving deep ulcers. In peracute cases the mortality may be as high as 80 per cent; in mild cases a figure of 5 per cent is to be expected. White nodules may be found in many organs at autopsy.

In the UK sheep-pox is a NOTIFIABLE DISEASE and compulsory slaughter is the policy in the event of its introduction.

Goat-pox In the tropics goats may suffer from stone pox or goat dermatitis, the signs of which are similar to those of sheep-pox – mortality varying from less than 10 per cent to over 50 per cent.

Ordinary goat-pox, which occurs in most parts of the world, is relatively mild, and if death occurs it is usually the result of a secondary bacterial pneumonia.

Horse-pox is usually a mild disease. Lesions may appear on the back of the pastern, hollow of the heels, and be confused with grease; or may involve the lips, mouth, nostrils and vulva. A painful stomatitis, with loss of appetite and salivation, may occur. Recovery may take two to four weeks. However, in a few cases lesions may affect much of the body; the horse becomes debilitated and young ones may die.

Swine-pox is usually mild. Lice may possibly spread the infection. (Cowpox may also appear in pigs.)

Monkey-pox (See under MONKEYS.)

Pox in birds Avian pox is the name by which a serious infection of wild birds (especially great tits [*Parus major*]) was reported in 2013. It is not known whether it can infect domestic birds. (See AVIPOX; FOWL POX; PIGEON POX.)

Squirrel-pox A concerning cause of mortality in red squirrels (*Scirrius vulgaris*).

PPE
(See PRE-PURCHASE EXAMINATION.)

PPH
(See PRURITUS, PYREXIA, HAEMORRHAGIC SYNDROME.)

PPID
Abbreviation of PITUITARY PARS INTERMEDIA DYSFUNCTION. (See CUSHING'S SYNDROME.)

PPR
(See PESTE DES PETITS RUMINANTS.)

PPV
(See PORCINE PARVOVIRUS.)

PRA
(See PROGRESSIVE RETINAL ATROPHY.)

P

Praziquantel
An ANTHELMINTIC, used as a topical skin preparation or an injection to treat tapeworms in dogs and cats. It is also presented as a tablet with pyrantel to control roundworms.

PRD
Abbreviation of progressive retinal degeneration (see PROGRESSIVE RETINAL ATROPHY) or PROGRESSIVE RETINAL DYSTROPHY.

PRDC
(See PORCINE RESPIRATORY DISEASE COMPLEX.)

Prebiotics
These are food ingredients (often short or long-chain OLIGOSACCHARIDES) that are non-digestible and are claimed to stimulate growth and/or activity of gut bacteria that are claimed to improve health. They include OLIGOFRUCTOSE and INULIN.

Precardial Region, Precordial Region
Precardial (Precordial Region) is the region of the chest cavity that lies in front of the heart.

Precipitins
Precipitating antibodies, e.g. to *Micropolyspora faeni* in 'farmer's lung'.

Precocial
In birds this term applies to those born with eyes open and able to walk. Only precocial birds can be NIDIFUGOUS.

Precordial Region
(See PRECARDIAL REGION.)

Precorneal Film, Precorneal Tear Film, Preocular Film
This covers the outer surface of the CORNEA and consists of three layers. The lowest, a deep, dense layer of MUCIN, produced by the conjunctival GOBLET CELLS; a middle watery fluid layer mainly secreted by the LACRIMAL GLANDS; and an outer oily layer mainly produced by the MEIBOMIAN GLAND. Absence of secretion results in KERATOCONJUNCTIVITIS SICCA.

Precursor
A substance which precedes another substance that is usually more active or a final compound. It may also occur before a chemical reaction. Clinically it is a sign or signs which precede an illness or syndrome.

Predetermined Sex of Calves
Research at the Babraham Institute in collaboration with the United States Department of Agriculture and Animal Biotechnology, Cambridge ('Mastercalf') led to a technique for separating the X- and Y-carrying sperm of bulls.

The technique is based upon the fact that sperm carrying the X chromosome, which results in heifer calves, have about 4 per cent more genetic material (DNA) than the male-determining Y-carrying sperm.

The sperm are stained with a fluorescent dye and separated by passage through a laser beam, using a specially modified flow cytometer/cell sorter.

Prednisolone
A CORTICOSTEROID which is used in treating inflammatory and allergic disorders. It can cause immunosuppression and exacerbate the effects of worm infestations (e.g. *Filaroides hirthi*, feline heartworms), and viral diseases such as cat-pox (see under POX). (See CORTICOSTEROIDS for reference to the treatment of rheumatoid arthritis and other diseases.)

Preen Gland
An oil-secreting gland situated on the PYGOSTYLE of birds. It is also called the UROPYGIAL GLAND.

VetBooks.ir

Preferred Body Temperature

The body core temperature that is optimal for a specified metabolic function in an ectothermic animal. Digestion in a given species occurs at one optimal temperature, reproduction at another temperature, etc.

Preferred Optimum Temperature Zone, Preferred Optimal Temperature Zone (POTZ)

The range of temperatures at which ectothermic animals will thrive best in captivity and at which their maximum metabolic activity will occur.

Pregnancy, Ectopic

The presence of a fetus (or more than one) inside the abdomen but outside the uterus. Many cases occur as the result of trauma, e.g. in a dog or cat struck by a car. The uterus is torn and the fetus becomes dislodged and undergoes mummification, and this also occurs when a fertilised egg has 'gone the wrong way'; i.e. instead of taking the normal route down the Fallopian tube to the corresponding horn of the uterus, it develops outside the uterus. Mummification is relatively common in rabbits, in which species it can also occur after rupture of the uterus.

Pregnancy, False

(See PSEUDO-PREGNANCY and 'CLOUDBURST'.)

Pregnancy, Termination of

Termination of pregnancy following misalliance of a bitch may be achieved with oestradiol benzoate, used with four to seven days of mating. In cattle, termination using prostaglandins may be undertaken up to 150 days gestation. Abortion also occurs from a variety of causes. (See RESORPTION; MUMMIFICATION OF FETUS; PARTURITION, DRUG-INDUCED; CLOPROSTENOL.)

Pregnancy and Gestation

The uterus, the ovaries, and the whole of the tissues of the mother are influenced directly or indirectly during pregnancy, but the gross changes exhibited, with certain exceptions, subside quickly after the birth of the young. The minor alterations which persist throughout life, such as increased size of the mammary glands, enlargement of the uterus, and of the whole of the genital canal, are not generally obvious except after repeated breeding, and in four to six weeks the dam has returned to normal to all intents and purposes, always excepting the flow of milk in the mammary glands. In most uniparous animals – producing one young at a time – the horn of the uterus which becomes pregnant greatly enlarges and becomes straightened out so as to be practically continuous with the body of the uterus, and the non-pregnant horn appears as a small appendage projecting from its side; in the multiparous animals, however, both horns usually carry a share of the number of the young, and both are consequently nearly alike in size.

As the organ gradually increases in size to accommodate its contents, the broad ligament, which supports it from the roof of the abdomen, increases in length and strength to allow the uterus to move further and further forward and downward in each animal, so that eventually it may occupy the greater part of the abdominal cavity. At the same time there is a very great increase in the muscular coat of the uterus.

Duration of pregnancy This varies greatly in different species and to some extent in different individuals. Male fetuses are carried longer than females. Debility, weakness, or illness in the dam shortens the duration of pregnancy. (See table on next page.)

A prolonged gestation period in ewes has been reported on occasion. In an incident in western Scotland, gestation periods extended up to eight months. Unless relieved their fetuses were removed surgically; the ewes usually died. Long hairy coats, skeletal deformities and extensive liquefaction of the central nervous system were characteristic of the fetuses. The cause is unknown, but could be a toxic plant.

A similar syndrome occurs in southwest Africa, associated with feeding on the shrub *Salsola tuberculata* var. *tomentosa*; and in the USA prolonged pregnancy in ewes has been linked to the plant *Veratum californicum*.

Gestation periods in small mammals

Guinea pig gestation 63 days
Chinchilla gestation 105 to 115 days
Degu gestation approximately 90 days
Rabbit gestation 31 days
Mouse gestation 23 days
Gerbil gestation 25 days
Syrian hamster gestation 16 days
Russian and Chinese hamster gestation 19 days
Rat gestation 21 days
Chipmunk gestation 31 days
Ferret gestation 40 to 44 days

Signs of pregnancy When well advanced, the typical signs of pregnancy are sufficiently known to the majority of livestock owners, and require no mention here; but in the earlier stages they are not always so clear, and for the first few weeks in the larger animal it is often difficult to diagnose pregnancy by clinical signs. The chief changes and differences to be looked for are as follows:

Cessation of oestrus: in the majority of cases, but not in all animals, the female exhibits no desire

VetBooks.ir

Periods of Gestation

	Average Period			
Animal	Months (calendar)	Days	Shortest period young born alive	Longest period young born alive
Mare	11	340	340	414
Ass	12 ½	374	365	385
Cow	9	283 or 284	200	439
Ewe and goat	5	144 to 150	135	160
(merinos)	—	145 to 155		
Sow	—	114	110	130
Bitch	—	58-63	55	76
Cat	—	55-63	—	—

Periods of Development During Pregnancy

State of pregnancy		Mare	Cow	Ewe and goat	Sow	Bitch
I	Duration of period	14 days	14 days	14 days	14 days	10 days
	Length of fetus	Ovum 2mm	Ovum 2mm	Ovum 1.25 to 1.5mm	Ovum 1.25 to 1.5mm	Ovum 1.25 to 1.5mm
	Stages in development	Fertilised ovum has reached uterus from oviduct				
II	Duration	3 to 4 weeks	3 to 4 weeks	3 to 4 weeks	3 to 4 weeks	10 days to 3 weeks
	Length of fetus	12.5mm	8mm	3mm	12.5mm	3mm
	Stages	Traces of fetus appear; head, body and limbs are discernible by end of this period				
III	Duration	5 to 8 weeks	5 to 8 weeks	5 to 7 weeks	4 to 6 weeks	3 to 4 weeks
	Length of fetus	55 mm	45 mm	32 mm	45 mm	25 mm
	Stages	First indications of hoofs and claws visible as little pale elevations at ends of digits				
IV	Duration	9 to 13 weeks	9 to 12 weeks	7 to 9 weeks	6 to 8 weeks	5th week
	Length of fetus	150 mm	140 mm	90 mm	75 mm	64 mm
	Stages	Stomach well defined in foal, pig and puppy; differentiation of four stomachs in ruminants at end of this period				
V	Duration	14 to 22 weeks	13 to 20 weeks	10 to 13 weeks	8 to 10 weeks	6th week
	Length of fetus	33 cm	30.5 cm	15.25 cm	12.5 cm	90 mm
	Stages	Large tactile hairs appear on lips, upper eyelids, and above eye. Teats visible in female fetuses.				
VI	Duration	23 to 24 weeks	21 to 32 weeks	13 to 18 weeks	11 to 15 weeks	7 to 8 weeks
	Length of fetus	68.5 cm	60cm	35.5cm	18cm	12.5 cm
	Stages	Eye-lashes well developed. A few hairs appear on tail, head and extremities of limbs				
VII	Duration	35 to 48 weeks	33 to 40 weeks	19 to 21 weeks	15 to 17 weeks	9th week (8th in cat)
	Length	107 cm	91 cm	46 cm	230-300 cm	15-20 cm (kitten 13 cm)
	Stages	Fetus attains full size. Body becomes gradually covered with hair, hoofs and claws complete, but soft				

VetBooks.ir

for the male after conception occurs. There are many instances, however, when service is allowed until late on in pregnancy, and there may be all the usual signs of oestrus evident on each occasion. In such cases abortion of the fetus may occur, or no harm may result. When the bull refuses to serve a cow which is apparently in season it may be taken as a strong sign that she is pregnant.

Alteration in temperament: vicious, troublesome, or easily excited mares generally become very much more tractable and quiet after conception, whereas if they are served and do not conceive they are frequently more intractable than previously. The same signs are sometimes seen in the cow.

Fattening tendency: in the sheep and the cow particularly, condition markedly improves during the first few weeks of pregnancy, but during the latter stages when the abdomen has increased in size the opposite effect is seen in all animals.

Easily induced fatigue: in the later stages, pregnant animals almost always show an increased desire to rest as much as possible.

Enlargement of the abdomen: this occurs in every direction, and is a most important sign of pregnancy; it occurs at about the same rate as the rate of development of the young, which is greatest towards the end of the period. The abdomen descends or 'drops'; the flanks become hollow; the spine appears more prominent, and its line tends to become flat or even concave in the thoracic and lumbar region; the muscles of the quarters appear to fall in, making the haunches and the root of the tail appear more prominent; and the pelvis tilts into a more vertical position.

Enlargement of the mammary glands: this commences very soon in pregnancy in those animals which are bearing young for the first time. The glands become larger, and firmer, and more prominent.

Increase in weight: this is of course, a sine qua non of normal pregnancy in a healthy, well-nourished animal. (See PREGNANCY DIAGNOSIS.)

Care of the dam during pregnancy In all species of animals, exercise (or work) is essential if the vigour of the dam is to be retained, and if her circulatory, digestive, muscular and nervous systems are to be maintained in a fit state for the strains they will have to withstand at parturition. Food is of great importance: no sudden changes in the ration should be made. It is better to give an extra feed each day rather then unduly to increase the quantities given at each feed. This avoids excessive distension of stomach and intestines which may lead to nausea and indigestion.

Mares should be treated as usual until the abdomen begins to increase in size (not always apparent in some mares).

During the last month an extra feed per day should be given, and if clover (or, better, lucerne) hay is available it should be given in preference to other kinds of hay. Lucerne, being rich in lime and magnesium salts, provides a plentiful supply of these for the mare's milk, as well as for the developing foal. During this last month it is well to allow the mare to sleep in the foaling-box, so that she may become accustomed to it, and settle better. The box should have previously been thoroughly cleaned out, its walls scrubbed with boiling water containing a suitable disinfectant, especially where joint-ill exists upon a farm. Where the climate is mild, mares may, with great advantage, be allowed to foal out of doors. The foal is often born during the night.

Food given should be gently laxative; for this purpose the addition of pulped roots, carrots, bran, or treacle to the food is good. (For further information see under PARTURITION.)

Cows are usually allowed to calve in a loose-box. (See under 'STEAMING UP'.)

Ewes may be either kept out on the hill to lamb (now rarely), or brought down to lower land, and housed in a lambing-pen during the last week or so of pregnancy, but otherwise little special attention is necessary except for an increase in feed especially in the last third of pregnancy. Chasing by dogs, crowding through gateways, and all other forms of rough treatment are to be avoided. Care is needed when catching. Heavy in-lamb ewes should not be turned up to have their feet dressed.

Sows are usually farrowed indoors in farrowing pens or, outside, usually in arcs. Pregnant sows are best fed individually or in twos: otherwise some sows get more than their fair share, while others suffer from under-feeding. Wet, cold floors and cold, draughty premises predispose to mastitis and agalactia.

Bitches must be given regular exercise and, after the first month, extra meals of protein-rich food, including a little liver once a week. An improvised whelping box is useful. (See also SUPERFETATION; BREEDING OF DOGS ACT 1973; BREEDING OF DOGS ACT 1991; PARTURITION; PREGNANCY DIAGNOSIS.)

Pregnancy Complications

In the mare these include twin foals (see ABORTION) and PREPUBIC TENDON, RUPTURE OF. (See also PREGNANCY, ECTOPIC; MUMMIFICATION OF FETUS; SUPERFETATION.)

Pregnancy Diagnosis

As well as traditional techniques such as rectal or abdominal palpation, confirmatory tests for

VetBooks.ir

pregnancy are widely used. There are 2 types: those relying on the detection of hormones in blood, urine or milk; and those depending on visualisation of the fetus by ultrasound scanning instruments.

Farm animals In cattle, rectal palpation is widely used. It may be carried out five or six weeks after insemination in cows and by five weeks in the heifer. Among more sophisticated tests is that for PROGESTERONE, based on a radioimmuno-assay technique for the detection of progesterone in a sample of milk. The milk sample is taken 24 days after the last insemination.

A test based on the measurement of oestrone sulphate in milk uses a milk sample taken 15 weeks or more after insemination.

An enzyme method of milk pregnancy testing, using do-it-yourself kits, is available; the test takes about 45 minutes.

Real-time ultrasonic scanning is widely used for the early detection of pregnancy. The technique, which requires special equipment, is applicable to most species.

Bitches Pregnancy cannot be diagnosed in the early stages. From 24 to 32 days is the best time for abdominal palpation; after 35 days pregnancy may be difficult to recognise by this means, though occasionally posterior fetuses can be felt at 45 to 55 days (when the fetal skeleton can be palpated). Auscultation of fetal hearts in the final week of pregnancy will differentiate pregnancy from pyometra and show that the fetuses are alive. Pregnancy has to be differentiated also from pseudo-pregnancy, ascites, adiposity, and diabetes mellitus.

A study of pregnant bitches using several different techniques showed that abdominal palpation 26 to 35 days after mating was 82 per cent accurate in detecting bitches that would whelp, and 73 per cent accurate in identifying those that would not do so. A-mode ultrasound was best used 32 to 62 days after mating, and was 90 per cent and 83 per cent accurate in diagnosing pregnancy and non-pregnancy respectively. It was completely accurate in detecting bitches which were not pregnant.

Mares An ultrasonic scanner is often used for pregnancy diagnosis in mares. It is possible to detect the presence of a developing fetus with great accuracy as early as 14 days after conception, and this technique is particularly useful in the diagnosis of twin pregnancies.

Pregnancy Examination

Pregnancy examination of cattle, when carried out by means of rectal palpation, requires expert knowledge not only of anatomy but also of physiology and pathology. It is not always a simple matter and an accurate diagnosis is not achieved every time. The dangers of attempts by herdsmen and other untrained people to carry out such an examination include: rupture of the heart of the embryo calf; perforation of the rectum; and abortion due to manhandling of the ovaries. In the mare, rectal palpation is a common method of pregnancy diagnosis. (See also PREGNANCY AND GESTATION – Signs of pregnancy; PREGNANCY DIAGNOSIS.)

Pregnancy Toxaemia in Ewes

An acute metabolic disorder occurring during the last few weeks of pregnancy; perhaps more accurately, a number of disorders – one of which may be acetonaemia.

Causes In the more typical outbreaks, ewes are generally in good bodily condition, are carrying twins or triplets *in utero*, or have a particularly large single lamb. They are on good rich grazing, seldom getting much exercise. Bad weather, e.g. a fall of snow, has often occurred previous to the outbreak. It has been claimed that the disease can be produced experimentally by a short period of starvation during advanced pregnancy, and that ewes which become fat during the first three months of pregnancy are especially susceptible.

Signs The first signs are incoordination of movement, the animal lagging behind others when driven, stepping high, and often staggering and falling. In another hour or two the ewe lies down and can only be induced to rise with difficulty. She stands swaying and will fall or lie down again almost immediately. In general appearance she is dull, hangs her head, her eyes appear to be staring – owing to widely dilated pupils – and breathing is laboured or stertorous. Fluid may be copiously discharged from the nostrils. ACETONAEMIA may be present, giving rise to the characteristic odour from breath and urine. A comatose condition develops. Death occurs within one to six days.

Prevention It has been recommended that after the pre-tupping flush, ewes should be kept in store condition for the first three months of pregnancy.

Treatment Ewes should be dosed at once with 150 ml (2 tablespoonfuls) of glycerine in water; or glucose, 60 g in 300 ml (2 oz in ½ pint) warm water; or, preferably, glucose solution may be given intravenously. A number of ready made-up proprietary products, most based on the glucose precursor propylene glycol, are available. (See ACETONAEMIA.)

Pregnant Mare's Serum

(See PMSG under CONTROLLED BREEDING – Synchronisation in ewes; HORMONES).

VetBooks.ir

Prehension
The act of taking hold of food prior to ingestion. The diet dictates the method that is used by each species to prehend food. Herbivores usually use the mouth as the organ of prehension – cattle use the tongue and lower incisors. Carnivores use their incisor and canine teeth. Grazers, like rabbits and sheep use their lips and incisors. Primates use their forelimbs, handling their food on its way to the mouth. Birds generally use their beaks, but some, e.g. woodpeckers, use their tongues.

Premature
Occurring before the expected time, usually referring to birth.

Premature Birth
PARTURITION that occurs before the usual time from conception. (See ABORTION and PARTURITION, and the table under PREGNANCY AND GESTATION.)

Premedication
Use of a drug or drugs before administration of a general anaesthetic. An analgesic will relieve pain in an animal awaiting surgery, and a tranquilliser will relieve anxiety and facilitate handling. Both effects may be obtained by the same drug. (See ANALGESICS; TRANQUILLISERS.)

Premilking
(See under PREPARTUM MILKING.)

Premolar Teeth
A type of tooth situated between the front teeth (incisors and canines) and the molars. The premolar are found in the temporary and permanent dentition. They are used to mainly grind up the food.

Premunition
Resistance to a disease following an injection. Animals which are premunised are infected with a micro-organism but are not affected by it.
The term has often been used in veterinary medicine in relation to trypanosomiasis (see TRYPANOSOMES, TSETSE FLY).

Preocular Film
(See PRECORNEAL FILM.)

Pre-Ovulatory Ovarian Stress (POOS)
(See EGG-BOUND; VITELLOGENESIS.)

Prepartum Milking
Milking a heifer or cow a few days before the birth of her calf. Where this is practised, the calf when born must be provided with colostrum from another cow.

Prepotency
The ability of one parent, in greater degree than the other, to transmit a characteristic (e.g. high milk yield) to the offspring.

Prepubic Tendon, Rupture of
A possible complication of pregnancy, especially in heavy mares. Diagnosis is difficult but the condition should be suspected whenever ventral oedema occurs suddenly in late gestation, and is associated with considerable pain (due to the trauma). The condition is usually fatal, and may be a cause of sudden death.

Prepuce
(adjective, Prepucial)
The fold of skin covering the end of the penis. Crystals on the hairs here in the calf are seen in some cases of UROLITHIASIS. (See also PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Pre-Purchase Examination (PPE)
These are often requested by prospective purchasers before buying a horse. This used to be called a 'soundness examination' or the horse being 'vetted'. The animal should receive a certificate, and usually the purchaser is requested to sign a letter, which indicates that they are aware of the limitations of the examination.

Presbyopia
Presbyopia is the term used to indicate the changes that normally affect the eye in old age, quite apart from any disease. The most important of these changes is a diminution of the natural elasticity of the lens of the eye, resulting in an impaired power of focusing objects near at hand.

Prescribing Behaviour of Veterinary Surgeons
(See ANTIBIOTIC - SELECTION OF ANTIBIOTIC.)

Prescription Diets
Specially formulated dog and cat foods designed to assist the treatment of certain metabolic and functional disorders. As the diets are formulated for specific disease problems, they should only be fed under veterinary supervision. They are available in both dry and moist form, from veterinary surgeons.

Prescription-only Medicines (POM)
Under the MEDICINES ACT 1968 these were medicines that could be supplied only on the prescription of a doctor, veterinary surgeon or dentist. Under the terms of the Act, veterinary surgeons in the UK may supply prescription-only medicines only for animals or herds under their care, and not to

VetBooks.ir

the public at large. Under the Veterinary Medicines Regulations this category has become POM-V. A new category, POM-VPS (Prescription Only Medicines-Veterinarian, Pharmacist, Suitable Qualified Person), was introduced to mainly replace the 1968 Act category of PML. (See PML.)

Presentation

1. A collection of signs which 'present' themselves when an animal is ill.
2. The positioning of the long axis of the fetus. (See under PARTURITION.)

Pressor

Pressor is the term applied to anything that increases the activity of a function, e.g. a pressor nerve or pressor drug. Producing a rise in blood pressure is its most common meaning.

Prestunning Slaughter

In the UK all animals being killed for meat must be stunned before slaughter. An exception is made for the Jewish and Islamic religious communities where suitable persons are allowed to kill the animals without previous stunning.

Prevalence

This is defined as the number of cases of disease or infection existing at any given time in relation to the unit of population in which they occur. It is a static measure as compared with the dynamic measure, INCIDENCE.

Preventive Medicine, Preventive Treatment

This is designed to prevent disease occurring. (See also PREVENTIVE VETERINARY MEDICINE, PROPHYLAXIS.)

Preventive Veterinary Medicine

This is the keynote of modern veterinary practice, and is of increasing importance in these days of intensive livestock husbandry and of very large units. (See HEALTH SCHEMES FOR FARM ANIMALS.)

Prey, Birds of

These can be DIURNAL (FALCONS, HAWKS) or NOCTURNAL (OWLS).

Priapism

Persistent erection of the penis. Cases of priapism in horses, with protrusion, oedema and paresis of the penis, have been recorded after neuroleptanalgesia and anaesthesia using acepromazine with etorphine chloride and other anaesthetic agents. It is recommended that following the use of neuroleptic drugs a check should always be made to ensure that penile retraction is taking place as the effects of the drug wear off. If not, treatment should be started without delay. (See also PENIS; PENIS AND PREPUCE, ABNORMALITIES AND LESIONS.)

Primary Case, Primary Infection, Primary Disease

A single disease which infects an animal, uncomplicated by damage or effects from other diseases. Often, secondary infections may follow, causing additional problems. (See CO-PRIMARY CASE; INDEX CASE; SECONDARY CASE.)

Primary Intention

A description of wound healing where the sides of the wound are in apposition and heal quickly. This is what happens with a surgical incision. (See INTENTION.)

Primary Mosaicism

Primary mosaicism is a sequel to fertilisation of an ovum by spermatozoa derived from the same zygote but having different chromosomes. (See ERYTHROCYTE MOSAICISM; GENETIC ENGINEERING.) Secondary mosaicism occurs in the FREEMARTIN.

Primates

These include about 200 species, ranging in size from the tree-shrew, weighing about 100 g (3 oz), to the gorilla, weighing up to 275 kg (600 lb).

Two suborders are recognised: New World monkeys; and Old World monkeys, apes, and man.

Primidone

An anti-convulsant used in dogs to treat nervous disorders, including EPILEPSY, epileptiform convulsions and HYSTERIA, CANINE; also to control the nervous complications of DISTEMPER. It is the active ingredient of MYSOLINE, an anti-convulsant drug used in epilepsy. The active ingredient is converted in the liver into phenobarbital and phenylethylmalonamide; the latter may be useful where animals have ceased to respond to phenobarbital alone. A side-effect of this drug may be thirst, polyuria resulting in urinary incontinence, in the dog.

Primiparous

Relating to a female animal that has produced one viable offspring or one litter.

Prions

Prions are proteins found in the brain which are, apparently, self-replicating. Specific forms of prion are responsible for such brain diseases as scrapie, BES and, in man, Creuzfeldt-Jacob

disease. It is not known how long prions survive in the environment. (See BOVINE SPONGIFORM ENCEPHALOPATHY; FELINE SPONGIFORM ENCEPHALOPATHY; SCRAPIE.)

Privet Poisoning

Privet poisoning is very rare, and occurs only when horses and cattle have free access to privet hedges, or break into gardens and shrubberies containing this common ornamental shrub. Privet (*Ligustrum vulgare*) contains a glucoside (ligustrin), which causes loss of power in the hind-legs, dilated pupils, slightly injected mucous membranes, and death in 36 to 48 hours.

Probang

A rod of flexible material designed to aid removal of foreign bodies from the oesophagus. (See 'CHOKING'.)

Probiotics

Preparations containing live or parts of dead micro-organisms such as lactobacilli and yeasts; yoghurt is an example. They are used in some animal-feed supplements to act as growth-promoters. Probiotics are believed to act by preventing colonisation of the gut by pathogenic organisms. Some have been shown to exert an immuno-modulatory effects at both systemic and intestinal levels, leading to increased production of specific immune cells and immunoglobulin IgA.

Procaine Hydrochloride

Procaine hydrochloride is used in solution as a local anaesthetic, and for EPIDURAL ANAESTHESIA. It is the only local anaesthetic with a market authorisation for cattle in UK. It is a prescription-only medicine. It is often combined with adrenaline, in order to lessen haemorrhage during minor surgery and to prolong its effect.

Toxicity Excessive amounts of procaine hydrochloride cause stimulation of the central nervous system. In the horse, 10 mg/kg (5 mg per lb) bodyweight gives rise to nervousness (tossing of the head, twitching of the ears, stamping of the feet, snorting, or neighing), while muscular incoordination and convulsion follows larger doses. In the dog, 44 mg/kg (20 mg per lb) causes salivation and vomiting, with muscular tremors and incoordination.

Procaine penicillin The procaine salt of penicillin is often used, the concentration of penicillin in the blood remaining for a longer period, and the injection being less painful.

However, procaine penicillin G can sometimes cause a febrile reaction in pigs. The toxicity can be potentiated by SWINE ERYSIPELAS.

Proctitis

Inflammation in, on or around the anus. Irritation is seen about the anal area. It can be a sign of the presence of parasitic worms in some farm animals and horses.

Prodromal

Prodromal is a term applied to signs of a disease which are among the first seen, but which are not necessarily characteristic.

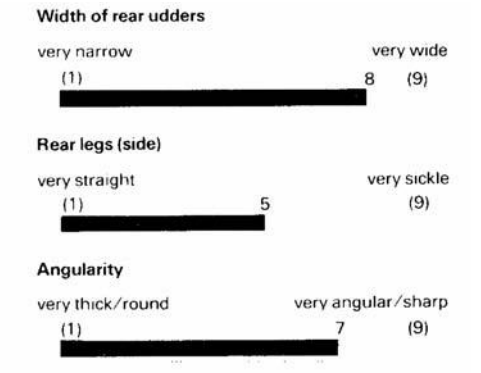
'Production Disease'

A name suggested to embrace all the syndromes formerly classified as metabolic disease. It has been used particularly in connection with intensive farm husbandry, because high production is frequently expected on diets which are not always suitable for the purpose.

GENERAL CHARACTERISTICS		No.	%
Size	Large	21	38
	Medium	34	60
	Small	1	2
Temperament	Quiet	54	96
	Nervous	2	4
Ease of Milking	Satisfactory	55	98
	Hard	–	–
	Too easy	1	2

Proestrus

The 1st phase of the oestrous cycle, when the ovary is producing hormones which bring about enlargement of uterus, oviducts and vagina, and when the ovarian follicle containing the ovum is also increasing in size. (See OESTRUS.)



Profibrinolysin

(See PLASMINOGEN.)

Progeny Testing

A method of assessing the genetic value of a male animal by measuring the performance of his offspring, e.g. a bull can be assessed as a sire, for the milk yield, milk contents, conformation etc., using figures for an unselected sample of his daughters. In males the more results obtained the better the validity of the assessment of his genetic worth. Dam: daughter comparisons may show whether a high-yielding cow can transmit her capability to her progeny, but these comparisons are valid only under identical systems of feeding and management.

Conformation Selection of proven bulls for use as artificial insemination sires depends not only on the production figures of the daughters, but also on an assessment of (as many as possible) daughters.

The progeny group illustrated in the diagram would have very high rear udders, legs about midway between very straight and very sickle, and would be rather sharper, cleaner cut animals than average, though not excessively so. (MMB.)

Qualities of commercial importance taken into account are size, temperament, ease of milking – plus appearance, dairy character, udder, legs, feet, etc. Gradings are Excellent, Very Good, Good Plus, Good, Fair and Poor.

Above is shown a summary for a particular bull which had 56 daughters inspected by a type assessment panel. It will be noted that all but two of his daughters were quiet, and over half of them were in the top three ratings. The score of 107 indicates that the fore udder was the best point when compared with the national average.

Linear assessment This is widely used in the USA and Canada, and in the UK. It does away with the idea of scoring against an ideal, makes no attempt to define good or bad, but simply describes where, between the biological extremes for agreed traits, an individual animal comes.

The linear system identifies the point between the extremes at which an animal is felt to come by describing it numerically in the range 1 to 9. Since the total number of single biological traits is very large, the most important ones have to be selected to keep the total a manageable one.

A common set of 16 traits was agreed following discussions with the British Friesian Cattle Society and the Associated AI Centres. The traits are: stature, chest width, body depth, angularity, rump angle, rump width, rear legs (side view), rear legs (rear view), foot angle, fore udder attachment, rear udder attachment, udder support, udder depth, teat placement (rear view), teat placement (side view) and teat length.

Other traits which need recording, such as weak pasterns, teats not plumb, or high pelvis, can be dealt with by means of a list of miscellaneous characteristics.

Progestagens
(See PROGESTOGENS.)

Progesterone
A sex hormone from the *corpus luteum* and (in the pregnant animal) the placenta which prepares the reproductive tract for pregnancy. It inhibits follicle-stimulating hormone (FSH) and action of oxytocin. (See under ENDOCRINE GLANDS.)

Progestogens, Progestagens
These drugs are used in CONTROLLED BREEDING and have a progesterone-like action. A progestogen is administered over a period of time so that the established oestrous cycle is arrested at the point at which all *corpora lutea* have regressed. The removal of the progestogen then allows the continuance of reproductive activity. Examples of progestogens are:

Name	*Product, or other name*
Altrenogest	Regumate
Delmadinone	Tardak
Megestrol acetate	Ovarid
Medroxyprogesterone acetate	MAP (Methyl acetoxy progesterone), Perlutex, Promone, Veramix
Fluorogestone (Flugestone) acetate	Cronogest
Norgestomet	*in* Crestar

NB. The list is not comprehensive

Their use can sometimes lead to diabetes in dogs and cats.

Proglottis
A segment, of an adult tapeworm, capable of reproduction.

Prognathism
The abnormal positioning of one or both jaws. It most commonly refers to the lower jaw. It can be seen in all species of mammals, birds and reptiles. Severe forms will result in death. In many other cases there are other congenital deformities. It can be genetic but there are many other reasons. Among dogs it is seen in BOSTON TERRIERS.

Prognosis
(adjective, Prognostic)
An opinion as to the likely course and result of a particular disease or surgical condition.

Progressive Axonopathy
An inherited condition in BOXERS. It is a degenerative condition of the central nervous system and the peripheral nerves. It is usually seen at six months old. The animals show ATAXIA, and a weakness of the hind legs with no patella reflex.

Progressive Retinal Atrophy (PRA), Progressive Retinal Degeneration (PRD)

A hereditary condition common in many breeds of dogs (especially AMERICAN COCKER SPANIELS, AUSTRALIAN CATTLE DOGS, AUSTRALIAN SHEPHERD DOGS, AUSTRALIAN SILKY TERRIERS, AUSTRALIAN STUMPY TAIL DOGS, BORDER TERRIERS, BRIARDS, BULL MASTIFFS, CHESAPEAKE BAY RETRIEVERS, CHINESE CRESTED DOGS, COCKER SPANIELS, CORGIS (Cardiganshire), DACHSHUNDS (Miniature Long-Haired, Miniature Smooth-Haired), ELKHOUNDS, ENTLEBUCHER MOUNTAIN DOGS, FINNISH LAPPHUNDS, GLEN OF IMAAL TERRIERS, GOLDEN RETRIEVERS, GORDON SETTERS, GRIFFON BRUXELLOIS, HUNGARIAN KUVASZ, IRISH RED AND WHITE SETTER, IRISH SETTERS, IRISH WOLFHOUNDS, ITALIAN GREYHOUNDS, LABRADOR RETRIEVERS, LHASA APSOS, MINIATURE SCHNAUZERS, NORWEGIAN ELKHOUNDS, NOVA SCOTIA DUCK TOLLING RETRIEVER, PAPILLONS, Miniature POODLES, Standard POODLES, Toy POODLES, PORTUGUESE WATER SPANIELS, ROUGH COLLIES, SAMOYEDS, Miniature SCHNAUZERS, SHETLAND SHEEPDOGS, SIBERIAN HUSKIES (X-linked), SLOUGHIS, SMOOTH COLLIES, SPANISH WATER DOGS, SWEDISH LAPPHUNDS, TIBETAN TERRIERS, and YORKSHIRE TERRIERS). It is a degenerative disease of the eye leading to impaired vision and ultimately loss of vision. In the UK there is a joint scheme operated by the British Veterinary Association and the Kennel Club to reduce the incidence of this disease in any breed of dog; certificates are issued to dog-owners. (See EYE, DISEASES AND INJURIES OF.) The disease also occurs in some breeds of cats.

The genetic defect responsible for causing the disease in Irish setters has been identified by US and UK researchers, and could provide a means for eliminating the condition from the breed.

Progressive Retinal Dystrophy (PRD)

A type of PROGRESSIVE RETINAL ATROPHY seen in GLEN OF IMAAL TERRIER DOGS and which is due to retinal cone degeneration normally seen from four years old onwards. The retina may be seen to thin from three years old. A genetic test is available.

Progressive Retinal Epithelial Dystrophy

(See CENTRAL PROGRESSIVE RETINAL ATROPHY.)

Projectile Injection

A method of administering SPECIFIC CHEMICAL INJECTIONS to wild animals, dangerous and fractious animals. It can be administered by DARTING, cross bows or gun. (See also PROJECTILE SYRINGE.)

Projectile Syringe

Fired from a cross-bow, gun or blowpipe, this instrument is useful for immobilising and/or anaesthetising wild animals. The apparatus and ammunitions come under Section 5 Prohibited Firearms of under the Firearms Act 1968. The use of dart guns is, in the UK, restricted under section 5 of the Firearms Act 1997.

Blowpipes and dart guns are short range – up to 36 m (40 yards) only. They use a compressed air discharge system to shoot a small hypodermic syringe loaded with the appropriate drug. They facilitate the treatment of dangerous or unapproachable animals with safety. They are often used to administer antibiotics, vaccines, and so are not purely for anaesthetics.

Projectile Vomiting

This term is used when the vomitus is thrown some distance (up to a metre) from the body – a sign of pyloric stenosis in the dog. It is very unusual in ruminants but is seen in RHODODENDRON POISONING.

Prokinetics

A compound or drug which enhances the action and/or the speed of action of the gastrointestinal tract.

Prolactin

A hormone associated with lactation secreted by the PITUITARY GLAND. Also called luteotropic hormone or luteotropin.

Prolan

An old name for chorionic gonadotrophin.

Prolapse

Prolapse means the slipping down or displacement of some hollow organ or structure. The term is applied to the displacements of the rectum and female generative organs, which result in their appearance to the outside.

The best plan is to seek professional assistance at once. (See PHALLUS, UTERUS, DISEASES OF; RECTUM, DISEASES OF; CLOACAL PROLAPSE.)

Prolapse of Oviduct

This condition is fairly frequently encountered in fowls, particularly in birds which have been laying heavily. It is nearly always associated with some aberration from normal of the cloaca or oviduct, irritation resulting and causing the bird to strain. Occasionally it is seen after an endeavour to pass a large or malformed egg, yolk concretion, etc., and in cases known as 'egg bound'. It is also sometimes

VetBooks.ir

met with in cases of vent gleet. The prolapsed oviduct appears as a dark red swelling protruding from the vent. Other birds are attracted by the swelling and peck at it, frequently leading to evisceration and death. Treatment consists in removing the affected bird from the flock. The prolapse should be washed with warm water containing a mild antiseptic, and then gently pressed back into the abdominal cavity after first removing the egg or other foreign body, if the presence of such can be detected. It greatly aids return to have the bird held head downwards by an assistant.

The condition also occurs in reptiles, especially snakes, and chelonians after egg laying. As these species move so close to the ground the organ is often so badly damaged that amputation (SALPINGECTOMY) is necessary.

Prolapse of the Nictitating Membrane Gland

(See NICTITATING MEMBRANE GLAND PROLAPSE.)

Proliferative
(noun, Proliferation)

Associated with the multiplication or reproduction of a similar form, it usually refers to cells.

Proliferative Enteropathy (PE)

An infectious intestinal disease of pigs associated with *Lawsonia intracellularis*. There may be diarrhoea but no specific clinical signs.

Proliferative Haemorrhagic Enteropathy in Pigs

(See HAEMORRHAGIC GASTROENTERITIS OF PIGS.)

Proliferative Kidney Disease

A disease mainly of fingerling salmonids; affected fish show abdominal swellings and any stress will result in death. The cause is unknown. At post-mortem examination, fluid is found in the abdominal cavity and the kidneys and spleen appear grey and swollen.

Proligestone

A hormone used to control the oestrous cycle of bitches, queens and jills and to treat false pregnancy. It may be used for the temporary or permanent suppression of heat and to stop 'calling' in queens. In jills, it can be used to treat prolonged oestrus and the problems associated with that condition.

Proline

An amino acid which is synthesised from glutamic acid; it is glycogenic (see GLYCOGEN), and a major constituent of COLLAGEN. Chicks have only a limited ability to synthesise proline and so care must be taken to ensure an adequate level in their diet.

Prolonged Soft Palate

An inherited abnormality of dogs. (See under PALATE.)

Promazine Hydrochloride

A sedative and aesthetic premedicant, administered to the dog by intravenous or intramuscular injection. It is now outmoded.

Pro-Oestrus

A period in the oestrus cycle when the Graafian follicles are increasing in size (see OVARIES) and the female reproductive organs are being prepared for possible pregnancy.

Propentofylline

A derivative of xanthine which increases blood flow to the heart and skeletal muscle and has an anti-arrhythmic effect in dogs with myocardial ISCHAEMIA. It also has a bronchodilatory effect. It is used to assist overcome lethargy, dullness, and it increases exercise tolerance. It increases blood supply to the brain thereby increasing its demand for glucose. A product is licensed for use in dogs, except pregnant bitches.

Prophylactic Medicine, Prophylactic Treatment

This is designed to prevent disease occurring. (See also PREVENTIVE MEDICINE, PREVENTIVE VETERINARY MEDICINE, PROPHYLAXIS.)

Prophylaxis

Prophylaxis means any treatment that is adopted with a view to preventing disease.

Propionate, Sodium

A bacteriostatic and fungicide which has been recommended in the treatment of obstinate infections of the conjunctiva and cornea. It is now little used. In North America it can be used to spray on fresh meat to help prevent spoilage. It can also be administered to ruminants with ketosis. It is found in the bile and sweat of mammals.

Propionic Acid

A VOLATILE FATTY ACID produced in carbohydrate digestion in ruminants.

(See MUSCLES, DISEASES OF - NUTRITIONAL MUSCULAR DYSTROPHY.)

Propofol

One of a group of alkyl phenols, propofol is useful as an intravenous anaesthetic for dogs and cats, as

VetBooks.ir

well as for minor surgical procedures and Caesarian section. Recovery from it is quiet and rapid – an advantage when the patient has to be returned to the owner's care with the minimum delay. The solution is opaque, which is very different to the clear solutions of other anaesthetics.

Propoxur
An anticholinesterase used in flea collars for cats. It provides flea infestation control for up to five months.

Propranolol
A non-selective beta-blocker.

Propylene Glycol
Propylene glycol is used in the treatment of acetonaemia in cattle and pregnancy toxaemia in sheep; it metabolises to proprionic acid and GLYCERIN. It is often formulated with minerals.

Propylxanthine
A drug used to promote and improve cerebral, cardiac, skeletal and peripheral blood supply in dogs, especially older dogs. It is not recommended for pregnant bitches as it has not been evaluated in them.

Prostaglandins
A group of hormone-like compounds which can cause contraction of the uterus, lower blood pressure, have an effect on platelets, and lower body temperature.

Prostaglandin $F_2\alpha$ or its analogues cloprostenol, dinoprost, luprostiol and tiaprost, are used in veterinary practice to bring about regression of the *corpus luteum* for control of oestrus or to induce abortion or parturition.

A code of practice relating to the use of prostaglandins in cattle and pigs has been agreed by the RCVS and the BVA. Care must be taken when handling prostaglandin products to avoid skin contact and self-injection. Asthmatics and women of child-bearing age are particularly at risk.

Prostaglandins can cause local ischaemia at the intramuscular injection site, followed by diffuse swelling and emphysema.

In one case, sloughing of skin and muscle occurred, and *Clostridium chauvoei* was isolated from the exudate. The mare became recumbent, and euthanasia was decided upon.

(See CONTROLLED BREEDING; PYOMETRA; PLACENTA - RETAINED PLACENTA. See also UTERUS, DISEASES OF - THE MARE - CHRONIC METRITIS; EGG-BOUND.)

Prostate Gland
Prostate gland is one of the accessory sexual glands that lies at the neck of the bladder in the male animal, and partly surrounds the urethra at that point. Hyperplasia is an enlargement of the prostate and is seen in older animals. When greatly enlarged, not only does it interfere with urination, but it may also obstruct the passage of faeces. Affected animals will show constipation, and eventually tenesmus with the production of ribbon-like faeces. The condition can cause perineal hernia. Oestrogens are used in treatment but castration may have to be carried out.

Apart from this gradually occurring HYPERPLASIA of the gland in dogs over five years old, enlargement may be due to an acute infection, when evidence of pain (with arched back and a stiff-legged gait) may be added to the signs. Cancer of the prostate is not rare in the dog; cysts sometimes occur. (See also BRUCELLOSIS.)

Prostatitis
Inflammation of the prostate occurring as a result of infection ascending the urethra. Affected animals are anorexic, show malaise and may vomit. There is severe abdominal pain with arching of the back. Urination will be difficult and painful. Antibiotics, oestrogens, smooth muscle relaxants and castration have been used in treatment, but in chronic cases the prognosis for improvement is not good.

Prosthesis
An artificial replacement of a part of the body.

Prostration
This is a condition of extreme exhaustion, lack of energy or weakness (COLLAPSE). It also means lying face downwards.

Protection of Animals Act 1911, Protection of Animals [Scotland] Act 1912
These are the Acts under which actions for cruelty to animals are taken in Britain. Both have been amended subsequently. The Acts make it an offence to carry out an act, or to do something, that results in a domestic or captive animal suffering unnecessarily, either by deliberate cruelty or neglect. These acts have been largely replaced by the 2006 Acts (2011 in Northern Ireland) but a few sections remain as law.

Protection of Animals (Anaesthetics) Act 1964
This Act has been repealed in its entirety by the ANIMAL WELFARE ACT 2006 and the WELFARE OF ANIMALS ACT (NORTHERN IRELAND) 2011. However, the ANIMAL HEALTH AND WELFARE (SCOTLAND) ACT 2006 Section 1 is now reworded so that any operation performed without an anaesthetic to prevent pain is an offence under Section 21 of the new Scottish Act. (See under ANAESTHETICS, LEGAL REQUIREMENTS.)

VetBooks.ir

Protein, Acute Phase
Proteins found in the blood that increase in response to infections and inflammatory disease. They include fibrinogen, haptoglobin and serum amyloid-A. Their production is stimulated by cytokines such as interleukin 1 and 6 and tumour necrosis factor. In dogs, the normal serum level is less than 1µg/l but a peak is reached about 24 to 48 hours after disease onset that can be 1,000 times that. The level drops rapidly during recovery.

Protein, Hydrolised
A mixture of amino acids and simple polypeptides prepared by enzyme digestion of whole muscle. A valuable source of protein used in cases of shock, malnutrition, convalescence, fevers, chronic nephritis, etc. It may be given by mouth or injection.

Protein Calories
A measure of the nutritional value of a food, not of a requirement by the animal.

Protein Concentrates
Products specifically designed for further mixing with planned proportions of cereals and other feeding-stuffs, either on the farm or by a feed-stuff compounder.

Protein Equivalent
This provides the measure of the value of a feeding-stuff, taking into account the protein content plus the non-protein nitrogen content, capable of being converted into protein by the animal's digestive system. It is expressed as a percentage. For example, the protein equivalent of linseed cake is 25 per cent; i.e. 100 kg of the cake is equivalent to 25 kg of protein and potential protein. The protein equivalent of grass silage is about 2 per cent; that of kale, 1.3 per cent.

Protein-Losing Enteropathy
Excessive loss of protein from the intestine. It can be seen in a variety of conditions including chronic alimentary disturbances, congestive heart failure, neoplasia, inflammatory bowel syndrome, food allergy, systemic lupus erythematosus, hyperadrenocorticism, etc. In dogs with chronic enteropathies with secondary protein-losing enteropathies CHLORAMBUCIL is beneficial.

Proteins
Proteins are complex chemical compounds containing nitrogen, carbon, hydrogen and oxygen, found in every body tissue and living cell. Proteins are formed from (and convertible to) amino acids. (See DIET AND DIETETICS.)

Protein Shock
A reaction following parenteral administration of a protein. (See ANAPHYLACTIC SHOCK.)

Proteinuria
The presence of excess serum proteins in urine. It is an important indicator of kidney (renal) disease. The condition is found in GLOMERULONEPHRITIS, AMYLOIDOSIS and NEPHROSIS. It can also be seen in congestive heart failure, renal infarction and renal ischaemia. In many cases there are also renal casts in the urine.

Proteoglycans
Proteins which are combined with a carbohydrate. Some are produced by fungi and are used to treat convalescent animals by aiding natural recovery. They are claimed to be useful when the immune system has been challenged.

Protetamphos
A compound used as a sheep dip, and also for fly strike and control of keds, ticks and lice.

Proteus
A genus of bacteria. *Proteus* species are common pathogens affecting the urinary system of the dog and generalised infections of duck.

Proteus vulgaris
An organism pathogenic for quail keets; infection causes severe depression, body and leg muscle tremors, coma and mortality up to 100 per cent.

Prothrombin
A substance formed in the liver with the assistance of vitamin K, and essential for the clotting of blood.

Protoplasm
(See CELLS.)

Protoporphyrins
These are TETRAPYRROLES containing propionic acid, vinyl and methyl groups which combine with cations. Combination with iron produces HAEMOGLOBIN, MYOGLOBIN, with magnesium CHLOROPHYLL and with zinc, ZINC PROTOPORPHYRIN.

Protothecosis
Poisoning by a colourless alga, prototheca; possibly a mutant form of chlorella, a green alga. (See MASTITIS.)

Protozoa
Single-celled organisms.

Proud Flesh
Tissue that can arise in the healing of surface wounds. It results in an area of soft moist GRANULATIONS which tend to rise above the surface of the normal skin. It is particularly seen in horses.

VetBooks.ir

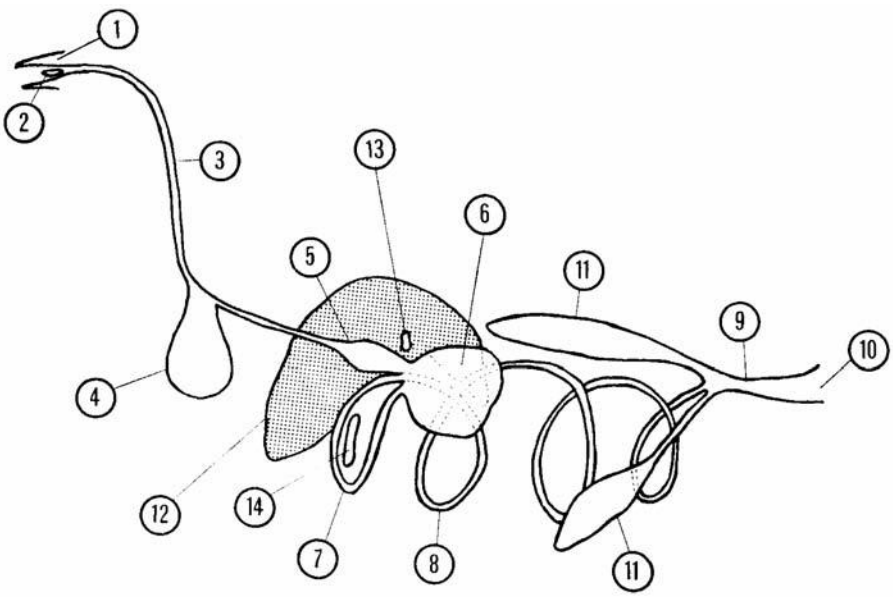
Proven Sire
Proven Sire is one having an adequate number of measured progeny. (See PROGENY TESTING.)

Proventricular Dilation Disease (PDD)
This is found in cage birds, especially psittacines, and is characterised by weight loss, regurgitation, undigested food in the droppings; in some cases it is fatal. The cause is AVIAN BORNAVIRUS (ABV). Affected birds may need help in feeding and an NSAID may be beneficial. However, the treatment may have to continue for life. Euthanasia should be considered.

Proventriculitis
This is seen in many diseases including Avian Infectious Bursitis (GUMBORO DISEASE), MAREK'S DISEASE, AVIAN INFECTIOUS ENCEPHALOMYELITIS ('EPIDEMIC TREMORS'), NEWCASTLE DISEASE, AVIAN INFLUENZA, and as a result of the MYCOTOXIN ciclopiazonic acid produced by some strains of *Aspergillus flavus* and some strains of *Penicillium* fungi.

Proventriculus
The true, glandular stomach of birds. In it digestion is effected by hydrochloric acid and enzymes. (See diagram below.)

Proventricular region of the horse's, and pig's, stomach is near the oesophagus.



Provirus
The virus genome (DNA) present in a cell, during the multiplication of a virus or it may remain inactive for long periods.

Proximal
Proximal is a term of comparison applied to structures which are nearer the centre of the body or the median line, as opposed to more 'distal' structures.

PrP
A protein found on the surface of neurons (nerve cells) and involved in the development of transmissible spongiform encephalopathies, including BOVINE SPONGIFORM ENCEPHALOPATHY. (See also PRIONS.)

PRRS
Abbreviation for PORCINE REPRODUCTIVE RESPIRATORY SYNDROME. (See 'BLUE-EAR' DISEASE OF PIGS.)

Pruritus
Pruritus is the sign of itching which is a prominent feature of most parasitic skin diseases, and of AUJESZKY'S DISEASE and SCRAPIE. Often in dogs and cats it is caused by ECTOPARASITES; it is seen in ALLERGIES, bacterial/fungal infections or overgrowths, IMMUNE-MEDIATED and AUTOIMMUNE DISEASE, NEUROGENIC diseases and NEOPLASIA.

Proventriculus. Its position in the digestive tract of the fowl is indicated (5). Other numbers indicate beak and tongue (1 and 2); oesophagus (3); crop (4); gizzard (6); duodenum (7); small intestine (8); large intestine (9); cloaca (10); caeca (11); liver (12); gall bladder (13); pancreas (14). (Reproduced with permission from the *UFAW Handbook on Care and Management of Farm Animals*, Churchill Livingstone.)

VetBooks.ir

Pruritus, Pyrexia, Haemorrhagic Syndrome (PPH)

A syndrome recorded mainly in dairy cows fed large amounts of silage, often after use of a silage additive. The signs vary but include fever and persistent skin lesions which sometimes result in self-mutilation and haemorrhages. The outcome is often fatal. It has also been reported in cattle fed on citrus pulp which was mouldy and contained citrinin.

Prussic Acid

(See HYDROCYANIC ACID.)

Przhevalskiana silenus

(See GOAT WARBLE FLY.)

Psammoma

Psammoma is a small hard tumour of the brain.

PSE

Pale, soft exudative muscle mainly seen in pigs and cattle. (See PORCINE STRESS SYNDROME.)

Pseudobranch

A vestigial red gill-like structure situated on the inside face of each operculum (flap covering the gills) in salmonid fish. Its purpose is unknown but it is believed to be part of the endocrine system.

Pseudo-Cowpox

Caused by a parapox virus, this infection is characterised by inflammation of the teats of cows, and of the hands of milkers.

Pseudomediastinum

The presence of air in the mediastinum, following damage to lung alveolar tissue near its root. It can also follow more serious trauma such as a damaged trachea, or rupture of the oesophagus. A swelling of a dog's whole face and neck due to subcutaneous emphysema may follow pneumomediastinum, the air tracking upwards. It may take weeks before the swelling totally disappears, but the condition is seldom serious unless trachea or oesophagus are damaged.

Pseudomembrane

A 'false membrane' containing bacteria covering a damaged mucous membrane.

Pseudomonas

A genus of bacteria. *P. pyocyanea* is a motile, Gram-negative rod, 1.5 µ to 3 µ long. It flourishes in suppurating wounds, and has been found in cases of otitis in the dog. It has also been reported as causing outbreaks of disease in turkey poults and other birds as well as in sheep.

Chronic mastitis, with diarrhoea and wasting resembling JOHNE'S DISEASE, has been caused in cows by *P. aeruginosa*. This organism, often found in non-mains water supplies, is thought likely to be increasingly involved in mastitis in cattle. It appears to have an increased incidence during August, September and October. (See WOUNDS; also MELIOIDOSIS.)

Pseudo-Pregnancy

Pseudo-pregnancy is a condition commonly seen in the bitch, but probably occurring in all breeding female animals to a lesser degree. In it the physical signs of pregnancy are exhibited in the absence of fetus or fetuses. The abdomen increases in size, the uterus becomes swollen and turgid, its walls are thickened, and in extreme cases mammary development may occur and milk may be secreted. The bitch may actually make a bed.

In time, since no fetuses are present, the organs and tissues return to their normal state without the occurrence of parturition; heat returns, and successful breeding may occur subsequently.

The condition has been described as an intensification and prolongation of metoestrus. The essential feature is persistence of the *corpora lutea* in the ovaries.

The condition can – where necessary – be treated by injection of the appropriate hormone.

In a review of 442 cases of pseudo-pregnancy in a total of 142 bitches, 19 had only one pseudo-pregnancy, 31 had two, 54 had three, and 39 had four or more pseudo-pregnancies.

In another reported series, a total of 81 per cent of pseudo-pregnancies responded to treatment with bromocriptine, and 80 per cent of the behavioural or psychological problems were resolved.

(See REPRODUCTION; BREEDING OF LIVESTOCK; 'CLOUDBURST'.)

Pseudo-Rabies

A name occasionally used for AUJESZKY'S DISEASE.

Pseudo-Tuberculosis

(See YERSINIOSIS; CASEOUS LYMPHADENITIS.)

Psittacine Beak and Feather Disease

This is caused by a circovirus which colonises the entire alimentary tract, liver and BURSA OF FABRICIUS. All psittacines can be infected but cockatoos seem to be more resistant. In very young birds, sudden death may be the only finding but in other cases there may fatal pneumonia. Older nestlings show a general malaise with loss of POWDER DOWN; they may show colour changes or ven fractures. The loss of powder down results in dull plumage and glossy beak, which can

VetBooks.ir

become overgrown and distorted. Later, beak and claws can become brittle. Scaling and thickening of the skin can occur in chronic cases. As the bursa is infected, surviving birds are immunologically compromised. There is no treatment and no vaccine available. The disease is avoided by breeding from virus-free stock and quarantining incomers, especially birds imported from abroad, which may have been taken from the wild.

Psittacines

PARROTS, PARAKEETS, cockatiels, BUDGERIGARS and other members of the order Psittaciformes.

Psittacosis, 'Parrot Fever'

A NOTIFIABLE DISEASE in the UK. It causes severe respiratory illness in man and birds of the parrot family (psittacines), including budgerigars and cockatiels. It is caused by *Chlamydia psittaci*. (See CHLAMYDOPHILA; ORNITHOSIS.)

Psoas

Psoas is the name of two muscles, psoas major and psoas minor, which lie along the roof of the abdomen immediately beneath the last two or three thoracic and the whole of the lumbar vertebrae, and stretch into the pelvis. The psoas minor is inserted in the psoas tuberele of the ilium, and the psoas major runs to the inner or lesser trochanter of the femur in common with the iliacus muscle. The action of these muscles is to bend the pelvis on the rest of the trunk, or if those of one side of the body are acting alone, to bend the posterior part of the trunk towards that side. In the horse, the act of crouching preparatory to kicking is accomplished by these muscles and others, and they are largely concerned in the movements of galloping. Disease or injury, such as a severe sprain, is shown by a difficulty in walking both forwards and backwards, by a crouching appearance of the back, and by extreme difficulty in rising from the ground.

Psoriasis

Psoriasis is a chronic inflammatory skin disease with scurf formation. It is an inherited chronic skin disease which is not seen in non-humans. However, a disease of a different aetiology occurs, rarely, in ENGLISH SPRINGER SPANIELS with somewhat similar skin lesions. It is seen as part of HORNER'S SYNDROME.

Psoroptic Mange

A type of mange caused by various species of *Psoroptes* mites. It can affect most animals, and causes sheep scab, ear mange in horses and widespread skin lesions in cattle. (See under MANGE.)

PSSM

(See POLYSACCHARIDE STORAGE MYOPATHY.)

Psychotropic Bacteria

These are bacteria capable of survival and possibly multiplying at low ambient temperatures. They can occur in the soil, sea water, surface water, and in foods. Various definitions have been used for them, but usually they are considered as able to survive and multiply at temperatures less than 7° C. Their growth is slow or stops at 0° C. In milk, high levels can indicate contamination of the water supply. The target level is <30 cfus/ml.

Ptosis

The drooping of the upper eyelid, due to paralysis of the oculomotor nerve. It is seen in the horse after accidents involving the head; and also in GUTTURAL POUCH DISEASE. A case of ptosis in a bird was treated by the topical application of phenylephrine, which rapidly resolved the condition. It is seen as part of HORNER'S SYNDROME.

Ptyalin

Ptyalin is the name of the enzyme contained in the saliva, by which starchy food-stuffs are changed into sugars, and so prepared for absorption.

Ptyalism

The overproduction of saliva. It may be the first clinical sign of epilepsy in dogs.

Puberty

Ewes, sows, and bitches may mate when only six or seven months old; mares reach puberty at from 15 to 18 months old; heifers from seven to 15 months old. In the cat oestrus may occur as early as 3½ months, or occasionally be delayed until the queen is about a year old. In the male, puberty commonly occurs at an age of 10 to 12 months, but here again there may be considerable variation. Some toms may reach puberty as early as six months, while others do not mate until their second spring.

Pubic

Relating to the pubic bone.

Pubic Symphysis Bone

The cartilaginous midline join for the right and left halves of the pelvic pubic bones.

Pubis, Pubic Bone

The pubis is the bone that forms the lower anterior parts of the pelvis. The pubes of right and left sides meet each other at the 'symphysis of the pubes', which in old age is no longer a separable union, bony fusion having taken place.

Public Health

(See MILK; FOOD INSPECTION; ANTIBIOTIC RESISTANCE; and information given under the

main animal diseases communicable to people. See also ZOONOSES.)

Puffer Fish
(See TOADFISH.)

Pug
A small dog with large rounded head, BRACHYCEPHALIC jaw, prominent eyes, smooth coat and tail arched over the back. It is susceptible to LEGG-CALVÉ-PERTHES DISEASE but other inherited defects are not common.

Puli
(See HUNGARIAN PULI.)

'Pullet Disease'
A transmissible enteritis of pullets and turkey poults, first described in the USA in 1951. (See also 'VISCERAL GOUT'.)

Signs Loss of appetite, diarrhoea with watery or whitish evacuations and, sometimes, darkening of the comb. Birds appear drowsy. About 10 per cent die. The cause is a REOVIRUS.

Pullorum Disease of Chicks, Bacillary White Diarrhoea
Pullorum Disease of Chicks (Bacillary White Diarrhoea) has been virtually eradicated in the UK. It is an acute, infectious, and fatal disease of chicks, causing much loss during the first two weeks of life. Adult fowls, especially laying hens, act as carriers and transmit infection through their eggs to the chick before hatching. They may also spread infection in their droppings.

Cause *Salmonella pullorum*, which is found in the ovary and oviduct of carrier hens – birds which themselves contracted the disease when young, but which survived.

Signs Lameness, with swelling of the hocks, is characteristic of chronic pullorum disease.

Prevention This can be achieved by testing all birds, eggs from which are to be used for hatching for the presence of *S. pollorum*. An agglutination test may be used.

Pulmonary
Pertaining to, or relating to, the lungs (but see also PULMONARY STENOSIS).

Pulmonary Adenomatosis, Jaagsiekte
Pulmonary adenomatosis (jaagsiekte) is caused by a retrovirus, often in association with a HERPESVIRUS and is a contagious neoplasm of the lung of adult sheep. First recognised in South Africa, it occurs also in the UK, Iceland, and the USA. In Britain, losses in ewes from Jaagsiekte can be high.

Pulmonary Diseases
(See LUNGS, DISEASES OF.)

Pulmonary Hypertension
This is an important cause of mortality in broilers. The incidence may be reduced by extra vitamin C in the diet.

Pulmonary Oedema
Occurs when fluid builds up in the lungs and is seen in CONGESTIVE HEART FAILURE, when the blood does not pass round the body fast enough. It is often associated with ASCITES, and OEDEMA of the legs and other areas. (See also LUNGS, DISEASES OF.)

Pulmonary Stenosis, Pulmonic Stenosis
A heart disease involving narrowing of the pulmonary valve. It is common in certain dog breeds including BEAGLES, BULLDOGS, CHIHUAHUAS, SAMOYEDS, SCHNAUZERS, SMOOTH-HAIRED FOX TERRIERS, WIRE-HAIRED FOX TERRIERS. (See HEART DISEASES.)

Pulpy Kidney Disease
Pulpy kidney disease attacks lambs between about three and 18 weeks of age, particularly those which are thriving. The disease has been seen in lambs under a week old; its occurrence is widespread.

Cause *Clostridium perfringens* (formerly *C. welchii* type D.

Signs As a rule the affected lambs are found dead without having previously been noticed ailing. Usually the lambs in the best condition are the first to be affected. The loss may be very heavy, especially with the larger earlier maturing breeds. The liver usually shows haemorrhagic spots on its surface.

Prevention It is recommended that immunity be maintained by autumn vaccination, with a second dose of vaccine in the spring, preferably about 10 days before lambing – unless the ewes are to be moved to a better pasture prior to lambing, when the second dose should be given before the move is made. These two doses should protect the ewe through the spring months and allow her to pass to the lamb via the colostrum sufficient antibodies to protect it for the first eight to 12 weeks of life. That temporary immunity in the lamb should be converted to an active one by the use of vaccine.

VetBooks.ir

Pulse, Pulse Rate

The forcing of blood from the heart into the arteries of the systemic circulation causes a pulsation (regular expansion and relaxation) in them. The beating of the heart drives blood out from the left ventricle into an already full aorta, in which it is imprisoned by the closing of the aortic semilunar valves. To accommodate this extra blood the aorta dilates, and the blood already in it moves onwards throughout the vessel, and through the larger branches arising from it. The wave of dilatation also travels along the course taken by the blood, and is therefore distributed along all the larger arterial trunks. If the fingers are placed over any of these latter, which lie near the surface, a periodic thrill or 'pulse' can be felt, occurring at a regular frequency according to the species; in the horse, it is about 35 to 45 times per minute.

The pulse-rate varies according to the state of the animal's health, being faster in fevers, and slower and weaker in debilitating non-febrile diseases; according to the age of the animal (faster in the very young and very old); according to the climate; according to bodily condition; and under other circumstances. During and immediately after exercise it is greatly increased, but in health it subsides rapidly subsequently. During sleep and unconsciousness it is slower.

The normal pulse-rates of the domesticated animals at rest are as follows:

	Per minute
Horse	36 to 42
Ox	45 to 50
Sheep, Pig	70 to 80
Dog	90 to 100
Cat	110 to 120

and of certain other animals as follows:

	Per minute
Elephant	25 to 28
Camel	28 to 32
Buffalo	40 to 45
Reindeer	60 to 65
Mouse	130 to 150

Roughly speaking, the smaller the animal, the faster the pulse. The same principle applies to animals of one species but of different sizes or of different breeds: e.g. the pulse of the Shire stallion is usually about 35 per minute, while that of the Shetland pony is 45 or more. These facts must be taken into account when counting the pulse of any given animal. (See also under HEART.)

Pupil

(See EYE - FRONT OF THE EYE.)

Pupillary Membrane, Persistent

A congenital condition in which a remnant of the membrane covering the lens during its development (tunica vaculosa lentis) persists. It may extend across the iris or from the iris to the cornea. It may produce a corneal opacity at the site of its attachment. If not large it may not severely impair vision. The condition can occur in all species, but is most common in dogs and especially BASENJIS, BULL MASTIFFS, COCKER SPANIELS, DACHSHUNDS (wire haired), HUSKIES, ROTTWEILERS, WEST HIGHLAND WHITE TERRIERS.

Puppies, Newborn, Infection in

(See 'FADING' PUPPY SYNDROME; *Toxocara*.)

Purgation

Evacuation of the bowel following administration of a cathartic medicine. It must be applied, if at all, with moderation. Excessive purgation involves dangers which include potassium depletion.

Purgatives

This is the age of LAXATIVES rather than purgatives. The old drastic purgatives are obsolete; they tended to make the patient's condition worse.

Purine

All living cells contain purine nucleotides such as ADENOSINE and GUANINE occurring in DNA and RNA and also XANTHINE and HYPOXANTHINE. It is metabolised to ALLANTOIN and this is found in the urine of most mammals except man, primates and DALMATIAN DOGS.

Purpura Haemorrhagica

Purpura haemorrhagica often occurs in a horse recovering from a respiratory infection such as influenza or strangles; *Streptococcus equi* is frequently involved. The disease is characterised by oedema of the head and also of the lower parts of the body. There may be kidney lesions.

Signs appear suddenly; often overnight. Swellings, very often the same on each side of the body, are found on the limbs, the breast, the eyelids, and almost always about the muzzle and nostrils. These swellings may be diffuse from the first, or they may begin as isolated circumscribed flat prominences which coalesce in the course of a day or more; when pressed with the point of the thumb, a little pit remains afterwards for some moments. Petechial haemorrhages are present in the nostrils (from which a bloodstained discharge is often seen) and on any mucous membrane.

The horse is dull, loses its appetite, moves stiffly and with difficulty, and if the swellings of the nostril are large, shows rapid and laboured breathing. Swollen lips may prevent a horse from feeding or

VetBooks.ir

drinking; swollen eyelids may hinder or prevent vision; and a swollen sheath in the male may make the act of micturition difficult. The temperature usually remains between 39° C and 40° C (102° F and 104° F); the pulse is soft, feeble, generally rapid, and may be very irregular.

The percentage of recoveries is not large in well-marked cases, and even where death does not occur, complete recovery takes a long time with relapses common. It is said that cases showing nervous complications always end fatally, and the same may be said of those with pneumonia.

Treatment The most careful nursing and feeding are essential in all cases of purpura. (See NURSING OF SICK ANIMALS.) Good results often follow the intravenous injection of an antihistamine.

After apparent recovery the horse must have a long period of convalescence.

Purring

This occurs in domestic cats and in some wild cat species. Its origin has been given different attributions but originates in the brain and probably results in impulses to the laryngeal muscles causing them to twitch at 25 to 150 times per second. On AUSCULTATION, purring can prevent listening to the heart and respiratory system. It can often be stopped by turning on a tap or spraying an ETHANOL-based aerosol on the examination table near the cat.

Purulent

An adjective describing containing, discharging or producing PUS.

Pus

This thick, often yellowish fluid, found in abscesses and sinuses, and on the surfaces of ulcers and inflamed areas where the skin is broken, comprises blood serum, bacteria, white blood cells, and damaged tissue cells. (See ABSCESS; STREPTODORNASE; PHAGOCYTOSIS.)

'Pushing Disease'

A colloquial name for poisoning of cattle by 'Staggers weed' (*Matricaria nigellaefolia*) in South Africa.

Pustule

A small circumscribed elevation of the skin that contains pus in a thin-walled membrane (See ABSCESS). 'Malignant pustule' is the name applied to the form that ANTHRAX most commonly takes when it affects the human being.

Putty

Eating of this can result in lead poisoning. A discarded drum of putty thrown into a field has led to many cattle deaths.

Pyaemia

The presence of pus in the bloodstream.

Pyelitis

Pyelitis means a condition of pus-formation in the kidney which produces pus in the urine. It is due to inflammation of the part called the 'pelvis of the kidney', which is connected with the ureter. The condition is commonest among cows after calving, when infection has reached the bladder, invaded the ureters, and has arrived at the pelvis of the kidney.

Pyelonephritis

This term is used when both the pelvis and much of the rest of the kidney are involved, as described under PYELITIS.

Contagious bovine pyelonephritis is a specific infection of cattle caused by *Corynebacterium renale*, giving rise to inflammation and suppuration in kidneys, ureters and bladder. As a rule, only one cow in a herd is attacked though others may be carriers. The passage of bloodstained urine and abdominal pain are signs. Penicillin is useful in treatment. Otherwise, death may occur (sometimes after several weeks).

In the pig, an infectious pyelonephritis is caused by *C. suis*. It is a common cause of death or culling.

Pygmy Goats

These are genetically dwarfed goats of variable colour, with short legs and a short body which is cobby and looks as if pregnant. These are usually used as companion animals. Some are derived from African stock. The maximum withers height of bucks is about 56 cm (22.5 in) with the does being shorter. They are sociable animals and so should not be kept singly.

Pygmy Goat Syndrome

Pygmy goats are frequently seen with non-pruritic crusty lesions, thickening of the skin, particularly but not solely around the eyes, head, axillae and the perineal regions. The disease is familial, although the aetiology is not proven. Long-acting CORTICOSTEROIDS will control, but not cure, the syndrome.

Pygostyle

The termination of the caudal vertebrae of birds. It consists of four to ten fused vertebrae to which the inner RECTRICES (tail flight feathers) attach. It also supports the UROPYGIAL GLAND.

Pyloric Stenosis

A rare congenital defect in the dog. Only liquid food can pass into the stomach. Projectile vomiting is a sign. The defect can be corrected by surgery. (See PYLORUS.)

VetBooks.ir

Pylorospasm
Pylorospasm means spasm of the pyloric portion of the stomach. This interferes with the passage of food in a normal, gentle fashion into the intestine, and causes distress from half an hour to three hours after feeding. It is associated with severe disorders of digestion.

Pylorus
Pylorus is the name of the lower opening of the true stomach. Exit of food from the stomach is controlled by a strong ring of muscular tissue called the 'sphincter of the pylorus', which opens under nervous activity and allows escape of small amounts of partly digested food material into the small intestine. (See STOMACH; DIGESTION, ABSORPTION AND ASSIMILATION.)

Pyo-
Pyo- is a prefix attached to the names of various diseases to indicate the presence of pus or the formation of abscesses.

Pyoderma
The term is used in dogs to denote bacterial infection of the skin ('superficial pyoderma'). As this may be secondary to another skin disease, it is important to rule out predisposing conditions such as allergies, parasites and nutritional deficiencies.

Pyogenic
Pyogenic is a term applied to those bacteria which cause the formation of pus, and so lead to the production of abscesses.

Pyometra
A collection of pus in the uterus: a condition not uncommon in maiden bitches, and occurring in all species. (See UTERUS, DISEASES OF.)

Pyorrhoea
Inflammation of the gums, in which suppuration is produced and ultimately interference with the integrity of the teeth. It is a common condition in aged dogs and cats. (See TARTAR.)

Pyosalpinx
Distension of a Fallopian tube with pus.

Pyothorax
The presence of pus within the chest. It may be a sequel to pneumonia, or to a penetrating wound of the chest, perhaps a bite. This is a fairly common condition in the cat, which is likely to rest on its brisket, be disinclined to move, and to have laboured breathing. Cyanosis may be present. Tenderness of the chest is another sign. The temperature may be 37° C (98.6° F). In many cases the condition develops very rapidly in the cat, death occurring before treatment has been obtained. Treatment involves aspiration of the pus, and the introduction of an antibiotic. In cats, however, the mortality despite treatment may be 50 per cent. In dogs various ANAEROBIC bacteria usually are present. Treatment is with ANTIBIOTICS but often surgery is required.

Pyramidal Disease
An exostosis affecting the pyramidal process (extensor process) of the 3rd phalanx of the horse's foot. It is usually found in association with low ringbone. (See RING-BONES.)

Pyrantel
An ANTHELMINTIC related to levamisole, used in dogs, cats and equines.

Pyrenean Mountain Dog
One of the largest breeds of dog, powerfully built with a thick, usually white, coat. HAEMOPHILIA (Factor XI deficiency) may be inherited and the breed is disposed to OSTEOCHONDRITIS DISSECANS and HIP DYSPLASIA.

Pyrethroids
Synthetic equivalents of some of the active principles of pyrethrum flowers are useful and potent insecticides.

Commercial preparations are widely available (See FLIES - FLY CONTROL FOR HORSES AND LIVESTOCK.)

Pyrexia
(See FEVER.)

Pyridine
Pyridine is an alkaloidal substance derived from coal-tar, tobacco, etc. It is added to methylated spirit in order to render this unpleasant to drink.

Pyridoxine
Vitamin B6.

Pyrimidine
An organic compound made up of pyrimidine bases such as CYTOSINE, THYMINE and URACIL.

Pyriprole
An ectoparasiticide for use in dogs (particularly small dogs). It kills fleas within 24 hours of application and ticks within 48 hours. Such treatments are becoming more important with the increase in numbers of animals visiting mainland Europe on a temporary basis.

VetBooks.ir

Pyriproxyfen
This is used as a spot-on treatment for long-term flea control in dogs and cats. On contact, blocks the development of eggs and larvae. Ingestion of the product sterilises the eggs within an adult flea.

Pyrrolizidine Alkaloids
These cause poisoning in animals which have eaten ragwort. (See RAGWORT POISONING.)

Pyruvate
Derived from pyruvic acid, it has an important function in many biochemical pathways. It can be produced from GLUCOSE by glycolysis and then it can be converted back to carbohydrates by GLUCONEOGENESIS or to fatty acids with ACETYL COENZYME-A. It can be made into the amino acid ALANINE.

Pyruvate Dehydrogenase Phosphatase
A part of the pyruvate dehydrogenase complex which is concerned with linking glycolysis with the KREB'S CYCLE; it converts PYRUVATE to ACETYL COENZYME-A.

Pyruvate Dehydrogenase Phosphatase Deficiency
A defect seen in CLUMBER SPANIELS, SUSSEX SPANIELS (DNA test available) and resulting in lactic ACIDOSIS.

Pyruvate Kinase Deficiency
A condition seen in humans, ABYSSINIAN CATS and also BASENJI, BEAGLE, CAIRN TERRIER, CHIHUAHUA, DACHSHUND, GERMAN SHEPHERD DOG and WEST HIGHLAND WHITE TERRIER breeds, and in each there is a DNA test to detect it. It is seen as non-spheroidal erythrocyte ANAEMIA. It is also seen in SOMALI CATS (DNA test available).

Pyruvic Acid
An organic acid which is an intermediate product in carbohydrate and protein metabolism. Excessive quantities accumulate in the bloodstream in cases of vitamin Bl deficiency.

Pyuria
Pus in the urine produced by suppuration in some part of the urinary tract. (See URINE.)

VetBooks.ir

Q

QDP
(See QUICKLY DEGRADABLE PROTEIN.)

Q Fever
A disease first recognised in Australia in 1935, and now known to have a worldwide distribution. The 'Q' stands for Query fever or Queensland fever. Q fever is an infection of most animal species including man, cattle, sheep, goats, fowls and rodents.

Cause A rickettsia, *Coxiella burnetii*, which is resistant to heat and drying, and can be transmitted by ticks. Human infection can be acquired from these, from inhalation, and from drinking unpasteurised, infected milk; as well as from handling or coming into contact with the fetal membranes, faeces or urine of infected animals.

Signs In farm animals, many Q fever infections may be present without obvious signs. However, the rickettsia is a cause of abortion, and less often of pneumonia. Infection persists in warm dry conditions.

Incidence In the UK a preliminary survey showed that 2,581 farms in England, 553 in Wales, and 240 in Scotland were infected. It has been found possible to isolate the parasite from 13,600-litre (3,000-gallon) milk tankers (pasteurisation removes the infection).

In a survey, sera from cattle and sheep in the northeast of Scotland were tested for antibodies to *C. burnetii*. Approximately 1 per cent of 4,880 cattle had antibodies to the organism. These potentially infected cattle were distributed throughout the area. Two flocks of sheep were tested; in one flock, 30 per cent of sheep had antibodies, while the other was negative. The flock with the high prevalence of *C. burnetii* antibodies appeared to be associated with an outbreak of human Q fever on that farm. In the Netherlands a severe outbreak of Q fever began in goats in 2007 and persisted at low levels in 2011. It has been a major problem in large indoor goat herds, resulting in widespread vaccination and slaughter of goats. Over 4,000 human cases and several deaths (11 in 2010) have occurred; usually in patients that also had other problems.

Treatment Most antibiotics are rickettsiostatic rather than rickettsiocidal; tetracycline has been used effectively. However, the organism can remain dormant for long periods inside the host's body cells.

Vaccination has been used in Europe and will reduce the incidence of disease, but it will not prevent infected female animals from shedding organisms at each parturition.

Public health In humans, Q fever is primarily an infection of those working with animals. Risk of infection is greatest at the time of the animals giving birth. The organism survives for several months in warm, dusty conditions where it attaches to dust particles and is distributed with them. Thus people living in houses near densely-stocked animal buildings may become infected. Manure removal is also a source of infection. Acute Q fever may involve the liver and heart (with resultant myocarditis). Mild cases may resemble food poisoning or influenza, with headaches. Chronic Q fever occurs and can arise two to five years after exposure. In the Netherlands it has been found vaccination of previously infected people can result in problems.

Q fever in snakes Many snakes imported into the USA are infested with ticks, which transmitted Q fever to dockside workers handling a shipment of Ball pythons.

Q fever from contaminated clothing This was the presumed cause of 16 out of 32 employees at a truck-repair plant becoming ill with the disease. Serological tests on a cat were positive for *C. burnetii*. The cat was fed at home by one of the workers at the plant.

QMS
(See QUALITY MEAT SCOTLAND.)

Quadriceps
Quadriceps means having four heads, and is the collective name applied to the powerful muscles situated above the stifle-joint. These are medial and lateral vasti, and the rectus femoris; the fourth muscle (vastus intermedius) in the horse combined with the medial vastus. It is a useful muscle for giving intramuscular injections in rabbits and large rodents.

Quadriplegia
(adjective, Quadriplegic)
Paralysis of all four limbs. It is also called TETRAPLEGIA. It results from a spinal cord injury or lesion in the cervical region; it can be progressive or sudden in onset, depending on the nature of the lesion and cause. Most cases are due to trauma but some are inherited. In dog breeds it is common in IRISH SETTERS. (See PARALYSIS; TICK PARALYSIS; RACCOONS; CURARE.)

VetBooks.ir

Quail
Small, rapidly-maturing game birds included as poultry in British legislation. Females start to lay eggs at five to six weeks of age; the first eggs laid are usually infertile, but thereafter high fertility can be obtained. Males are sexually active at five weeks. The nutritional requirements of quail are usually met by basic turkey starter diets. Among the diseases they may suffer are: BOTULISM, LYMPHOID LEUKOSIS, MAREK'S DISEASE, NEWCASTLE DISEASE, pasteurellosis, MYCOPLASMOSIS, SALMONELLOSIS, QUAIL DISEASE (ulcerative enteritis), quail bronchitis and COCCIDIOSIS.

Quail Bronchitis
A highly contagious infection caused by an adenovirus. Signs appear in all susceptible birds in a flock within three to seven days of infection having been spotted in individuals. Clinical signs are very severe respiratory distress with 100 per cent morbidity and mortality from 10 per cent to 100 per cent.

Quail Disease, Ulcerative enteritis of quail
A severe bacterial infection caused by *Corynebacterium perdicum*. Birds may die suddenly without showing clinical signs; these birds are usually in good condition with feed in their crop. Birds less acutely affected are listless, huddling with eyes partly closed and with ruffled feathers. Emaciation develops within a week. Survivors become immune. Streptomycin, chloromycetin and bacitracin have been used in treatment. Effective control of other diseases will help to reduce the severity of quail disease.

Q

Quality Meat Scotland (QMS)
The organisation responsible for the development, promotion and marketing of red meat (beef, lamb, pork) in Scotland. It is supported by a levy on all animals killed for meat. It evolved from the MEAT AND LIVESTOCK COMMISSION and is the equivalent of EBLEX and HCC. (See also ENGLISH BEEF AND LAMB EXECUTIVE; HYBU CIG CYMRU.)

Quarantine
The imposition of measures for preventing the spread of infectious disease by which an animal or animals, which have come from potentially infected countries or areas, are kept separate from indigenous animals until their disease-free status is confirmed (or otherwise).

The regulations dealing with quarantine of animals are altered from time to time, and so information on the matter is best obtained direct from the government department that deals with livestock in a particular country.

The length of quarantine depends on the disease whose entry is being prevented. For rabies it is six months (except in the case of dogs and cats from specified countries, for which new regulations apply); for foot-and-mouth and Newcastle disease it is 30 to 35 days. It is a sensible precaution that new stock introduced to farms, zoos, etc. should be kept separate until it is certain that they have not brought in new diseases or virulent strains, even if this is not required by law.

(See RABIES; IMPORTING/EXPORTING ANIMALS; NOTIFIABLE DISEASES; PET TRAVEL SCHEME; PIGEONS.)

Quarter Horse
(See AMERICAN QUARTER HORSE.)

Quaternary Ammonium Compounds
Quaternary ammonium compounds are used as antiseptics, and have found widespread application in dairy hygiene. Cetrimide (cetyl trimethyl ammonium bromide) is an example. It is used in 0.1 per cent solution for washing cows' udders, teats, and milkers' hands, being effective against *Streptococcus agalactiae*. In higher concentrations it acts as a detergent. Such compounds are readily neutralised by organic matter and should only be used on visibly clean surfaces. (See also CETRIMIDE; HIBITANE.)

Queen
A female cat.

Queensland Itch
This is caused by sensitisation to bites of the midge *Culicoides robertsi*. The lesions resemble those of mange or eczema, and are seen usually along the animal's back. Antihistamines are useful in treatment. The condition is regarded as an allergic dermatitis, and is similar to 'sweet itch'. (See under FLIES.)

Quey
A heifer.

Quickly Degradable Protein (QDP)
A term used in ruminant nutrition to denote protein which is quickly degraded to ammonia and urea in the rumen. This can be converted into amino acids provided there are sufficient available energy substrates. If there is inadequate energy, blood urea levels are likely to rise. Grass and grass products (especially silage and haylage) are high in QDP.

Quidding, Cudding
Quidding (cudding) is the name given to that condition in horses, depending upon injuries to

VetBooks.ir

the mouth or diseases of the teeth, in which food is taken into the mouth, chewed repeatedly, and then expelled on to the floor of the stall or into the manger. It may result from the teeth being too sharp, irregular in height, uneven in alignment, or from permanent teeth pushing the temporaries out from the gums; it may also arise when the gums, cheeks, or tongue have been injured or are diseased. Paralysis of the throat, or some other condition which causes inability to swallow, can cause quidding. Some other animals may display the habit. (See MOUTH, DISEASES OF; TEETH, DISEASES OF.)

A similar sign is seen in cage-birds in MEGABACTERIOSIS or AVIAN GASTRIC YEAST infection. Birds that normally dehusk seed and swallow the kernel are seen to drop the kernel without swallowing. (See *Macrorhabdus ornithogaster*.)

Quinapyramine

An aminoquinaldine derivative used to treat toxoplasmosis in camels, cattle, cats, dogs, goats, horses, pigs and sheep. Usually, the sulphate form is used as an injection. It should not be used in animals with impaired renal or hepatic function. The side effects in cattle can occur within two hours of administration and can include dyspnoea, incoordination, salivation, sweating, tachycardia and tremors.

Quinine

An alkaloid obtained from the bark of various species of cinchona trees in South America. The bark contains four alkaloids, of which quinine is the most active and important, the others being quinidine, cinchonine and cinchonidine.

Quinine is usually used in the form of one of its salts, i.e. sulphate, hydrochloride, or hydrobromate of quinine.

Action Quinine causes a lowering of temperature in fevers. In man, it is used for the relief of malaria.

Uses These have dwindled. Before the advent of the sulfa drugs and antibiotics it was much used in influenza, distemper, and similar conditions. It is sometimes given as an intramuscular injection. Owing to its very bitter taste it is seldom that it will be taken in the food.

Toxicity The dog is very susceptible to quinine and may become blind at plasma concentrations readily tolerated by man.

Quinolones

A group of antibiotics with a wide spectrum of activity against Gram-positive and Gram-negative organisms and mycoplasmata. They can be identified by the suffix, –floxacin, in their names. Given orally or by injection, they are useful in treating farm and companion animals and birds as well as some of the more exotic species kept as pets.

Quittor

Quittor is a condition of the 'lateral' cartilages of the horse's foot, in which suppuration occurs, with pus escaping from an opening in the region of the coronet. This, and the bulbs of the heels, are swollen and painful. The cause is an injury to the cartilage or to infection, or both. There is usually some degree of lameness. Antibiotics are used in treatment.

R

3Rs
The term used to aid and improve the use of animals in scientific research where no alternatives exist. Reduction, replacement and refinement has been used as a concept in the UK since first described by W. M. S. Russell and R. L. Burch in 1959 in 'The Principles of Humane Experimental Technique', Methuen, London ISBN 0900767782. (See also LABORATORY ANIMALS.)

Rabbit Epizootic Enterocolitis (REE)
(See EPIZOOTIC RABBIT ENTERITIS.)

Rabbit Fur Mite
This may be picked up by dogs and rabbit-keepers, and cause intense irritation. (See CHEYLETIELLOSIS.)

Rabbit Haemorrhagic Disease, Viral Haemorrhagic Disease
Rabbit haemorrhagic disease is widespread throughout the UK and the rest of Europe. The disease, caused by a calicivirus, originated in China and may have been imported into Europe in rabbit meat. Cases are not known in rabbits under four months, at which age liver metabolism changes. This makes it a serious problem for breeders when a doe dies, leaving an orphan litter. Clinical signs are often transient: difficulty in breathing, or a short squeal followed immediately by the rabbit falling over, is often accompanied by sudden death. Animals surviving the acute stage develop jaundice and die after a few weeks. Haemorrhage from the nostrils and/or anus may be seen. Prevention is by vaccination; a combined vaccine with MYXOMATOSIS is available. Deliberate introduction of the disease has been tried as a means of limiting wild rabbit populations, e.g. in Australia.

Rabbit Rings
The British Rabbit Council issues 100,000 metal rings each year in the UK to members to use in identifying rabbits, but advises that the rings should be removed from rabbits sold or given away as pets. 'Injury can occur if bedding material becomes trapped between ring and leg,' or if the ring has become – with the rabbit's growth – too tight, with the risk of causing necrosis. Should that occur, surgical intervention or euthanasia will be needed.

Rabbits
These are members of the Order *Lagomorpha*, and are known as lagomorphs. Most domestic pets are the European rabbit (*Oryctolagus cuniculus*). Males are called bucks, females are does and the young are kittens or kits. Breeds of domesticated rabbits used for table purposes include the New Zealand white, the California, and the Dutch rabbit. (See also PETS, CHILDREN'S AND EXOTIC.) Rabbits are FIBREVORES and their feed should consist of good quality hay and grass given ad libitum, and small amounts of fresh greens and concentrated feed. Healthy treats like carrots and apples should be fed no more than twice a week. Rabbits can develop OBESITY mainly from poor diet and lack of exercise as well as age, sex and neutered status. They practise COPROPHAGY. Overgrown claws, dental problems, diarrhoea and URINE SCALD are common.

Handling Rabbits are flighty creatures tending to react to the slightest stimulus by attempting to escape. They may try and leap from a smooth surface (such as a table top) on which their claws cannot obtain purchase. They thus should be restrained on a rough surface such as secure sacking or carpet. When lifting a rabbit, a fold of skin over the shoulder should be grasped with one hand, while the palm of the other hand supports the rump. A rabbit should not be lifted by its ears. Struggling while being inexpertly handled can lead to fractures of limbs. A startled rabbit may leap and fracture the spine.

Diseases include APPENDICITIS; ATROPHIC RHINITIS; COCCIDIOSIS; ENCEPHALITOZOON CUNICULI; HYDROMETRA (the accumulation of watery fluid in the uterus); IMPACTION of colon or stomach (often the result of insufficient hay being provided); JOHNE'S DISEASE; LISTERIOSIS; MAGGOTS IN RABBITS; MASTITIS; METRITIS; MYXOMATOSIS, INFECTIOUS; PASTEURELLOSIS IN RABBITS; PNEUMONIA; RABBIT HAEMORRHAGIC DISEASE; 'RABBIT SYPHILIS'; SALMONELLOSIS; SCHMORL'S DISEASE; 'SORE HOCKS' (PODODERMATITIS); TOXOPLASMOSIS; TUBERCULOSIS; TYZZER'S DISEASE; YERSINIOSIS.

Pasteurella multocida causes a pneumonia which may be acute and fatal in rabbits under 12 weeks old. It may cause also middle-ear disease with a loss of balance, circling, and head held to one side, epiphora, and also 'snuffles' in which there is a discharge from eyes and nose and sneezing.

Rabbits act as hosts of the liver-fluke of sheep, and of the cystic stages of some tapeworms, e.g. *Taenia pisiformis*, *T. serialis*.

Rabbits have been used experimentally as incubators for sheep's eggs.

VetBooks.ir

A hermaphrodite rabbit served several females and sired more than 250 young of both sexes. In the next breeding season the rabbit, which was housed in isolation, became pregnant and delivered seven healthy young of both sexes.

Pregnancy diagnosis An ELISA test is available for this purpose. It can also differentiate between pseudo-pregnancy and pregnancy, and detect rabbits about to ovulate.

Anaesthesia A wide range of anaesthetics is suitable for use in rabbits. Halothane and other inhalation anaesthetics are suitable and convenient to administer. Premedication with atropine (50 micrograms per kg by hypodermic or intramuscular injection) or acepromazine (1 mg per kg intramuscularly) is advisable half an hour earlier. Alfaxalone/alfadolone is one of several injectable anaesthetics recommended for surgery. Oxygen should be ready to hand.

The Veterinary Formulary, published by the BVA/Royal Pharmaceutical Society, gives comprehensive details of anaesthetics and analgesics suitable for rabbits and small rodents.

'Rabbit Syphilis'

'Rabbit syphilis' is caused by a spirochaete, *Treponema cuniculi* (which does not affect humans). It is a venereal disease characterised by the appearance of nodules and superficial ulcers covered with thin, moist, scaly crusts and oedematous swellings of the surrounding tissues mainly in the region of the genitalia (hence the colloquial name, 'vent disease') and also sometimes in the region of the nose. The specific diagnostic is by the Silver Warthy Test, but generally response of the disease to parenteral PENICILLIN is regarded as diagnostic.

Rabbit Welfare Association and Fund

Address: PO Box 603, Horsham, West Sussex, RH13 SW1. Telephone: 0844 324 6090; helpline: 0870 046 5249; website: www.rabbitwelfare.co.uk

Rabies

The Latin word for madness (also known as HYDROPHOBIA), it is a specific inoculable CONTAGIOUS disease of virtually all mammals, including man; and occasionally it occurs in birds, e.g. domestic poultry and vultures. It is characterised by nervous derangement, often by a change in temperament, with paralysis occurring in the final – and sometimes in the intermediate – stages.

Foxes and cattle are both highly susceptible to infection.

Rabies occurs in all continents with the exception of Australasia and Antarctica. In Turkey, dogs remain the principal vectors; in a few countries in Europe cats attack more people than do dogs. In Asia and South America dogs are still the most important vectors, but in many countries wild animals provide a reservoir of infection, and infect dogs and cats and farm animals – which in turn may infect man, who is an incidental host of the disease. (See table of vectors.)

Rabies in wild animals – principal vectors in various regions	
Foxes, roe-deer, badgers, martens	Europe
Wolves, jackals, bats, mongooses	Asia
Foxes, skunks, coyotes, bats	North America
Bats	Central America South America and Trinidad

Public health Rabies is virtually always fatal in the human being, and there is danger not only from being bitten by rabid animals, but also from contamination by their saliva of wounds, cut fingers, eyes, etc. Scratches may convey infection as well as bites.

People have died from rabies following attacks by rabid dogs, cats, foxes, wolves, badgers, skunks, racoons, mongooses, bats, rodents, etc.

Pet animals, such as rabbits, may be bitten by rabid animals and themselves become rabid; and it has sometimes happened that wild or exotic animals (originating in countries where rabies is endemic) were bought as pets while in the incubation stage of rabies, with unfortunate results.

In the UK as in most other countries, rabies is a NOTIFIABLE DISEASE, and must be reported to DEFRA or to the police. Bitten persons should seek medical advice immediately.

Cause A Lyssa virus (one of the Rhabdovirus group). When it is injected into the tissues, either naturally (from a bite) or artificially, the virus passes along the nerves and reaches the central nervous system. The time elapsing between infection and onset of signs varies greatly with the location of the bite, its severity, and – no doubt – the quantity of virus in the saliva. In the most rapidly developing cases the signs may be shown as early as the ninth day after being bitten, and at the other extreme, cases have appeared several months after the incident. It is owing to this fact that the six-months period of quarantine insisted upon in Britain is something of a compromise. The average incubation periods in dogs, sheep, and swine are from 15 to 60 days; in horses and cattle, from 30

VetBooks.ir

to 80 days. In young animals the period of incubation is shorter than in adults. In 2011, a new strain (a divergent novel Lyssa avirus) was found in an African civet (*Civettictis civetta*) in Tanzania, possibly originating from bats.

Signs

Dog There are two distinct forms of rabies in the dog – the 'furious' and the 'dumb'; but these are in reality two stages only. It is customary to consider three stages of typical signs.

1. Melancholy. The prodromal dull stage is often not noticed, or, if it is, only scant attention is paid to it. The habits of the dog change. It becomes morose and sulky, indifferent to authority, disregards its usual playthings or companions, shows a tendency to hide in dark corners, and may appear itchy or irritable as regards its skin. Noisy, boisterous animals become quiet and dull, while animals that are normally of a gentle, quiet disposition may become excitable. After two or three days of such behaviour the next stage is reached.
2. Excitement. The signs described above become exaggerated, and there is a tendency towards violence. The dog pays no attention to either cajoling or threatening. It becomes easily excited and very uncertain in its behaviour. Food is either disregarded completely or eaten with haste. Vomiting is a not uncommon sign. A fear of water is **not** a sign to expect in the rabid dog, which will often drink or attempt to do so even when partly paralysed. After a time the appetite becomes deranged. The dog refuses its ordinary food, but eats straw, stones, wood, coal, carpet, pieces of sacking, etc., with great avidity. If the animal is shut up in a kennel, it persists continually in its efforts to escape. Should it be released or should it escape, it almost invariably runs away from home. It may wander for long distances. In its travels it bites and snaps at objects which it encounters, real or imaginary, animate or inanimate. Some rabid dogs bite several people. The tone of voice is altered.
   The face has a vacant stare, the eyes are fixed and expressionless, and the pupils are dilated. This stage lasts from two to four days, unless the dog's strength gives out sooner, and the next stage appears.
3. Paralysis. The characteristics of the last stage in the train of signs of rabies are those of paralysis, especially of the lower jaw and the hindquarters. The dog begins to stagger in its gait, and finally falls. It may manage to regain its feet when stimulated, but soon falls again. The lower jaw drops, the tongue lolls out of the mouth, and there is great salivation. The muscles of the throat and larynx are soon involved in the progressive paralysis.

The dumb form of rabies consists of this paralytic stage – the stage of excitation having been omitted. The dumb form is the more common in the dog: barking ceases – hence the name. Vomiting may suggest merely a digestive upset. Protrusion of the nictitating membrane partly across the eye, together with a dropped jaw, i.e. partly opened mouth which can be closed by gently raising the lower jaw by means of a stick, are highly suggestive of rabies.

In parts of Africa and Asia, the classical form of rabies in dogs (described above) is replaced by a form called (in Africa) 'OULOU FATO'.

Cat In this animal the furious form is more common than in the dog. The aggressive stage is most marked, the cat attacking other animals and man with great vigour, and attempting to injure their faces with teeth or claws. Sometimes the rabid cat will at first show extra affection. The course of the disease is usually shorter than in the dog.

Occasionally dogs and cats die from rabies without any observed signs. They may be found dead or dying. It is not unknown for a cat to be found lying in a field or garden unable to walk but still able to bite.

Cattle These animals are usually affected through having been bitten by a rabid fox or dog. The stage of excitement is short and the dumb stage most evident. Affected cattle behave in an unusual manner; they may stamp or bellow, salivate from the mouth, break loose, and may do much damage. Rumination and milk production cease, muscular quiverings are seen, sexual excitement is noticed, and there is a great loss of condition. Exhaustion soon follows and paralysis sets in. Death occurs within two to six days or more after the commencement of the condition.

Rabies may be mistaken for hypomagnesaemia, milk fever, botulism, anaplasmosis, listeriosis, lead poisoning, choking, etc.

In Central and South America, cattle are infected with rabies by vampire bats, and may show long streaks of blood on their shoulders, necks and backs.

Sheep, goats and swine The sheep and the goat are affected in a manner similar to cattle, but the stage of excitement is shorter or absent, and the dumb paralytic stage is more often noticed. Pigs become excitable; they may squeal and show muscular spasms before paralysis ensues.

Horse The furious form is common but the animal may appear calm between bouts of aggressiveness. Dumb forms also occur and may be mistaken for colic, paresis or encephalitis from other causes. Signs

VetBooks.ir

may include a facial twitch, biting of woodwork or self-mutilation, head-tossing, frequent whinnying, abnormal posture, apparent lameness, ataxia and paralysis of hindquarters. The horse may continue to eat and drink until shortly before death. The tone of voice may be altered.

Diagnosis The routine examination for Negri bodies has now in most countries been superseded by the fluorescent antibody test, with confirmation by mouse inoculation if necessary. (If a dog which bit someone is still alive after 10 days, it **cannot** be assumed that the dog is not rabid.)

Differentiation between laboratory and street rabies virus, between rabies vaccine virus and street virus, and between rabies virus and rabies-like viruses (e.g. Mokola, Lagos bat, and Duvenhage viruses) is possible by laboratory tests based on differentiation of monoclonal antibodies.

Prevention Prevention of the disease in man and animals stems from the research of Louis Pasteur in the 1880s. He discovered the process of attenuation, by which the virulence of a micro-organism is reduced but not its ability to produce antibodies against disease. Pasteur achieved this by infecting rabbits with rabies from a dog. Although this was fatal to the rabbits, dogs survived infection with the rabbit virus. Tissue from the spinal cord of an infected rabbit was then used to prepare a vaccine. His triumph came in 1885 when the vaccine saved the lives of two badly bitten boys.

In the intervening years many modifications have been made, and new techniques developed, to make rabies vaccines which would be safe and free from dangerous side-effects, and so could be used to immunise people and animals against rabies ('pre-exposure' – vaccination), as well as provide 'post-exposure' treatment of those bitten by rabid animals.

The table shows examples of vaccines prepared from tissue culture cells. The last one, the Merieux, was developed by the Merieux Institute of France using a technique pioneered at the Wistar Institute of Philadelphia. Only 1 ml doses are required, and two injections (apart from any booster doses). (See also VERO CELLS.)

In the UK, two vaccines approved for use in dogs and cats: Rabisin rabies vaccine (Merial) containing inactivated GS-57 Wistar virus strain; and Nobivac Rabies (Intervet) prepared from virus grown on cell-line tissue culture.

Mass vaccination of dogs is carried out in many countries as a control measure; and in Central and South America, cattle on ranches are vaccinated against vampire-bat-transmitted rabies. In France and other countries of Europe, hundreds of thousands of cattle are vaccinated against rabies (often a combined rabies/foot-and-mouth disease inoculation).

It must be remembered, however, that no vaccines are 100 per cent effective, that certificates of vaccination can be forged, and that consequently it is still essential to control the import of animals, whether vaccinated or not, and to enforce quarantine measures where appropriate.

Control of rabies in Britain The last case acquired by a dog living in Britain was in 1902. From 1902 until 1918, no cases occurred in the British Isles; but in that year infected dogs were smuggled from the Continent, and the disease obtained a fresh hold for a period of little more than three years. The last case in Northern Ireland was in 1920. Britain had been free since then, but in 1969 a dog released from quarantine 10 days earlier showed signs of rabies and bit two people at Camberley, Surrey; a second case occurred in 1970. In 1965 there was a case in a recently imported leopard in quarantine at Edinburgh Zoo. In Britain, in 1969, the danger of allowing the importation of rabies-susceptible exotic animals, for sale as pets or for research, was officially recognised, and the quarantine regulations amended to include monkeys, mongooses, etc.

Following strong pressure to replace quarantine for pet dogs with a vaccination/identification policy, a government committee was set up in 1997 to examine the issue. The committee recommended that a strict scheme of medical examination, rabies vaccination and veterinary certification should replace the compulsory quarantine regulations for dogs and cats. The recommendation was accepted and an arrangement introduced in 2000 under which dogs and cats may travel to and from the UK and specified countries without quarantine under the PET TRAVEL SCHEME. (See also IMPORTING/EXPORTING ANIMALS.)

Examples of rabies vaccines prepared from tissue culture cells		
Live virus:	Cells used:	
ERA	Pig kidney	Cats, dogs, cattle and other animals
HEP-Flury	Dog kidney	Cats, dogs, and cattle
Inactivated:		
Fixed	Hamster kidney	Cats, dogs, cattle and other animals
	Hamster embryo	Cats, dogs, horses, cattle and sheep

VetBooks.ir

Other points to note (1) the saliva is sometimes infective before signs of rabies appear – a hazard for a person licked; (2) farmers have died through mistaking rabies for 'choking' and, with abraded fingers, examining their cow's mouths; (3) non-typical cases of rabies are not uncommon; (4) a dog may bite a small child or household pet and promptly run away – rabies not being suspected, though running away is in itself a canine sign; (5) the virus may be present in semen, as well as in milk, tears, faeces, and urine; and (6) subclinical rabies, and a 'carrier' state, have long been recognised in Africa (see 'OULOU FATO') and in Asia.

Vaccination of foxes has been an outstanding success in controlling the disease in Western Europe. Currently Britain, Andorra, Ireland, Italy, Netherlands, Norway, Sweden, Denmark, Greece, Spain and Portugal are all rabies-free. There are still black spots in Germany, while there are enzootic areas in Poland and Turkey. The oral vaccine is genetically engineered on vaccinia virus so that the antigen to rabies is absorbed from the intestine. The vaccine is put into fish-flavoured capsules scattered from helicopters. In the areas so treated, up to 93 per cent of foxes, stoats, weasels, polecats and badgers caught and blood-sampled have been found to have taken up the vaccine.

Rabies (Control) Order 1974

This, plus amendments, gives powers to deal with an outbreak of rabies outside quarantine premises. In a declared infected area, an order may be made for the destruction of foxes and other wild mammals, and for access to land for this purpose. Fences or other types of barrier may be erected to restrict movement of animals into or out of an area while such destruction is in progress.

Orders may be made for compulsory vaccination, confinement, and control of domestic animals, including strays. Anyone knowing or suspecting that an animal has rabies must notify that suspicion to the police. Deaths of animals in an infected area must also be notified, and the authorities can take over ownership of carcases and determine the means of their disposal. This is because it is essential to confirm a diagnosis of rabies, so that precautions can be taken concerning in-contact animals and human beings. The order can override a dog-owner's reluctance or refusal to part with the body of a dead pet or working dog.

The Rabies (Importation of Dogs, Cats and Other Mammals) Order 1974 prohibited the landing of susceptible mammals in Britain unless from Ireland, Isle of Man, or the Channel Islands. Any animal brought in from elsewhere has to undergo a period of quarantine (but see PET TRAVEL SCHEME). Imported animals are vaccinated while in quarantine as a precaution against a quarantined animal developing the disease. Those animals not a threat to human health (ruminants, pigs and horses) do not go into quarantine for rabies but may be quarantined for other diseases. Control under the Order is exercised on the transport of imported susceptible animals within Britain.

If an animal is landed at a port or airport not authorised to receive such animals, that constitutes an illegal landing even if the circumstances are outside anyone's control (e.g. if an airport is fogbound).

Under a 1984 amendment order (and subsequent amendments), animals which have not been in contact with another animal (e.g. have been on an oil rig) are permitted to be landed in Britain. A similar relaxation applies to animals belonging to the police, HMRC and HM Forces, if the animal has been abroad but under the constant control of a trained handler while outside Britain. Within Europe it is now possible with suitable vaccination and paperwork to move animals relatively freely between the various Member States. (See also PET TRAVEL SCHEME (PETS).)

Rabies-Related Viruses

These include *Duvenhage virus*, the cause in fruit-eating bats of a disease very similar to rabies; the *Mokola virus*, which has been isolated from shrews, and causes nervous symptoms in man; the *Lagos bat virus*; the *Nigerian horse virus* and *Lyssa virus*.

Raccoons

Raccoons are, in Canada and the USA, among the wildlife creatures which sometimes transmit RABIES and BAYLISASCARIOSIS.

A dog bitten by a (non-rabid) raccoon may become paralysed in all four limbs (quadriplegia).

Racehorses

Every year thoroughbred mares go to stud in the UK. About 67 per cent of them foal successfully, and for every 1,000 mares covered, 340 or so of the resulting progeny finally appear on the racecourse. Provided they are sound and of an even temperament. The number of foals born in Great Britain in 2009 was 5,595 and in Ireland (including Northern Ireland) there were 17,000. There are about 16,000 horses in training in Great Britain under Jockey Club rules. Fewer than 5 per cent of horses in training are imported into Great Britain, other than from Ireland.

An epidemiological study of wastage among racehorses has been conducted among six stables, five of which were in Newmarket. The basis of the survey was the inability of horses to take part in cantering exercise as a result of injury or disease. The greatest number of days lost to training was

VetBooks.ir

caused by lameness (67.5 per cent) and respiratory problems (20.5 per cent). Conditions of the foot (19 per cent), muscle (18 per cent), carpus (14 per cent), fetlock joints (14 per cent), tendons (10 per cent) and sore shins (9 per cent) were the major reasons for training days being lost in 198 cases in which a positive diagnosis of the site of lameness was made.

Pulmonary haemorrhage In horses which show blood at their nostrils after exercise or racing, the blood does not come from the nasal cavity but from the lungs. Endoscopic examination revealed that many more horses show haemorrhage (42 per cent) than showed blood in the nostrils (15 per cent). Affected horses might appear distressed, with dilated pupils.

(See HORSES; EXERCISING HORSES; etc.)

Rachitis

(See RICKETS.)

Racoon Dogs

This dog (*Nyctereutes procyonoides*) was introduced into European Russia and has spread into Poland and Scandinavia. It is an important source of reservoir of RABIES in Eastern Europe.

Ractopamine

A BETA-ADRENERGIC AGONIST used as a growth promoter in pigs in the USA and other countries but not the EU and China. Its use can be controversial: there is no clearance period to ensure complete clearance of residues in meat. Its main activity is on striated muscle and at high doses it can affect the heart. It has been reported to cause muscle tremors, increased heart rate and death. (See CLENBUTEROL HYDROCHLORIDE.)

Radial Paralysis, 'Dropped Elbow'

Radial paralysis ('dropped elbow') is commonest in horses and dogs, though it may be seen in any animal.

Causes Probably the majority of cases are due to a fracture of the first rib on the same side of the body, the broken ends of the rib lacerating the nerve-fibres as they pass the rib, or pressing against them. In other cases the origin of the paralysis seems to be situated in the end-plates of the nerve-fibres where they are distributed to the muscles, and in some cases a neuritis involving the radial nerve, or a tumour pressing upon it at some part of its course, is responsible for producing the condition.

Signs In a typical case the horse stands with the elbow dropped lower than normally, and with the knee, elbow, and fetlock joints flexed. Little or no pain is felt, unless there is a fractured rib, or some inflammatory condition which has caused the paralysis. The limb is held in the position assumed at the commencement of a stride, but the animal is incapable of advancing it far in front of the sound limb. No weight is borne upon the leg, the muscles are flaccid and soft, and if the horse is made to move forward either it does so by hopping off and on to the sound fore-limb, or it may fall forwards. If the hand is forcibly pressed against the knee, so that the limb is restored to its natural upright position, the horse is able to bear weight upon it and may lift the other limb from the ground, but as soon as the pressure is released, the joints fall forward again. Sometimes the toe is rested upon the ground, but at other times the horse stands with the wall of the foot in contact with the ground. In cases that are not so severe, the flat of the foot may rest on the ground, and the limb can be advanced forwards to a considerable extent.

Treatment The majority of such cases as these will recover in a few weeks. Physiotherapy under the direction of a Chartered Physiotherapist with training or experience in treatment of horses may be beneficial. Patience on the part of the owner is essential.

Radiation, Exposure to

The 1986 Chernobyl nuclear power-station disaster in the former USSR led to controls being imposed on the movement and slaughter of sheep in parts of Scotland, Cumbria and Wales, after between 1,000 and 4,000 Becquerels/kg of caesium-137 had been detected in lambs. Similar controls were applied in other countries affected by the fallout. The ban temporarily affected about 2 million sheep and lambs in some 500 flocks.

The Atomic Energy Authority stated that 10,000 Bq/kg represents a health risk.

However, the contamination figures exceeded, in nine cases, the internationally recommended action levels for radiocaesium of 1,000 Bq/kg. The highest figure was 4,000.

'Although the physical half-life of radiocaesium is 30 years, its biological half-life is much shorter. In an adult animal, the half-life is estimated at between 30 and 100 days, but for lamb it would be between 25 and 50 days.' (MAFF)

The final restrictions involving 327 north Wales and eight Cumbrian sheep farms, originally started in 1986, were removed in March 2012, with the final control measures being lifted by the FOOD STANDARDS AGENCY on 29 November 2012.

(See also RADIOACTIVE IODINE; RADIOACTIVE STRONTIUM.)

Annual human exposure Of the average UK citizen's annual exposure to radioactive discharges,

VetBooks.ir

only 0.1 per cent comes from the nuclear power industry, according to the Radiological Protection Board.

For radiation exposure associated with veterinary practice, see RADIOISOTOPES and X-RAYS.

Carbon-14 is among internal sources of natural radiation, and is present in the human body to the extent of about 2,000 Bq.

Radiation, Protection against

Regulations governing the use of X-ray equipment, and the precautions to be taken by those handling it, are very strict. Details are given in the Health and Safety at Work Act. (See under X-RAYS.)

A concise guide to the Health and Safety at Work Act 1974 can be obtained from HSE Books, PO Box 1999, Sudbury, Suffolk CO10 2WS. Telephone: 01787 881165; email: hsebooks@prolog.uk.com.

Radiation Sickness

Dogs exposed to radiation following a nuclear explosion will vomit as a result of gastroenteritis, become dull and lose their appetite. This may return after a day or two, but leukopenia develops, and may be followed by haemorrhage or septicaemia.

Radioactive

Emitting or caused by radiation or radioactive particles. It can be measured by a Geiger counter.

Radioactive Caesium

High levels of caesium-137 were found in areas of Wales and Scotland following the nuclear power-station explosion at Chernobyl in 1986. Certain flocks of sheep were affected by the fall-out and the meat declared unfit for human consumption for some time.

R

Antidote Ammonium ferric-cyano-ferrate (AFCF), in the form of a dark blue powder, can bind radiocaesium both *in vitro* and in the gastrointestinal tract of animals very effectively, preventing the isotope from being absorbed and secreted into the milk or transferred to the meat of cows, etc. The addition of only 3 g AFCF per day to the diet of lactating cows reduced the radiocaesium content of their milk by between 80 and 90 per cent, and of their meat by 78 per cent.

The radiocaesium content of the meat from sheep fed 1 g AFCF per day or of calves or pigs fed 2 g AFCF per day was reduced by approximately 90 per cent. The compound was given official clearance as a feed additive against radiocaesium in Germany.

Radioactive Discharges

Of the average UK citizen's annual exposure, only 0.1 per cent comes from the nuclear power industry, according to the Radiological Protection Board.

Around 90 per cent comes from natural sources, principally radon gas released from building materials.

For radiation associated with veterinary practice, see RADIOISOTOPES and X-RAYS.

Radioactive Fall-Out

Radioactive fall-out, following the explosion of nuclear bombs, etc., or accidents at atomic plant, may be dangerous to farm livestock on account of the radioactive iodine and strontium released. (See also RADIATION, EXPOSURE TO; RADIATION SICKNESS; RADIOACTIVE IODINE.)

Radioactive Iodine

Cattle grazing pasture contaminated by fall-out pick up 10 times as much radioactive iodine as do people in the same locality, according to American reports. Large quantities are excreted in the milk, and much concentrated in the thyroid glands.

Feeding-stuffs or pasture contaminated by fall-out containing radioactive iodine and strontium may give rise to illness in cattle. Digestive organs may be damaged, changes in the blood occur, and deaths follow within a month or so, after a period of dullness and scouring. (See RADIOACTIVE STRONTIUM.)

Radioactive Strontium

Whereas the half-life of radioactive iodine is a matter of days, that of strontium is 30 years. Following the grazing of contaminated pasture or the eating of other contaminated feed, radioactive strontium is excreted in the milk, but much of it enters the bones and is liable to set up cancer many years afterwards.

The UK average ratio of strontium 90 to calcium in milk was 2.8 picocuries per gram of calcium in 1975, compared with 3.3 picocuries per gram in the previous year; this result is about one-tenth of the maximum reached in 1964. The average concentration of caesium-137 (7 picocuries/litre) was about four-fifths of the value in 1974 and less than one-twentieth of the 1964 maximum.

Radio-Frequency Treatment

(See under CANCER - TREATMENT.)

Radiography

(See under X-RAYS.)

Radioimmune Assay

A method of measuring antigen or antibody concentration by means of radioactively labelled reagents. (See RADIOISOTOPES.)

Radioisotopes

A radioisotope is a form of an element that undergoes decay while emitting radiation. Artificial

VetBooks.ir

radioisotopes (radiopharmaceuticals) are widely used in diagnosis and in human medicine. NUCLEAR MEDICINE involves the use of unsealed radioisotopes for diagnosis and therapy. For example, in bone scanning, the most commonly used radiopharmaceutical is methylene diphosphonate, labelled with Technetium 99 mm (Tc-99). With a half-life of only six hours, high doses can be given for a low radiation burden, permitting high-resolution pictures to be obtained.

Radiolucent

This term refers to the appearance of an anatomical part or organ through which X-RAYS travel easily. Radiolucent features show up as dark shadows or areas on a (negative) photographic film or light areas on a (positive) digital image. It is customary for the negative plates produced by imaging to be read rather than the positive plates which would be like a monochrome photograph. (See RADIOPAQUE, X-RAYS.)

Radiopaque

This refers to the appearance of an anatomical part or organ through which X-RAYS travel with difficulty. They show up as white shadows or areas on the plate which is the (negative) photographic film, but as dark areas on a (positive) digital image. (See RADIOLUCENT, X-RAYS.)

Radio 'Pills', Telemetering Capsules

Radio 'pills' (telemetering capsules) have been developed for research purposes. A radio transmitter, the size of an ordinary drug capsule, can give information concerning pressure, temperature or pH within an organ.

Radiosurgery

The application of highly focused beams of ionising radiation in the treatment of benign and malignant TUMOURS, often in the BRAIN or CENTRAL NERVOUS SYSTEM. In one technique, linear precision is applied to radiowaves used to incise the skin in routine surgery, it being possible to tune the source and so 'aim' the waves precisely so that there is minimal lateral damage to surrounding tissues. (See also FULGURATION.)

Radiotherapy

The use of radiation to treat disease in man and animals. Its greatest use and benefit is in the treatment of various forms of CANCER. Due to the side-effects in the patients and the potential danger to personnel, the use of radiotherapy is confined to specialist centres. Computers are used to ensure an efficient dose is delivered to a specific area, avoiding normal tissues which lie in the way. (See also CANCER (NEOPLASIA); COMPUTED TOMOGRAPHY; HYPERTHYROIDISM; X-RAYS.)

Radius

The inner of the two bones of the fore-limb. In the horse and ox particularly, the radius forms the main bone of this part, the ulna being much smaller and not taking part in weight-bearing. (See BONE.)

Radnor Sheep

Also known as Hill Radnor sheep, they are a hardy mountain or upland breed. In Britain, they are most commonly found in Powys (Wales) and extend to Monmouthshire (Wales) and Herefordshire (England). The rams are horned but the ewes polled. They have a dense white fleece with a light brown face and legs. The lambing percentage is about 155 per cent.

Radon

A colourless gas produced by the disintegration of radium. It is found naturally in low concentrations in certain areas, e.g. parts of Cornwall, where it has given rise to public-health concerns (see under RADIOACTIVE).

Rafoxanide

A flukicide with activity against *Haemonchus contortus* and *Oestrus ovis*. It can be administered orally or by injection.

Ragdoll

A breed of cat originating in the USA, so called because it tends to 'flop' if carried. They have a high pain threshold and, if involved in a fight, could continue long after a normal cat would have stopped. As a result, it could sustain serious injuries even if it won the fight. They are susceptible to HYPERTROPHIC CARDIOMYOPATHY and MUCOPOLYSACCHARIDOSIS VI (DNA tests available). They are prone to CHRONIC NEPHRITIS and POLYCYSTIC DISEASE. (See KIDNEYS, DISEASES OF.)

Ragwort Poisoning

Ragwort poisoning causes losses among cattle and sheep in Great Britain, Europe, Canada and New Zealand. It is probably the most common cause of chronic hepatic pathology in UK horses. It is the cause of the 'Pictou cattle disease of Canada', and of 'Molteno cattle disease' in South Africa. The plant (*Senecio jacobaea*, or sp.) is very often fed off by sheep when it becomes too plentiful in grassland. In the UK fatal poisoning has followed the giving of hay contaminated with ragwort – death occurring many weeks (two to four months in some cases) after the last mouthful. Acute ragwort poisoning may also occur, causing death in five to 10 days with signs of dullness, abdominal pain, and sometimes jaundice.

Ragwort contains PYRROLIZIDINE ALKALOIDS, which produce cirrhosis of the liver, inflammation of the fourth stomach, and other lesions.

VetBooks.ir

In grazing horses, ragwort will be eaten only if other food is not available but may be ingested in hay or silage. After a mild, damp winter, when the plant grows earlier in the year than usual, and is sprouting among the grasses, horses may eat it.

Chronic liver damage may result, with acute signs apparent when the cirrhosis becomes advanced.

Milk from a cow which has eaten ragwort may be dangerous to children, causing liver damage.

Signs include loss of appetite and of condition, constipation, sometimes jaundice. Cattle may strain and later become excited and violent; horses may become drowsy, with a staggering gait. Secondary gastric impaction and rupture in horses has been reported.

Treatment There is no specific antidote, but methionine has been reported to be helpful. (See LIVER, DISEASES OF.)

Diagnosis A liver biopsy may be helpful in the diagnosis of chronic ragwort poisoning in horses.

Rainbow Trout

Oncorhynchus mykiss (See FISH, DISEASES OF; FISH-FARMING.)

Rainfall

Rainfall may influence outbreaks of HYPOMAGNESAEMIA; BLOAT; FOOT-AND-MOUTH DISEASE.

'Rain Scald'

An old name for *Dermatophilus* infection in horses subjected to prolonged wetting. Lesions occur on withers, shoulders, and rump. For appearance of the lesions, see under GREASY HEEL, and DERMATOPHILUS.

R

Raisins

Being dried grapes they are as toxic to cats and dogs as the fresh fruit. If eaten they can cause kidney failure. (See also GRAPE.)

Rales, Moist Sounds

Rales (moist sounds) are sounds heard by auscultation of the chest during various diseases. They are divided into two main classes: (1) crepitant or vesicular rales, which are heard in the first stages of pneumonia, and are sharp, fine, crackling noises noticed during inspiration only; and (2) mucous rales, which are heard during expiration as well as during inspiration and may be described as bubbling or gurgling sounds.

Ram Epididymitis

This is a disease of economic importance in most of the sheep-farming areas of the world, including Australia and Mediterranean Europe, but not the UK. The cause is *Brucella ovis*. Diagnosis by clinical means (palpation, mainly) is not very satisfactory. Laboratory tests to confirm the organism confirm the diagnosis. Vaccination and culling are methods of control, but vaccination is not free from problems.

Contagious epididymitis is a NOTIFIABLE DISEASE throughout the EU.

Ramipril

A drug used in congestive heart failure in dogs. It can be used with diuretics and digitalis derivatives. It must not be used where there is vascular stenosis.

Rancidity

Rancidity of cod-liver oil or other fish oils, etc., can be extremely dangerous. Rancid mash may bring about deficiencies of vitamins A, D, and E, with acute digestive disorders and death in chicks. Growing and adult birds may also suffer losses from this cause; with osteomalacia, and decreased egg production. (See also under VITAMINS - VITAMIN E.)

'Randy Budgie' Syndrome

Chronic regurgitation of feed with sexual motivation. (See CAGE AND AVIARY BIRDS, DISEASES OF; REGURGITATION.)

Rangifer tarandus

(See REINDEER.)

Rangoon Beans

(See JAVA BEAN POISONING.)

Ranitidine

It is an IMMUNOMODULATOR used to improve immunity when given by mouth.

Ranula

Ranula is a swelling which sometimes appears below the free portion of the dog's tongue. It is caused by blockage in one of the salivary ducts and the resulting accumulation of saliva. When of some size, a ranula may cause considerable interference with feeding. It is treated by incision or excision, and is usually not serious.

RAO

(See RECURRENT AIRWAY OBSTRUCTION.)

Rape Poisoning

Rape poisoning occurs in animals which are not given hay or other food in addition to rape. Poisoning can be extremely serious, especially in sheep.

Signs include dullness, red-coloured urine and blindness. Mortality of 10 per cent has been recorded.

A form of light sensitisation called 'rape scald' occurs in sheep on rape. Swelling of the head occurs, there is irritation leading to rubbing, the ears may suffer damage. Jaundice may occur.

Rapeseed Cake
A compressed 'cake' of rapeseed is used as a cattle feed. The oil is first removed and the cake may be processed to remove any toxicity.

Rapeseed Oil
Also known as concha oil, this contains traces of the toxic erucic acid. Strains of rape for culinary use have a very low content of this. Rapeseed oil is also used to produce biofuel.

Rapeseed meal fed to poultry may depress growth and egg yield, and cause hypertrophy of the thyroid gland, liver haemorrhage, abnormalities of the skeleton, and a fishy taint in the eggs. The liver haemorrhages resemble those associated with the 'fatty liver/haemorrhagic syndrome'. Rapeseeds of low toxicity, such as the Canadian variety canola, have now been bred.

Raphe
Raphe means a seam, ridge or furrow where two halves of a symmetrical organ join. Thus the linea alba is the abdominal raphe.

Raptors
Birds of prey which include the Orders *Falconiformes* (eagles, FALCONS, HAWKS and VULTURES) and *Strigiformes* (OWLS). (See also FALCONS, DISEASES OF; HAWKS, DISEASES OF.)

Rarefaction of Bone
A decrease in the mineral content.

Raspberry Leaves
A mild ECBOLIC, which can be used in cases of dystokia in very small mammals where the dosage of more active pharmaceuticals may be difficult to achieve.

Rat and Mouse Poisons
(See under RODENTS.)

Rat-Bite Fever
This is a disease recognised in man and caused, following the bite of a rat (or, sometimes, dog, cat, mouse, weasel, or squirrel), by infection with *Spirillum minus* or *Streptobacillus moniliformis*. In addition to fever there may be an extensive rash.

Rational Medicine, Rational Treatment
This is based on knowledge of the illness or disease and the action of the medicines or remedies used.

Rations for Livestock

Dairy cattle

Winter rationing The home-grown foods available naturally vary from farm to farm. Farm-mixed rations often make good use of barley. Proprietary compound feeding-stuffs are well balanced and formulated to contain all necessary ingredients such as vitamins, trace elements, etc., and are nowadays extensively used. Proprietary barley balancers and straw balancers are also much used. (See also under WINTER DIET.)

Rations: theoretical basis for calculation
Traditionally, it is customary to regard the ration as being composed of two parts: (1) the 'maintenance' part, which provides the material for all vital activities and makes good the normal wear and tear of the body without causing increase or decrease in liveweight; and (2) the 'production' part, which supplies the materials used for increase in body size, fat production, growth of the fetus, and milk production.

Different classes and weights of ruminant stock have different needs for maintenance and production.

Maintenance and 4.5 litres (1 gallon) rations for cows of Friesian breed (500 kg, 1,100 lb) or similar:

		kg (lb)
(a)	Hay	8 (18)
	Brewer's grains	4.5 (10)
	Dried sugar beet pulp	1.8 (4)
(b)	Hay	8 (18)
	Dried sugar beet pulp	1.8 (4)
	Silage	23 (50)

with parlour-fed concentrates, 1.5 kg (3½ lb) per 4.5 litres (1 gallon), for both (a) and (b).
Maintenance plus 9 litres (2 gallon):
Ryegrass/lucerne haylage *ad lib*
Brewer's grains plus minerals 7 kg (15 lb)

with every 1.8 kg (4 lb) hammer-milled maize fed in parlour for every additional 4.5 litres (1 gallon).

Summer rationing Grass is the standard summer food for cattle. On a good, well-managed pasture – where over-stocking is avoided – young, leafy grass will supply enough protein for high yielders, but they will require additional carbohydrate. This may be supplied in the form of cereals, e.g. 1.8 kg (4 lb) for each 4.5 litres (1 gallon) of milk over about 20 litres (4½ gallons) produced per day.

It has been recommended that in April, cows grazing young, leafy grass 10 cm to 15 cm (4 in to 6 in) high for four hours daily, should receive 3 kg

(7 lb) hay and cereals (plus a mineral mixture) at the rate of 1.8 kg (4 lb) for each 4.5 litres (1 gallon) over 13.5 litres (3 gallons). In May, with unrestricted grazing of grass 20 cm or 25 cm (8 in or 10 in) long at the pre-flowering stage, the hay is discontinued; the cereal ration remaining as before. In June and July, with grass at the flowering stage, the cows receive balanced concentrates for yields over 11 litres (2½ gallons) (June), then over 9 litres (2 gallons). In August, grazing aftermath (or green fodder during a drought), the cows receive concentrates for each 4.5 litres (1 gallon) over the first 4.5 litres (1 gallon). In September, with young aftermath or maiden seeds, there is a hay ration of 3 kg (7 lb) (or 13 kg (28 lb) kale) plus concentrates for yields over 9 litres (2 gallons) per day.

More sophisticated calculations for feed requirements are based on the metabolisable energy requirements of specific herds or even animals. Calculations take into account the amount of energy required for maintaining condition; the quantity of milk produced; and the stage of pregnancy. For growing cattle, rations are calculated based on the maintenance requirement plus the daily liveweight gain.

Beef cattle (See table re suckler cows and under BEEF CATTLE HUSBANDRY IN BRITAIN.)

Calves (See CALF-REARING.)

Pigs

Creep feed	*Per cent*
Barley meal	40
Flaked maize	30
White fish-meal	15

Vitamin pre-mix	2

Rats

They are part of the suborder Myomorpha of the Rodentia order. Besides being pets and used as laboratory animals, rats are important from a veterinary point of view as carriers of infection to cattle, pigs, dogs, etc. Examples of rat-borne diseases are: AUJESZKY'S DISEASE, LEPTOSPIROSIS, SALMONELLOSIS, RINGWORM and TRICHINOSIS. (See also PETS, CHILDREN'S AND EXOTIC; RODENTS.)

In pets and laboratory animals, respiratory disease caused by MYCOPLASMA, STREPTOCOCCI, fungi and the environment is common. Rats can suffer tumours such as those of the PITUITARY GLAND in older males and females, and MAMMARY GLAND. Kidney problems are common in old age.

Rats are inquisitive creatures and pet rats are best handled by allowing them to explore the forearm of the handler before grasping under the thorax (chest). Do not 'SCRUFF' or grasp by the tail.

'Raw' Milk

(See UNPASTEURISED MILK.)

RBC

Red blood cells.

RBV

RELATIVE BREEDING VALUE (see PROGENY TESTING).

RCVS

(See ROYAL COLLEGE OF VETERINARY SURGEONS.)

RDA

(See RIGHT DISPLACEMENT OF THE ABOMASUM.)

Reaginic Antibodies

These are immunoglobulins which become fixed to mast cells and, in the presence of antigen, cause the release of histamine (and other compounds) giving rise to allergic reaction. (See ALLERGY; ASTHMA.) They react with antigens produced by parasitic worms.

Real-Time Polymerase Chain Reaction (RT-PCR)

A polymerase chain reaction test which amplifies and identifies a specific DNA molecule and also can be quantitative. It can be combined with REVERSE TRANSCRIPTION to quantify messenger RNA and non-coded RNA in tissues and cells.

Receptors

These are or contain antibody molecules, occur on the surface of lymphocytes, and enable specific antigens to be recognised. (See under IMMUNE RESPONSE; BLOOD.)

Physiological receptors include those for enzymes, and for hormones.

Recessives

(See GENETICS, HEREDITY AND BREEDING.)

Recombinant DNA Technology

A process by which genes from one organism are transferred – usually by a modified bacterium or virus – to another to reproduce a desirable characteristic. For example, some vaccines are made by modifying a virus so that its virulence is removed but its antigenic potential – its ability to confer immunity – remains. Similarly, bacteria have been modified so that they produce human insulin. The possibility for using the technique to synthesize biological medicines not currently commercially available, or to improve plant breeds to enhance food yields, is likely to become increasingly important.

Plants may also be modified so that desirable characteristics such as resistance to disease are 'bred' into them.

Recombinant Feline Interferon

It has been shown to have efficacy against feline RETROVIRUSES and CANINE PARVOVIRUSES. It has been used for the treatment of FELINE CALICIVIRUS.

VetBooks.ir

Recovery Quilts

Recovery quilts for cats and dogs have been developed. Marketed as Flectabed, the quilts contain Flectalon, a special fibre developed for emergency blankets. It is stated that the product reflects back 95 per cent of the infra-red heat lost by the body.

Rectrices

The plural of RECTRIX. It is also spelt retrices.

Rectrix

(plural, Rectrices)

This is a large tail feather originating at the pelvic inlet. It is also spelt retrix. (See SKIN - APPENDAGES OF THE SKIN - FLIGHT.)

Rectum

The posterior end of the intestine. It commences on a level with the anterior opening of the pelvis and extends to the anus, passing through the upper part of the pelvic cavity. In most of the domesticated animals it possesses a dilatation, known as the 'ampulla', which serves to collect the faeces that are slowly passed into it from the colon, and holds them until time and circumstances are convenient for their evacuation to the outside. (See INTESTINES.)

Rectum, Diseases of

With the exception of the dog, the domestic animals are comparatively free from disease of this part of the alimentary system.

Impaction This occurs mainly in dogs (and to a lesser extent in cats, which tend to suffer more from colonic impaction) when pieces of bone, string, and other foreign materials form with the faeces a hard mass. The affected animal attempts to pass faeces, but after considerable efforts fails to do so. If the impacted material contains spicules of bone or other hard material, every effort at defaecation causes the animal to cry out with the pain.

Removal of the offending matter is effected by the administration of an enema formulated to soften the material (glycerine, oil, or soapy water), and the introduction of the gloved finger. Hard masses are broken up and taken away in portions if too large to remove whole. A mild laxative should be given by the mouth after the impacted material has been cleared from the rectum, and the dog should receive a soft semi-fluid diet for some days afterwards.

Inflammation of the rectum may follow impaction, or it may commence as the result of an injury. The animal frequently strains, and the owner may surmise that it is constipated, but exploration reveals the absence of faeces.

Abscesses, tumours and ulcers may also affect the rectum, but they are not common. (See also under ANUS.)

Prolapse of the rectum may occur in any animal, but is especially common in the smaller animals. A portion of the gut is protruded from the anus to an extent of a few inches. It appears as a tumorous swelling of a bright-red appearance, cold to the touch, and usually covered with mucus or faecal material. There is usually some straining when the condition is of recent origin, but after a time the animal appears to become used to the protrusion of the piece of bowel, and only strains when it is handled or when attempts are made to return it. Anaesthesia or analgesia will be needed. It may be gently bathed with warm water containing common salt in solution (5 per cent) while awaiting assistance. An operation, in which the rectum is sutured to some part of the abdominal roof, is sometimes necessary to prevent its recurrence after replacement. Prolapsed rectum is not uncommon in the horse. Sometimes it may be easily returned by placing the neck of a litre (quart) bottle within the central depression that is always present, and pressing slowly and cautiously in a forward direction. Care must be taken to avoid injury of the personnel involved.

In some instances amputation of the protruded portion becomes necessary, especially if it has been outside for some considerable time and has become gangrenous.

Recumbency

In a veterinary sense, this means not merely lying down but also a failure to get up. (See 'DOWNER COW' SYNDROME.) In animals in dorsal recumbency (lying on the back) during anaesthesia, pressure of viscera on the posterior VENA CAVA may result in hypotension. In rare cases, this has been followed by spinal cord necrosis, leading to paralysis of a horse's hind-legs, necessitating euthanasia. It has been suggested that a slightly oblique dorsal recumbency is advisable.

Anaesthetised horses, when positioned in left lateral recumbency (lying on the side), showed least muscle or nerve injuries when lying on a water mattress. Foam rubber was 'far from satisfactory'. Sternal recumbency means lying on the chest. (See DECUBITUS.)

Recumbent

Lying down. (See RECUMBENCY.)

Recurrent Airway Obstruction (RAO)

The name for CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD). It has also been called HEAVES and 'BROKEN WIND'.

VetBooks.ir

Recurrent Laryngeal Nerve

Recurrent laryngeal nerve is a branch of the vagus nerve which leaves the latter at different points on the right and left sides of the body. On the right side it leaves the parent nerve opposite the second rib, curves inwards round the subclavian or the costo-cervical artery, and runs up the neck on the lower surface of the trachea and below the carotid of the same side. In the case of the left, the branch leaves the vagus where that nerve crosses the arch of the aorta, winds inwards around the concavity of the aortic arch, and runs up the neck in a position similar to that of the right side. Both nerves supply the muscles of the larynx which are concerned in the production of voice and in maintaining the glottis open during ordinary and forced respiration.

Recycled Farmyard Manure (RFM)

(See RECYCLED MANURE SOLIDS.)

Recycled Manure Solids (RMS)

The separation of urine and the liquid component from faeces results in a dry, brown, odourless and fibrous material that has been used in the USA as bedding and is now becoming utilised in Britain and Europe. It is being called a 'green bedding' as it is reusing a waste material at a time when bedding costs were high. It is a category 2 animal by-product under the EU Animal By-Products legislation and so under the ANIMAL BY-PRODUCTS REGULATIONS 2003 it should not be used for bedding. However there is provision for animal by-products and their derivatives to be used or technical uses provided there is no risk to human or animal health. When managed properly it does provide a comfortable, dry and safe floor bedding.

Red Blood Cells

(See ERYTHROCYTE; BLOOD.)

Red Dane Cattle

(See DANISH RED CATTLE.)

Red Deer, *Cervus elaphus*

Wild deer can show DWARFISM. (See DEER.)

Red Dysentery

Another name for COCCIDIOSIS in cattle.

'Red Eye'

Conjunctivitis. (See ALLERGIC CONJUNCTIVITIS; EYE, DISEASES AND INJURIES OF.)

'Redfoot'

A condition seen in newborn lambs, mainly SCOTTISH BLACKFACE, in which the sensitive laminae of the feet become exposed owing to detachment of the overlying horn. The cause is unknown, no treatment effective, and the lambs soon die.

Red Gut in Lambs

Sudden death usually due to a torsion or displacement of the intestines. Post mortem examination show red small and large intestines. The torsion results in obstruction and congestion of the blood vessels, shock and death. It is common on LUCERNE pastures.

Redmouth Disease

A disease of trout. (See FISH, DISEASES OF.)

Red Poll Cattle

An uncommon breed in the UK today; it was developed in England in the second half of the 19th century. It has a dark red coat, a white switch to the tail and is hornless. It is a dual-purpose breed but mainly used in beef production. There are a few dairy herds in Britain and the USA. Its semen has been used to create the PITANGUEIRAS breed.

Red Squill

Preparations of the dried ground bulbs of the sea onion *Urginea maritima* were formerly used for poisoning rodents, baits being made up to contain 10 per cent red squill. Signs of poisoning include profuse vomiting (in the pig but not in the cat), excitement, muscular incoordination and convulsions. Poisoning in rodents by red squill may be agonising and prolonged. Its use in the UK is banned.

Red Squirrel

(See SQUIRRELS.)

Reducing the Impact of Non-Native Species in Europe (RINSE)

This is an organisation funded by the EU. This involves animal, invertebrate and plant species. Since 1950, over 600 non-native species have arrived in Britain. It has been estimated in 2012 cost the global economy of £1.4 trillion annually.

Reduction Division

(See MEIOSIS.)

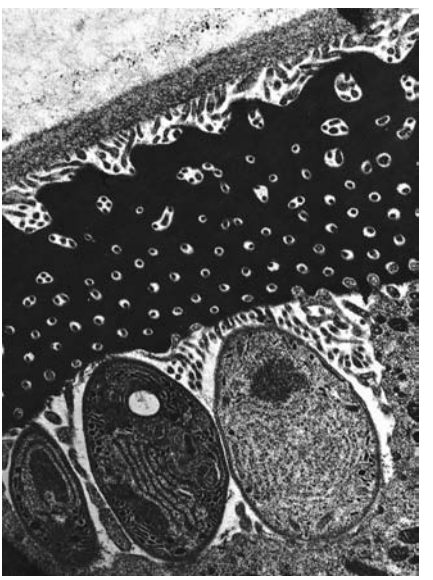
Reduplication

Reduplication is a term applied to a duplication of the normal heart-sounds as heard by auscultation. There are heard a first and a second sound in a normal heartbeat, and in the above condition one or both of these may be doubled. It is found in certain diseases of the heart, such as obstruction of the valve between the auricle and ventricle on the left side of the organ (the mitral valve).

Red Urine

Causes of red discoloration of the urine include: haematuria – blood in the urine, which settles out on standing; haemoglobinuria – the breakdown of red blood cells, in which urine does not change

colour on standing; and pigments. The coloration is usually a sign of disease: pyelonephritis and cystitis cause haematuria; red-water fever, leptospirosis, infection with *Clostridium haemolyticum*, kale and rape poisoning, copper poisoning, and the drinking of very large quantities of water all result in haemoglobinuria. Azoturia results in breakdown of muscles to produce myoglobinuria, a brown-red coloration. Dosing with phenothiazine produces a red pigment.



Rabbit urine is normally darker in colour than that of other domestic animals, red being a predominant colour. This is due to the presence of the pigment PORPHYRIN. Causes of extreme redness include the ingestion of acorns, brassicas and dandelions, and diseases including uterine adenocarcinoma, uterine ANEURYSM and rectal PAPILLOMA. Haematuria is rare in rabbits.

Red-Water

Also called bacillary haemoglobinuria, or icterohaemoglobinuria, in the USA it occurs in California, Colorado, Idaho, Louisiana, Montana, Nevada, Oregon, Texas and Utah. *Clostridium haemolyticum* is the cause. (See also TEXAS FEVER, the American red-water fever.)

Red-Water Fever

In the British Isles, babesiosis or piroplasmosis (see under BABESIA), to give red-water fever its proper names, is a disease of cattle and sheep, due to the presence in the blood of a protozoon parasite which attacks the red blood cells, destroying their envelopes and liberating haemoglobin, which is excreted by the kidneys and colours the urine reddish or blackish. It occurs mainly in the south and west of England, in the north and west of Scotland, and practically all over Ireland, but it is also seen at times in districts that are not included in these areas. It is common in low-lying, rough-pastured, and moorland districts, where ticks, which harbour and transmit the parasite, can find abundant shelter and suitable breeding places. Cattle are usually attacked from the age of about six months upwards, but young calves are practically immune. One attack gives a degree of immunity, and cattle that have been bred upon infected farms, and from infected cattle, are more resistant than those brought from a clean district. It is more prevalent in the spring and autumn months, since the ticks are then at their maximum activity.

An electron microscope picture showing three profiles of *Babesia divergens* — the cause of red-water fever — inside the egg of a tick. (With acknowledgements to IRAD, Compton.)

Cause *Babesia (Piroplasma) divergens*. This is transmitted by the common tick *Ixodes ricinus*, and occasionally by *Haemophysalis punctata*. (See under BABESIA and TICKS; also MUSCLES, DISEASES OF; MYOGLOBINURIA.)

Signs Two varieties of the disease are recognised: an acute and a mild form.

The acute type is sudden in its onset and frequently fatal. The animal becomes very dull and depressed, separates itself from the rest of the herd, moves slowly or not at all, grunts, groans, arches its back, salivates freely, grinds its teeth, and often staggers and falls. The coat becomes hard and staring, the skin is dry and often hide-bound, and there is almost always a profuse, watery, violent 'pipe stem' diarrhoea, due to spasms of the anal sphincter. The temperature rises to as high as 40.5° C to 41.5° C (105° F to 107° F), the pulse is fast and weak (often 100 beats per minute), and the respirations are laboured, blowing and rapid (80 to 100 breaths per minute). The visible mucous membranes are pale. After a few days the animal's distress becomes less acute, and the most alarming signs subside. The signs of fever, however, are still evident, and the cow is still in a serious condition. The urine usually shows some degree of coloration, which varies from a clear reddish claret to a deep dark brown or black – almost like stout.

The duration of acute attacks varies, but it is seldom that the high temperature lasts for more than a week. Death may take place in three to five days, or later on, when it is usually due to exhaustion.

In the mild type the urine is not usually highly coloured; there is only slight dullness and loss of appetite. The animals are ill for a week or 10 days, and the only marked sequel is anaemia.

There are irregular forms of red-water met with at times, in which the general signs are similar to these seen in the typical acute attack, but the urine

does not become discoloured. Many of these cases end fatally.

Treatment Imidocarb (Imizol). For use under prescription only. A single dose of 1 ml per 100 kg bodyweight for treatment, or 2.5 ml per 100 kg bodyweight for prevention; the dose must be given subcutaneously. Cattle must not be slaughtered for human consumption for 90 days after administration, and milk from treated animals must be withheld for 21 days. Veterinary surgeons who prescribe Imizol are advised that:

1. Full records of product administration to identifiable animals must be maintained, and that it is the duty of the farmer to keep a careful record of all administration of the product, as required by the Animals and Fresh Meat (Examination for Residues) Regulations 1988.
2. The local DVM must be notified of the address of the farm where treatment is to take place.
3. Farmers should be informed that they must notify the local DVM when treated animals go for slaughter for human consumption or when milk from treated animals is intended for human consumption.

Any suspected adverse reactions, including evidence of lack of efficacy, should be reported to the Veterinary Medicines Directorate, Woodham Lane, New Haw, Addlestone, Surrey KT15 3LS. Telephone for adverse reactions: 01932 338427, immediately.

Ticks should be removed, either by hand-picking or by spraying with a suitable parasiticide. (See TICKS - CONTROL OF TICKS.)

The few piroplasms taken into the bloodstream, when young cattle are bitten by infected ticks, tend not to multiply but to give rise to a useful degree of immunity. This may wane if the piroplasms die, so that the animal becomes susceptible again. Immunity may likewise break down if the animal becomes ill from some other cause.

Control Measures involve tick control, and not mixing cattle from red-water areas with susceptible cattle. Even then there are risks.

Twenty deaths occurred when local cattle were placed on sea marshland in Lincolnshire that had previously been used for fattening imported Irish steers which were carriers of *B. divergens.* Cornish cattle brought to a farm in Sussex set up a focus of infection because infected ticks became established in the new habitat. And Simmental, Charolais and other European breeds are imported into Britain with no screening for blood parasites.

Red Wattle Pigs

These came from New Caledonia, near Australia, and are also known as Red Waddle pigs. The breed developed interest because of its leanness. The pigs have wattles, are docile and are red in colour.

Red Worms

The common name for strongyles. These can cause severe anaemia, unthriftiness, and debility. (See under FOALS, DISEASES OF; also under EQUINE VERMINOUS ARTERITIS; HORSES, WORMS IN.) Benzimidazoles, ivermectins and thiabendazole are useful drugs for the removal of red worms. (See also ROUNDWORMS.)

REE

Rabbit epizootic enterocolitis. (See EPIZOOTIC RABBIT ENTERITIS.)

Refeeding Syndrome

Metabolic disturbances that occur when nutrition is reintroduced to starving or severely malnourished patients. An individual mammal with a negligible nutrient intake for five consecutive days is at risk of refeeding syndrome, which usually occurs within four days of feed reintroduction. Fluid and electrolyte disorders develop, especially HYPOPHOSPHATAEMIA, with neurological, pulmonary, cardiac, neuromuscular and haematological complications. It is thought that, during prolonged fasting, the body aims to conserve muscle and avoid protein breakdown by switching from ketone bodies to fatty acids as the main energy source. The liver decreases its rate of GLUCONEOGENESIS, thus conserving muscle and protein. Many intracellular minerals become severely depleted during this period, although serum levels remain normal. Importantly, insulin secretion is suppressed in the fasted state and glucagon secretion is increased.

Reflex Action

Reflex action is one of the simplest forms of activity of the nervous system. For the mechanism, see NERVES.

Superficial reflexes are well instanced in the sudden shivering movement that is seen when a fly or other insect settles upon the skin of a horse, particularly in the region of the back of the shoulder.

Visceral reflexes are those connected with various organs, such as the narrowing of the pupil when the eye is exposed to a bright light. (See SPINAL CORD.)

Refugia

A term used when considering worm parasites and anthelmintic resistance. It really means an area that has escaped ecological changes thereby helping maintain biodiversity. However, in parasitology it is used for the worms remaining that have not been exposed to ANTHELMINTIC treatment, and are present in untreated animals or on the pasture.

VetBooks.ir

Regional Anaesthesia
This consists in the anaesthetisation of a region of the body by means of a local anaesthetic solution injected either into the connective tissue surrounding a sensory nerve trunk or into the spinal canal. (See EPIDURAL ANAESTHESIA, ANALGESICS.) The most common example of perineurial injection is plantar block in the horse.

Register of Veterinary Surgeons
The Register of Veterinary Surgeons lists veterinary surgeons who can practise in the UK, those who live outside the UK but can practise in the UK, and those who have retired. It is now in electronic form. It may be consulted in some public libraries or is obtainable from the Royal College of Veterinary Surgeons, Belgravia House, 62–64 Horseferry Road, London SW1P 2AF. Telephone: 0207 222 2001.

Regurgitation
The reflux of undigested food is part of the normal behaviour of some psittacines, when they feed the sitting mate, or chicks, in the nest. In the absence of a mate, a cage bird may regurgitate to its image in a mirror. Any infection of the digestive tract (e.g. Candidiasis, TRITRICHOMONIASIS, etc.) should be controlled to prevent infection of the young. In mammals regurgitation occurs naturally in ruminants. In other species it is the result of regurgitation of food from the oesophagus whereas vomiting is from the stomach.

Rehydration
The restoration of the correct levels of water and electrolytes in animals suffering from DEHYDRATION.

Reindeer, *Rangifer tarandus*

They are unique in that both sexes have antlers. The males shed their antlers at the end of the rut (September to October) and the females in May to June. Calves are weaned at two months. A herd has long been established in the Grampian Mountains in Scotland. Both in northern Europe and North America these animals are of economic importance. Parasites include WARBLES. Subcutaneous injections of ivermectin are recommended for prevention of infestation and treatment.

Relapse
The recurrence of clinical signs after apparent recovery (with or without treatment). A relapse occasionally occurs when antibiotic or sulfa drug treatment of an infectious disease is stopped – the infection having been suppressed but the animal's powers of resistance not having been stimulated to establish a sufficient degree of immunity. Some forms of lameness in the horse are particularly liable to relapses, especially those associated with sprains of tendons or ligaments.

Relative Breeding Value
(See PROGENY TESTING.)

Religious Slaughter
Animals being prepared for slaughter by the Jewish and Muslim communities are by law permitted to be killed without prior stunning. The slaughter must be undertaken by a suitably recognised person. (See HALAL SLAUGHTER; PRESTUNNING SLAUGHTER; SHECHITA.)

RELU
(See RURAL ECONOMY AND LAND USE.)

REM
Abbreviation for rapid eye movement, usually during SLEEP. REM movements vary between species and are often related to dreams (in those animals which can dream). (See SLEEP (NON-HUMAN); SLEEP (HORSES).)

Remex
(plural, Remiges)
The large flight feather of a bird found on the wing. (See SKIN - APPENDAGES OF THE SKIN - FLIGHT.)

Remiges
The plural of REMEX.

'Remote Injection' Method
(See PROJECTILE SYRINGE.)

Renal
Relating to the kidney.

Renal Agenesis
The absence of a kidney as a result of the lack of presence of the primordium in the embryo. This has been recorded in BEAGLES.

Renal Cortical Hypoplasia
A condition seen particularly in some breeds of dog, including ELKHOUNDS, LHASA APSOS. The renal cortex is not properly developed resulting in signs of chronic renal insufficiency at an early age. Signs including POLYDIPSIA, POLYURIA, pale mucous membranes, poor growth, low weight gain and secondary OSTEODYSTROPHIA FIBROSA.

Renal Dysfunction
A reduction in the ability of the kidney to remove metabolic products from the body, which start to accumulate in the tissues. It can be detected by renal function tests and is an initial stage of URAEMIA.

VetBooks.ir

Renal Dysgenesis
The congenital malformation or defective development of one or both kidneys. This has been recorded in BEAGLES.

Renal Dysplasia
A condition resulting in small, misshapen kidneys at birth and which can be inherited or due to intrauterine infection. In severe cases the animal will become URAEMIC. It is seen particularly in SHIH TZUS and SOFT COATED WHEATEN TERRIER (DNA tests available).

Renal Failure
The kidneys are unable to maintain normal function.

Renal Insufficiency
(See RENAL DYSFUNCTION.)

Renin
A protelytic enzyme, synthesised, stored and secreted by the kidneys, which controls the secretion of the hormone aldosterone by the adrenal glands, and also plays a part in regulation of blood pressure by catalysing the conversion of the plasma glycoprotein agiotensinogen to angiotensin.

Reovirus
The name derives from the words 'respiratory enteric orphan virus'. Reoviruses have double-stranded ribonucleic acid (RNA), and will replicate and produce changes in cells of cattle, pigs, dogs, cats, rabbits, monkeys and man. Reovirus in poultry is often seen as tenosynovitis. They can survive for at least ten days on feathers, wood shavings and feed and longer where there is organic matter present. The tendon sheaths, synovial membrane and the myocardium are all affected. Vaccination is possible but attention to hygiene is also essential for effective control. Only flocks known to be free from the infection should be selected for producing hatching eggs. Ducks can become infected, with mortalities reaching 15 to 40 per cent. There are pin-head necrotic foci in the liver, spleen, pancreas and kidneys. (See also CALF PNEUMONIA.)

Repair
Repair of tissue after injury is described under WOUNDS; for the repair of special tissues, see under BONE, MUSCLE, NERVES, etc. (See also HOOF REPAIR WITH PLASTICS.)

Reproduction

Ovulation At OVULATION the Graafian follicle bursts, and the ovum is expelled by the rush of the escaping fluid. The cavity of the Graafian follicle becomes filled with special cells to form the corpus luteum, and the ovum begins its life as an absolute entity. In normal circumstances the fimbriated and dilated funnel-shaped end of the Fallopian tube, or oviduct, is applied to the point at which a follicle will burst, so that upon escape of its ovum this latter may be caught and retained. The dilated end of the oviduct is usually known as the vestibule, and it is in this part that the sperm usually meets the ovum and fertilises it. (See also under OVARIES.)

Coitus The act of copulation. As mentioned under OESTRUS, service by the male is only allowed during the period of oestrus by the females of the majority of species of higher animals. At other times there is little or no desire exhibited by the male, and all attentions are resented by the female. Artificial methods of domestication have to some extent modified the frequency and duration of oestrus, so that the domestic animals sheltered under the protection of man breed more frequently than do the majority of wild animals of similar species.

During a single ejaculation of an adult vigorous stallion about 80,000,000 sperms are released. As soon as the sperms are free in the uterus or vagina, they travel towards wherever the ovum is situated. This they accomplish partly by a kind of wriggling movement of their tail, which drives them onwards always in the same direction and they are attracted to the ovum by 'chemotaxis' (response to chemical stimuli).

Fertilisation Somewhere in the oviduct, generally in its vestibule but not necessarily so, the spermatozoa arrive in the region of the waiting ovum. More than one sperm may penetrate the wall of the ovum, but except in rare instances (giving rise to PRIMARY MOSAICISM) only one sperm fertilises the ovum.

The sperm, having penetrated the ovum, loses its tail, which is no longer required, and lies within the protoplasm of the ovum. The nucleus of the ovum and that of the head of the sperm now fuse, each contributing half the number of chromosomes that are to be found present in nearly all the cells of the future young animal. The fused body is known as the segmentation nucleus, and from it, when it begins to divide, all the body cells of the embryo are formed. The process of the formation of the young embryo is considered under EMBRYOLOGY. (See also TESTICLE; OVARIES; OESTRUS; BREEDING OF LIVESTOCK; PREGNANCY AND GESTATION; PARTURITION; PARTHENOGENESIS.

Reproductive Organs
(See diagrams under UTERUS and PENIS.)

VetBooks.ir

Reptiles

A class of animal which includes chelonians (tortoises, turtles and terrapins), lizards and snakes. About a fifth are threatened with extinction. They are all ECTOTHERMIC, although larger specimens of turtles and snakes are known to be capable of ENDOTHERMY. Reptiles tend to favour warm places when they are ill. Reptile housing should be heated at all times, but a range of heat should be available in different areas, within the normal limits for the species, so that they can choose which suits them best. Radiant heat is preferred. Under no circumstances must they be allowed to come into direct contact with the heat source. Many species require ultraviolet light, otherwise bone rarefaction (weakening) may occur; expert advice must be sought before buying such a pet. Bearded dragons (*Pogona vitticeps*) can be aggressive, a trait that may be chemically controlled by DESLORELIN, a gonadotrophin-releasing hormone agonist. From 2004 to 2010 in England and Wales, there were 740 episodes of bites by crocodiles, other reptiles and contact with venomous snakes and lizards. (See also PETS, CHILDREN'S AND EXOTIC.)

Resection

Resection is an operation in which a part of some organ is removed – as, for example, the resection of a piece of dead bone, or resection of a part of the intestine which is diseased; resection of a rib in thoracotomy; aural resection, to overcome chronic disease of a dog's ear.

Resistance Transferability

(See under PLASMIDS; ANTIBIOTIC RESISTANCE.)

Resistant Strains

This phrase is commonly used of bacteria which are not sensitive to antibiotics, or of insects which are not killed by an insecticide.

Resorption

Mummification. Resorption of the fetus occurs, e.g. in heifers receiving a high calcium and low phosphorus diet. In sows, mummification can be a feature of AUJESZKY'S DISEASE, 'BLUE-EAR' DISEASE OF PIGS (PRRS), and both AFRICAN SWINE FEVER and Classical SWINE FEVER. With the banning of sow stalls and the need to find alternatives, it has been reported that the level of mummification tends to be higher in dry sows kept in straw yards. The reason is not clear, but bullying has been suggested as a cause. (See MUMMIFICATION OF FETUS.)

Fetal resorption can occur in rabbits before the 20th day of gestation and can be very rapid.

Respiration

(See also NOSE AND NASAL PASSAGES; LUNGS.)

Mechanism of respiration For the structure of the respiratory apparatus see NOSE AND NASAL PASSAGES; LUNGS, etc.

Inspiration is due to muscular effort which enlarges the chest in all three dimensions, so that the lungs have to expand in order to fill up the vacuum that would otherwise be left; and since, although the lungs are not fixed to the chest wall, surface tension between the pleura lining the chest and the pleura covering the lungs, has much the same effect.

In most vertebrates, except birds, the lungs are not normally attached to the walls of the chest, but are rather suspended in them from their 'roots', so that there is no direct pull upon the lungs when the chest cavity increases in size. The vertical diameter of the chest is increased during inspiration through the downward tilting of the sternum. This movement is best seen in the dog when it is out of breath; at other times, and in other animals, it is so slight that it escapes detection. The transverse dimension of the chest increases when any of the ribs behind the first two or three are forcibly pulled forward by muscular action. Each rib only moves a small amount, but the mass effect of the series is considerable. The muscles which bring about these changes in ordinary inspiration are the diaphragm, the intercostal muscles which are situated in two layers between each rib and its two neighbours, and possibly the levators of the ribs, and the serratus muscles.

When the chest expands, the lungs expand too; but initially the quantity of air within them remains the same. Accordingly, the pressure falls, leading to an inflow of air.

	Inspired air	Expired air
	per cent	per cent
Nitrogen	79.04	79.04
Oxygen	20.93	16.02
Carbon dioxide	0.03	4.38

Expiration is, in ordinary circumstances, merely an elastic recoil, with the diaphragm moving forward and the ribs settling back into their original positions, partly through muscular action, and partly through the elasticity of their cartilages. It occupies a slightly longer period of time than does inspiration.

Nervous control Respiration is usually an automatic act under the control of the respiratory centre in the medulla oblongata.

Although the respiratory centre is itself capable of carrying on respiration, it is in its turn liable to be controlled by the higher conscious centres. This is

VetBooks.ir

seen particularly well in human beings, where it is possible to 'hold the breath', or inhibit respiration for considerable periods (when diving underwater, for example).

Rate of respiration The speed of the respiration varies with many internal and external factors. It is faster during fevers, after violent exercise, or even after mild exercise (though it soon returns to normal upon cessation); during powerful emotions, such as fear, anger, sexual excitement, etc.; during very cold or very hot weather; when the body condition is very fat, or when radiation is obstructed, through too thick a covering of wool, fur, etc., or too much clothing. (See also ANAEMIA.)

It is slower than normal during resting, either when merely lying or when sleeping; and in cases of unconsciousness.

The normal rates in adult domesticated animals are as follows:

In each case, the larger the particular animal, the slower it breathes, other things being equal. For instance, a Shetland pony respires about 12 times per minute, while a shire stallion respires only 8 times; also, the young of any species breathe faster than adults; and females breathe faster than males – especially during pregnancy.

When this air is taken into the lungs its composition is altered, so that upon leaving the lungs its CO_2 content is about 4 per cent greater and its oxygen content about 4 per cent less.

Quantity of air The lungs do not by any means completely empty themselves at each expiration and refill at each inspiration. What is left after maximum expiration is called the residual volume. The volume of air exchanged during normal breathing (i.e. passing in and out of the nose) is the tidal volume – about 5 litres in the horse. The volume of air in the airways leading to the alveoli of the lungs is the anatomical dead space. Air available for the supply of oxygen in the lungs is the tidal volume minus the anatomical dead space.

Irregular forms of respiration Apart from mere changes in rate and force, the respiration is modified in various ways under certain conditions. Coughing is a series of violent expirations, during each of which the larynx is at first closed until the pressure of air in the lungs and lower passages is considerably raised, and then suddenly opened, so that the contained air is released under pressure and rushes to the outside; its object is to expel some irritating object from the air passages. Sneezing is a single sudden expiration, which differs from coughing in that the sudden rush of air is directed by the soft palate up into the nose in order to expel some source of irritation from the nasal chambers. It is particularly well exhibited by the dog.

Yawning is a deep slow inspiration followed by a short expiration, the air being taken in by the open mouth as well as by the nose. Hiccough is due to a sudden spasmodic contraction of the diaphragm, along with a sudden closing of the larynx, producing a sound not unlike a very loud heartbeat. Hyperpnoea is a term applied to the slightly increased frequency and depth of respiration occurring during gentle exercise, or from some mild stimulus to the respiratory centre. Dyspnoea means that there is distinct distress in breathing, due to a more powerful stimulus to the respiratory centre, and is usually characterised by convulsive movements of the chest and diaphragm. It is frequently the forerunner of asphyxia. Apnoea is seen when there is a hyperoxygenation of the tissues, and consequently no further immediate demands for oxygen. It consists of a complete cessation of the respiratory movements without the exhibition of any distress. It is artificially produced in human beings when a diver takes 10 or 12 deep breaths before entering the water, where he must hold his breath. It is not commonly seen in the domestic animals, but the seal and other diving animals have developed the power of inducing apnoea to a marked extent. (See also under ASTHMA; LARYNGEAL PARALYSIS; VOICE; TACHYPNOEA.)

Respiratory Difficulty, Respiratory Failure

(See under BREATHLESSNESS; ANAEMIA; ANAESTHESIA, GENERAL; ASPHYXIA; BRONCHITIS; 'CHOKING'; FOG FEVER; 'FRYING PAN' DEATHS (PTFE); OEDEMA; PNEUMONIA; RECURRENT AIRWAY OBSTRUCTION; CHRONIC OBSTRUCTIVE PULMONARY DISEASE; syringeal plugs in birds with ASPERGILLOSIS.) Many poisons bring about respiratory failure, e.g. chloroform, hydrocyanic acid, paraquat.

Respiratory Disease in Pigs

Pigs are susceptible to a number of respiratory problems; the most common being the following (see also under main dictionary entries).

Atrophic rhinitis This is generally agreed to be the result of bacterial infection with *Bordetella bronchiseptica* followed by toxigenic strains of *Pasteurella multocida*, leading to progressive atrophy of the turbinate bones (see RHINITIS; a vaccine is available. A few cases are caused by cytomegalovirus (inclusion body rhinitis).

Enzootic pneumonia is a common problem, particularly in growing pigs; affected animals have a dry cough, reduced weight gain and poor feed conversion efficiency. The cause is *Mycoplasma hyopneumoniae*.

VetBooks.ir

Pleuro-pneumonia of pigs is a rapid onset respiratory disease resulting in dyspnoea and, often, death in acute cases. Less severely affected animals have a variety of subclinical problems. The cause is *Actinobacillus pleuro-pneumoniae*. Often seen following other disease problems, pleuro-pneumonia can affect only some of the animals in a herd, causing high temperatures, laboured breathing with, often, a bloody frothy discharge from the nose. Early antibiotic treatment can effect a recovery; tetracyclines, lincomycin and ceftiofur are among drugs used. Vaccines are available for control.

Swine influenza can sweep through a pig unit, causing a variety of respiratory signs and sometimes precipitating other respiratory diseases. Little can be done to control the spread of infection, but the pigs recover after four to six days; subsequent immunity lasts about three months.

Porcine respiratory reproductive disease (PRRS) ('blue-ear' disease) results in variable signs, but affected animals may have respiratory difficulties; it often exacerbates any underlying respiratory diseases, such as pneumonias.

Porcine respiratory-coronavirus infection (PRCV) Outbreaks are often relatively mild, but other respiratory problems may result. Coughing, sneezing or dyspnoea can occur.

Porcine respiratory disease complex (See PORCINE RESPIRATORY DISEASE COMPLEX entry.)

Ascarids Infection with *Ascaris suum* can result in coughing during the migratory stage of the larvae.

Aujeszky's disease sometimes causes respiratory signs such as sneezing, coughing and nasal discharge, occasionally with dyspnoea. Vaccines are available (in Ireland).

Lungworm Infection with *Metastrongylus apri* is usually only a problem in outdoor pigs; signs are often limited.

Not all the factors involved in respiratory disease are infections: management factors play their part, too. Space allowance per pig, number of pigs per group, effects of mixing and crowding, temperature, humidity, nutrition, age and genetic status of the pigs all exert their effects. (See also under ATROPHIC RHINITIS.)

Respiratory Stimulants

Respiratory stimulants are used to promote breathing in the newborn and to relieve respiratory depression associated with, for example, general anaesthesia. They include doxapram, cropropamide and crotethamide, and etamiphylline. In cases of respiratory depression due to anaesthetics, it is often better to use an antidote to the anaesthetic, for example ATIPAMEZOLE, YOHIMBINE or even turning off the vaporiser.

Respiratory Syncytial Virus (RSV)

Respiratory syncytial virus was first isolated from chimpanzees showing 'cold-like' signs; since the mid-1950s it has been detected in clinical cases of respiratory disease in man, cattle, sheep, goats, and horses. It is a cause of acute bronchiolitis and alveolitis.

Respiratory System

This is a group of structures whereby air from the environment passes into and out of the animal. The structures are virtually a series of hollow tubes which culminate in the alveoli. All the time the air is technically outside the body. The system is in two parts. The **Upper Respiratory System** which starts at the NOSE AND NASAL PASSAGES, passes through the PHARYNX, LARYNX, TRACHEA and ends in the BRONCHI. The **Lower Respiratory System** consists of the BRONCHIOLES and ALVEOLI.

Restraint

In order to examine an animal thoroughly for signs of injury or disease, in order to carry out inoculations, or even to administer an anaesthetic, some form of restraint is often necessary.

The introduction of effective tranquillisers and sedatives facilitated the handling of horses, cattle and small animals, and may assist or replace the use of several means of restraint described below. (See also TRANQUILLISERS; XYLAZINE; ANALGESICS.)

The following methods should not be used indiscriminately upon any and every animal. A method that is sufficient to restrain one animal may prove aggravating to another; e.g. while the common twitch may serve for a heavy draught gelding, it is likely to cause a thoroughbred stallion to be more restive than ever. A person who finds it necessary to employ some means of restraint should first of all consider the temperament, age, breed, and, if possible, the individual characteristics of the animal, as well as the purpose of the restraint, before deciding upon what methods will be employed. Firm gentleness, a kindly spoken word, and a hand-pat, with a little coaxing or urging, will very often allay an animal's fears, but there are those of a temperament which will not respond to gentleness; it is to those particularly that such methods as described here are applicable.

Horses The usual halter, head-stall, or bridle is generally sufficient to control broken horses that are to be handled or examined without the infliction of pain. In some cases it may be necessary

VetBooks.ir

to tie the animal to a ring in the wall or manger, or to the heel-posts, but it is better in such cases to take a couple of turns round the ring and have a man hold the end of the rope. For measures which involve handling of the hind-parts of the body, it is usually advisable to have one of the fore-feet picked up and held (preferably that upon the same side of the body as the operator is to work).

For greater control a TWITCH may be applied. (See also TRANQUILLISERS; ANAESTHESIA, GENERAL.)

Cattle A cattle CRUSH; either of a commercial pattern or one constructed of timber by farm labour, is useful; a gate may be hinged to a wall and closed so as to act as a crush for inoculations, etc. (See also VETERINARY FACILITIES ON THE FARM.)

A halter is also useful in cattle, as in horses.

In the case of comparatively quiet cattle, milk cows, etc., it will generally suffice if an assistant takes the animal by the nose. The thumb and middle finger of one hand are inserted into the respective nostrils, and the nasal septum is pinched between them. It is important that the stockman's fingers do not block up the airway.

The other hand may be placed under the jaw. In this position the majority of adult quiet cattle can be easily held. For bulls and those cattle that are more difficult to control it is usual to use a pair of bull-holders ('bull-dogs'; 'bull-tongs'); or if the animal is already rung (with a copper or aluminium ring), to attach a rope or bull-leader to the ring in the nose. For drenching purposes it is necessary to keep the head and neck in as straight a line as possible to obviate the risk of choking. If an assistant is needed he should stand on the opposite side of the beast and take the horns in his hands so that he may tilt the head upwards and at the same time keep the head and neck straight out. A pair of bull-holders may be inserted into the nostrils, and have a rope attached to them which is passed over a beam and the head pulled up.

For lifting a hind-leg, a pole, broom handle, etc., may be placed in front of that hock and behind and above the other. Two helpers take hold of ends of the pole and pull the leg upwards and backwards, at the same time steadying the animal's balance by leaning against its thighs with their shoulders. For the fore-feet it is usual to pass a rope around the cannon or above the heels and over the back to the opposite side, where it is held by an assistant. (See also TRANQUILLISERS.)

Sheep For most purposes the sheep may be turned up into a position in which it sits upon its rump, by placing the left hand round under the neck from the near side, and the right hand over the back to seize the wool of the abdomen, lifting the animal's fore-end off the ground and twisting its hind-legs from under it. In this position its feet may be dressed, its fleece may be examined, etc. It is not advisable to turn in-lamb ewes, due to the possibility of harming them or the fetus; they may be held against a wall or fence by an assistant while their feet, etc., are being dressed. Sheep stocks are sometimes used, or modern shearing tables.

Pigs The adult pig is proverbially a difficult animal to handle and restrain, especially when the handling involves pain or discomfort, but piglets are easily held by the hind-legs with the hands, while the knees grip the dependent head. With large sows and boars it is wise to remember that they are apt to be vicious with strangers, and to use a shield of wood or a hurdle to prevent a rush by the angry animal.

A method of securing a large pig is to drive it into a corner and pen it there with a door, gate, or heavy hurdle carried by two helpers, and held so that the pig has no room to turn, while a pig snare should be placed over the top jaw behind the tushes and then pull forward. The pig will naturally pull back and is restrained. Ideally, boars and sows should be restrained in a custom-made pig crate.

Dogs and cats These animals are usually more easily restrained than some of the larger animals because of their intimate association with man, but there are certain animals that present difficulty when angry or excited. A kind word and a caress will often be necessary to gain the animal's confidence before attempting to examine it, and, wherever possible, severe methods of restraint should be avoided except as a last resort. The human voice often exercises a degree of control over an excitable animal, and there are certain people who appear to possess the faculty of immediately gaining almost any dog's confidence and of being able to do anything with it.

However, it is always wise in any case of doubt to take no risks. The safest way of dealing with a dog is to muzzle it first. A tape muzzle may be applied; this is simply a piece of tape or a bandage about 118 cm (3 ft) long whose middle is wound round the dog's nose, the ends being crossed under the jaw and tied round the neck or on to the collar. With bulldogs, and those with a short face and a pug nose, it is better to tie the tape round the jaws, finishing with the end above the nose, tying them together there, and then passing the ends back to the collar.

Cats can be rolled in a sack or towel. With cats it is important to prevent them from using their claws, which inflict injuries more often than the teeth. (See also under TRANQUILLISERS; ANAESTHESIA, GENERAL.)

Resuscitation

A basic method of pulmonary resuscitation with expired air, using a device portable and simple

VetBooks.ir

enough for emergency use by herdsmen and shepherds, is in use on farms. The device consists of a mouthpiece, non-return valve, flange, and mouth tube. (See ARTIFICIAL RESPIRATION; RESPIRATORY STIMULANTS; ACUPUNCTURE.)

Retained Foetal Membranes (RFM)
(See PLACENTA - RETAINED PLACENTA.)

Retained Placenta
(See PLACENTA - RETAINED PLACENTA.)

Retained Spectacles
A clear film over the eyes of some reptiles. (See also SPECTACLES.)

Retention Cyst
A swelling caused by the accumulation of a secretion, when the outlet of a secreting gland is blocked. Retention cysts can occur in any secretory gland, such as kidneys, mammary glands, mucous membrane glands, pancreas, salivary and skin or SEBACEOUS GLANDS.

Retention of Afterbirth
(See PLACENTA - RETAINED PLACENTA.)

Reticulitis
Inflammation of the RETICULUM.

Reticulocytes
The penultimate stage in the formation of red blood cells. Reticulocytes are numerous in the blood only in anaemic conditions and indicate an effort of the blood-forming tissues to restore the red blood cell count to normal levels.

Reticulo-Endothelial System
This consists of macrophages, lymphocytes which are special cells present in the liver, spleen, lymph nodes and bone marrow. The system has a number of functions including the regulation of immune responses (see under ANTIBODY). It also removes disintegrating red cells from the blood.

Reticuloendotheliosis
Conditions affecting the reticulo-endothelial system. Many of the conditions are seen in poultry and are caused by reticulo-endothelial virus of the RETROVIRUS group. It results in immunosuppression and neoplastic problems including MAREK'S DISEASE and AVIAN LYMPHOID LEUKOSIS.

Reticulum
The second stomach of ruminants.

Retina
The innermost layer of the eye; it includes the light-sensitive rods and cones which transmit impulses to the optic nerve. Detachment of, or haemorrhage into, the retina is a cause of sudden blindness in dogs and cats. It is often due to hypertension, the long-term effects of which may be hypertrophy of the left ventricle of the heart and kidney failure. (See EYE - COATS OF THE EYEBALL – The Retina and EYE, DISEASES AND INJURIES OF.)

Retinal Diseases
Many are inherited and include COLLIE EYE ANOMALY, PROGRESSIVE RETINAL ATROPHY, RETINAL DYSPLASIA, and RETINAL PIGMENT EPITHELIAL DYSTROPHY. (See also EYE, DISEASES AND INJURIES OF.)

Retinal Dysplasia
A congenital condition seen in most species. There is abnormal differentiation of the retinal cells and proliferation of the photoreceptors which form rosettes. The effects can vary from no noticeable impairment of sight to complete blindness. It can be the result of viral infections such as BLUE-TONGUE, BOVINE VIRAL DIARRHOEA, CANINE HERPESVIRUS and FELINE PANLEUKOPENIA. It is also an inherited condition seen in some breeds of dogs and cattle. It can be seen in AMERICAN COCKER SPANIELS, BEAGLES, BEDLINGTON TERRIERS, CAVALIER KING CHARLES SPANIELS, COCKER SPANIELS, ENGLISH SPRINGER SPANIELS, HUNGARIAN PULIS, LABRADOR RETRIEVERS, ROTTWEILERS, SEALYHAM TERRIERS.

Retinal Pigment Epithelial Dystrophy (RPED)
This is also called CENTRAL PROGRESSIVE RETINAL ATROPHY: it is not the same as PROGRESSIVE RETINAL ATROPHY. It involves the retinal pigment epithelium. There are changes in the tapetal fundus, with attenuation of retinal vasculature and atrophy of the optic disc. Signs begin with effects on day vision followed by further visual impairment, although blindness does not always result. It is usually seen in middle-aged dogs including BORDER COLLIES, BRIARDS, COCKER SPANIELS, CORGIS, ENGLISH SPRINGER SPANIELS, GOLDEN RETRIEVERS, IRISH SETTERS, LABRADOR RETRIEVERS, ROUGH COLLIES, SHETLAND SHEEPDOGS, SMOOTH COLLIES.

Retinoblastoma
A type of TUMOUR which occurs on the RETINA.

Retriever Dogs
(See LABRADOR RETRIEVER.)

Retro-
Retro- is a prefix signifying behind or turned backwards.

VetBooks.ir

Retrognathia
The underdevelopment of the maxilla and/or mandible. It is seen particularly in dogs and in breeds including BOSTON TERRIERS and PEKINGESE.

Retrognathism
The state of RETROGNATHIA in an animal.

Retropharyngeal Abscess
Retropharyngeal abscess is the name given to an abscess occurring at the back of the throat in the region behind the pharynx. Such abscesses generally make swallowing difficult or impossible until they burst, which they frequently do into the cavity of the pharynx, whence the pus is swallowed. (See STRANGLES.)

Retrovirus
A member of the Retroviridiae, the family of viruses which includes the lentiviruses and the oncornaviruses. Retroviruses are naturally occurring gene transfer organisms. When the virus infects a cell, it is uncoated; the viral RNA is transcribed into DNA and this DNA integrates into one of the cell's chromosomes. This property could be used to produce disease-resistant transgenic animals. Certain viral groups appear to need the presence of a receptor on the cell membrane in order to gain access into the cell. Retroviruses are enveloped viruses and carry a glycoprotein on their surface; a specific interaction with this glycoprotein and the cellular receptor is a prerequisite for infection. Immunodeficiency viruses of humans, cats, cattle and primates are retroviruses.

(See table under VIRUSES; also GENETIC ENGINEERING.)

Reverse Transcription
A method of acquiring or obtaining a gene. It is the direct opposite of TRANSCRIPTION.

Reverse Transcription Polymerase Chain Reaction (RT-PCR)
A laboratory technique: a polymerase chain reaction which results in the transcribing of a RNA strand into its DNA complement (complementary DNA or cDNA) using the enzyme reverse transcription. The resulting DNA can then be amplified using PCR.

Revivon
(See IMMOBILON/REVIVON.)

RF
Abbreviation for RHEUMATOID FACTORS.

R Factor
(See PLASMIDS.)

RFM
Abbreviation of RETAINED FOETAL MEMBRANES. (See PLACENTA - RETAINED PLACENTA.)

RFM
(See RECYCLED FARMYARD MANURE.)

Rhabdomyolysis
Rhabdomyolysis, also called azoturia, is a breaking down of skeletal muscle in consequence of which the urine contains myoglobin. (See EQUINE RHABDOMYOLYSIS; POLYSACCHARIDE STORAGE MYOPATHY.)

Rhabdovirus
A group of bullet-shaped viruses which includes the RABIES virus and that of VESICULAR STOMATITIS. Several rhabdoviruses are associated with disease conditions in fish.

Rhea
A flightless bird with grey-brown plumage, long legs and long neck; it is smaller than the ostrich, about 120 cm (4 ft) tall, and has three toes. There are several species, of two types: the greater rhea (e.g. American rhea) (*Rhea Americana*) and the lesser rhea (e.g. Darwin's rhea) (*Rhea pennata*).

Rheumatism
A general term indicating a painful condition of muscles, tendons, joints, bones or nerves; it may be less common in animals than in humans (or they are more stoical).

Rheumatism is seen in dogs, pigs and horses most commonly, but it can affect all of the domesticated animals. Young animals are most often attacked by the acute type, especially young pigs and puppies, and adults by the muscular form and by chronic or particular rheumatism.

For the muscular type see under MUSCLES, DISEASES OF.

Treatment This should be directed at the specific cause of the problem. However, certain drugs have enjoyed a reputation in the alleviation of this disease, especially salicylates. Phenylbutazone has been used with reported success. It is important that treatment is under veterinary control as many proprietary human analgesics are toxic to dogs and cats. (See also CORTISONE.)

Rheumatoid Arthritis
An uncommon autoimmune disease that affects multiple joints, leading to cartilage damage and joint collapse. It is seen in dogs (usually small breeds) and in cats. It usually affects young to middle aged individuals.

VetBooks.ir

Signs are at first vague; the dog appears depressed, often with a poor appetite and some degree of fever, but with no lameness. There is reluctance to move, with swelling and pain in several joints simultaneously, sometimes affecting one limb and then shifting to another. As the disease progresses crepitus and collapse of the joints occurs.

Diagnosis depends for confirmation upon radiography, joint fluid analysis and on laboratory tests demonstrating the presence of autoantibodies or rheumatoid factors (RF).

Treatment requires immunosuppression therapy: the prognosis is guarded.

(See also AUTO-IMMUNE DISEASE.)

Rheumatoid Factors (RF)

Autoantibodies (antibody directed against an animal's own tissues). The antibodies, mainly of IgM but also IgG, are directed against antigenic determinants on the Fc region of other immunoglobulins. The Fc region mediates the half-life and effector functions such as complement-dependent cytotoxicity. When the immunoglobulin binds with an antigen there are changes in the folding at the protein at the Fc region. This change in folding allows exposure of new non-self antigenic determinants and it is to these that rheumatoid factors (other antibodies) are directed.

Rhinitis

Inflammation of the NOSE AND NASAL PASSAGES.

Rhinitis, Atrophic

This has been defined as the product of a severe persistent inflammatory reaction in the nasal mucosa of a growing, and therefore very young, pig, and as such is non-specific with regard to aetiology.

The generally accepted view is that in the first two or three months of life, the rapidly growing nasal structures are extremely liable to attack by infectious agents – but quite often, recovery from these is complete. In herds with severe disease, however, the condition may progress to give rise to the marked displacement or atrophy of the turbinate bones and also to an associated pneumonia (see illustration opposite).

Causes *Bordetella bronchiseptica, Pasteurella multocida* and *Pseudomonas aeruginosa*, as well as INCLUSION BODY RHINITIS virus, may all be involved at some stage. Respiratory disease in the pig is a changing, developing process with many agents and factors involved; rhinitis and pneumonia often occur together.

From other sources it is known that *B. bronchiseptica* secretes a substance which inhibits the deposition or transfer of calcium salts in the infected tissues. Accordingly the bones may fail to ossify properly or may become weak and liable to distortion.

The disease in a severe form may occur only when there is a double infection with *B. bronchiseptica* and *P. multocida*.

Signs The acute form is to be found in piglets two or three weeks old, when there is no deformity of the snout to be seen and not always an overflow of tears. Sneezing is perhaps the most common sign. The eyelids may be puffy, and sometimes the piglet has a copious discharge from its nose and breathes through its mouth. The disease can be so mild that signs pass unnoticed, or so severe that death occurs within a week. In some outbreaks the mortality is 10 per cent or more, and survivors suffer a growth check from the disease which continues in the subacute form.

Distortion of the pig's snout as a result of atrophic rhinitis. (With acknowledgements to Professor R. H. C. Penny and the Royal Veterinary College.)

Incidence A 1974 survey of production pigs in England and Wales in five abattoirs revealed obvious atrophy of the turbinate bones in over 44 per cent and severe atrophy in over 17 per cent of the snouts examined. The condition has become much rarer, and any changes tend to be mild.

Prevention Inactivated vaccines prepared from *B. bronchiseptica* and *P. multocida* are available.

Rhinopneumonitis

(See EQUINE VIRAL RHINOPNEUMONITIS.)

VetBooks.ir

Rhinosporidiosis

A chronic disease of the nasal mucous membrane, and associated with polyp formation leading to difficulty in breathing, caused by a fungus *Rhinosporidia seberi*. The disease occurs in cattle and horses, in the USA, South America, Australia and India.

Rhinotracheitis, Infectious Bovine (IBR)

A disease of cattle recognised in the USA in 1951.

Cause The bovine herpesvirus 1, which can produce disease of the respiratory, reproductive, nervous and digestive systems.

Signs In America the disease is usually severe in feedlot cattle, but mild in dairy/range cattle. In Britain outbreaks of severe IBR occurred in 1978–9, causing heavy losses on some farms, with reduced milk yield, loss of appetite, fever (up to 42° C [108° F]), laboured breathing, a discharge from eyes and nose, and sometimes drooling of saliva. Reproductive disorders such as vulvo-vaginitis and orchitis have also occurred in Britain. In America abortion has followed natural infection or vaccination against IBR.

IBR is sometimes associated with a fatal pneumonia. The disease may closely resemble mucosal disease, with which at one time it was thought to be possibly identical, and also malignant catarrh.

At least one strain of the virus is neurotropic and has caused encephalitis in calves in Australia and elsewhere.

Control Live vaccines are available; depending on the product, they are given by intranasal application or by intramuscular injection.

Rhinovirus

This genus of viruses have RNA as their nucleic acid and include equine rhinovirus. They can cause upper respiratory tract infections.

Rhipicephalus sanguineus

Also known as the Brown dog tick. It is found in many parts of southern Europe and is the main vector for BABESIOSIS, EHRLICHIOSIS and HEPATOZOONOSIS. (See also TICKS.)

Rhode Island Red Chickens

A breed originating in Rhode Island and Massachusetts, USA. It is dual purpose and produces about 200 brown eggs per year; more if well fed. It is red-brown in colour with yellow legs and a single wattle. The hen weighs 2.9 kg (6.5 lb) and the cockerel 3.4 kg (7.5 lb).

Rhodesian Ridgeback

A very large, smooth coated, tan or red-coated dog with the unique characteristic of a strip of hair running from tail to the base of the neck along the back opposite to the normal lie of the rest of the coat. This may account for the breed being prone to sebaceous cysts in that region and to DERMOID SINUS. MEGAOESOPHAGUS or ACHALASIA OF THE OESOPHAGUS may be inherited but the mechanism is unknown. HIP DYSPLASIA appears to be multifactorial and 'WOBBLER' SYNDROME (CERVICAL SPONDYLOPATHY) is possibly a recessive trait. There is a DNA test for DEGENERATIVE MYELOPATHY.

Rhodococcus

Rhodococcus equi causes pneumonia especially in foals. It was formerly called CORYNEBACTERIUM.

Rhododendron Poisoning

Rhododendron poisoning is not common. There are about 20 varieties which have been recorded as causing poisoning in sheep, cattle, goats (especially) and even man. The shrubs contain a glycoside called andromedotoxin, which is the only poison capable of making ruminants vomit.

Poisoning may occur when sheep are brought in to graze former amenity land on an estate. In one outbreak, lambs were turned into a crop of rape bordered by rhododendrons, before having had time to adjust to the new diet. Signs include projectile vomiting, salivation, dullness, recumbency and death.

Weak tea may be helpful in countering the effects; the tannin acts as an antidote.

Rhonchi, Dry Sounds

Rhonchi (dry sounds) sometimes referred to as 'dry rales'; continuous sounds heard during breathing by auscultation of the chest, when there is some obstruction of the bronchi. (See also RALES.)

Rhoncus

An abnormal sound detectable by means of a stethoscope and indicating chronic inflammation of a bronchial tube.

Riboflavin

(See under VITAMINS - VITAMIN B.)

Ribonucleic Acid (RNA)

A substance related to DNA, RNA includes the sugar ribose combined with nucleic acid. It appears to be concerned with protein synthesis within the cell. (See CELLS.) In some experiments it has been shown that RNA from malignant cells will cause normal cells *in vitro* to show characteristics of malignancy; and the converse is possible. (See VIRUSES; CANCER; GENETIC ENGINEERING.)

Ribose

A 5-carbon sugar found in RNA (RIBONUCLEIC ACID).

Ribosomes
Ribosomes are granules containing RNA. (See CELLS.)

Ribs
Ribs are the long bones which together form the cage of the thorax. Their numbers vary in the different animals, according to how many thoracic or dorsal vertebrae are present, as follows: horse, 18 pairs; ox, 13 pairs; pig, 14 or 15 pairs; dog, 13 pairs. In any of these animals an extra rib (often called a 'floating rib' because it possesses little or no cartilage to unite it to the costal arch) may be present on one or both sides of the body. The first eight of these in the horse and ox, the first seven in the pig, and the first nine in the dog, have cartilages which are united to the sternum, and are called sternal ribs, while those further back in the series in each case have cartilages which do not reach the sternum, but form an arch by overlapping each other, and are known as asternal ribs. (See STERNUM.)

Each rib possesses a 'head', by which it is joined to the anterior part of the vertebra to which it corresponds in number, and to the posterior part of that immediately in front, and this is succeeded by a 'neck'; a short distance further down the shaft is a 'tubercle', which articulates with the transverse process of the vertebra to which it corresponds. The rest of the rib is composed of a long, curved, flat shaft, whose curve varies according to the position of the rib in the chest, being greatest about the middle of the series, and also according to the animal to which it belongs. Posterior to each runs the intercostal nerve and blood vessels which are situated in a little groove along the borders of each rib. The ribs are attached to each other by the intercostal muscles to form the continuous wall of the chest. (See BONES.)

R

Ricinus communis
The plant from which castor oil is obtained.

Rickets, Rachitis
Rickets (rachitis) is a deficiency disease of young animals characterised by a tendency towards the formation of enlarged extremities of the long bones, and a bending of their shafts. Dogs, pigs, lambs, foals and calves are all affected, the first two more frequently than the other species of domesticated animals. It has also been encountered in intensively managed poultry establishments where chicks are deprived of sunlight.

Cause Rickets may be caused by a deficiency of either vitamin D or phosphorus, or in some cases both of these.

Absence of sunlight is a contributory cause and animals kept in dark buildings, especially if inadequately fed, are prone to rickets.

Often a diet consisting largely of oatmeal or maize meal, such as is commonly the lot of sheepdogs, results in rickets. (See PHYTIN.)

Signs The typical changes consist of the development of bony swellings upon the ends of the long bones of the limbs, where they meet other bones to form joints, and the production of swellings at the point where a rib joins its rib cartilage, i.e. along each side of the chest about two-thirds the way down from the spine. In puppies, there is also a tendency for the shafts of the long limb to bend in an outward direction under the influence of the weight of the body.

Treatment A vitamin D supplement is recommended or fresh COD-LIVER OIL. (See also OSTEOMALACIA.)

Rickettsia
The generic name for a group of minute Gram-negative bacteria that are non-motile and pleomorphic: they can be present as cocci, rods or are thread-like. They will not grow in ordinary culture media, and their metabolic requirements are more akin to those of the filterable viruses. They are distinguished from *Chlamydiales* and other bacteria by being found in the cytoplasm of arthropods such as ticks, lice, mites and fleas. (For rickettsial infections in cattle, see TICK-BORNE FEVER OF CATTLE; Q FEVER. For tropical diseases caused by rickettsiae, see BOVINE INFECTIOUS PETECHIAL FEVER; HEARTWATER; see also ROCKY MOUNTAIN FEVER.)

Rickettsial Pox
A mild form of mite typhus transmitted to people by the mouse mite *Allodermanyosus sanguineus*, and caused by *Rickettsia akari*.

Ricobendazole
A broad-spectrum anthelmintic licensed for use in sheep. It is ovicidal and effective against mature and immature round worms, lungworms, tapeworms and adult flukes.

Rida
A disease of sheep involving the nervous system, similar to SCRAPIE, in Iceland.

Rideal-Walker Coefficient
Expresses the comparative efficiency of antiseptics, as based on the Rideal-Walker Test, taking carbolic acid as unity. It does not take into account the influence of body fluids or organic matter upon the efficiency or otherwise of the antiseptic.

Ridgling
(See RIG.)

VetBooks.ir

Riding Establishments Act 1970

The Riding Establishments Act 1970 sets out the standards which riding schools and similar establishments must meet to obtain a licence to operate. It empowers local authorities to select a veterinary surgeon to inspect, and report upon, a riding establishment. The decision on whether to grant a licence is based on that report. Points taken into consideration include the competence of the owner, the suitability of the accommodation, the supply of food, water and bedding, the availability of veterinary treatment, and satisfactory provisions for evacuation of horses in case of fire. Prosecution may follow if the terms of the Act, or licence, are broken.

Rifampicin

This bactericidal antibiotic has proved effective against some bacteria resistant to other antibiotics. It is sometimes used in combination with erythromycin.

Rift Valley Fever, Enzootic Hepatitis

A disease of sheep, cattle, buffaloes, goats, camels, horses, donkeys and man, occurring in Africa. Until 1973 it had not been recorded in northern Africa, but in that year it reached the Sudan, and then Egypt, where major epizootics occurred in 1977–8. In 1982 the World Health Organisation (WHO) stated that this disease might be of greater concern outside Africa than in many of the countries where it is endemic; and expressed anxiety over its possible spread to Mediterranean and Middle East countries that were unprepared for it. Rift Valley fever is a NOTIFIABLE DISEASE throughout the EU.

Cause A bunyavirus, transmitted by mosquitoes. The virus causes necrosis of liver cells; also abortion.

Signs The disease is seen at its most acute in young lambs, which die within a few hours. Fever, vomiting, ataxia, and death within a day or two may occur in older lambs, calves, and occasionally adult sheep. Mild or subclinical infections also occur in adult animals. Abortion accounts for much economic loss; also a temporary halt in lactation.

Prevention A live vaccine made from the attenuated Smithburn strain of the virus was WHO approved in 1983.

Public health The human illness is like an acute attack of influenza, and sometimes there is also an encephalitis lasting 5 to 15 days, which may prove fatal. Jaundice may occur in another fatal form of the disease. Impairment of vision may be permanent as a result of inflammation of the retina.

The 1977–8 outbreaks in Egypt involved over 200,000 human cases, with nearly 600 deaths, and about 800 cases of eye disease and encephalitis, respectively.

Rig, Ridgling

A male animal in which one or both testes do not descend into the scrotum from the abdomen at the usual time. (See also under CRYPTORCHID; MONORCHID; GELDING.)

Right Displacement of the Abomasum (RDA)

A condition usually of dairy cows and is much less common than LEFT DISPLACEMENT OF THE ABOMASUM in the UK and USA, although common in Denmark. The cause is unknown but follows ATONY, and then food and fluid accumulate within the ABOMASUM. Onset is insidious, with varying degrees of inappetance, KETOSIS and reduced milk production. Often there is then TORSION and the condition becomes severe and acute, with usually noticeable right side distension, and a dull, depressed HYPOTHERMIC cow. Once torsion occurs, treatment is by surgery. When there is just distension, METOCLOPRAMIDE HYDROCHLORIDE has been used successfully.

Rigor Mortis

Temporary stiffening of the muscles several hours after death (e.g. four to eight hours in the pig carcase). It is associated with the breakdown in the muscles of adenosine triphosphate (ATP), which also occurs when muscles contract during life.

Rigors

Shivering fits. When prolonged, rigors may be the warning sign of the approach of some disease or fever.

Rima

Rima is a term meaning a crack or fissure, applied to any narrow natural opening, e.g. rima glottidis, the space between the vocal cords.

Rinderpest, Cattle Plague

Rinderpest (cattle plague) is an acute, specific, inoculable and febrile disease of cattle, characterised by an ulcerative inflammation of mucous membranes, especially those of the alimentary tract. It is caused by a morbillivirus related to canine distemper virus. It is a NOTIFIABLE DISEASE throughout the EU.

This disease ravaged Europe intermittently for 15 centuries. In France, a very severe outbreak resulted in the government establishing the first veterinary college at Alfort in the late 18th century. Following the Great Exhibition of 1851, the UK adopted a free trade policy and rinderpest entered

VetBooks.ir

the country with cattle from the Baltic states. This prompted the British government to set up the Cattle Plague Department of the Privy Council, which was the forerunner of the State Veterinary Service. The last case in Britain was in 1877.

A global rinderpest eradication programme was set up by the UN FOOD AND AGRICULTURE ORGANIZATION (FAO) in the 1990s with the aim of eradicating the disease by 2010. The disease was declared eradicated worldwide by the World Organisation for Animal Health in May 2011, confirmed by the FAO on 28 June 2011. It is only the second disease to be eradicated (the first was human smallpox).

One of the most serious threats to world food supplies, cattle plague – like foot-and-mouth disease – is caused by a virus, but causes more fatalities. When cattle plague strikes a herd, 9 out of 10 animals may die – a catastrophe which is not infrequently followed by famine – and the total loss of food and draught animals (cattle and buffaloes) from this cause is immense.

Susceptibility Cattle are by far the most susceptible animals. Eland and bush pig are known to contract rinderpest, and ailing wild game may carry infection to healthy cattle. Sheep and goats occasionally become infected; and the disease may exist subclinically in sheep and goats for a time, with consequent risk of an outbreak among unvaccinated cattle.

Most pigs show only a mild fever, with some depression and anorexia; they could, therefore, act as a means of transfer of virus from contaminated meat to cattle. Horses are immune.

Incubation period three to nine days.

Signs include fever, dullness and loss of appetite. Soon the nasal mucosa becomes red and gives off a watery discharge which then becomes mucoid. The mouth is found to be pasty and inflamed.

Ulcers occur in front of the incisor teeth, on the gums, inside the cheeks, on the borders of the tongue, and in front of the dental pad. The epithelium comes off in bran-like scales, leaving a ragged surface. This feature of the ulcers is important as one of the distinguishing characters from the ulcers found in foot-and-mouth disease.

Constipation gives place to diarrhoea of a fetid nature. The diarrhoea is followed by dysentery. The affected animal becomes very weak and emaciated.

In milking-cows the milk falls off. Pregnant cows usually abort at the height of the disease. The lungs are affected only in chronic cases, as a rule.

Course and duration The disease is usually acute, lasting 4 to 10 days. Death may claim up to

Rinderpest. This buffalo is showing what is usually the first sign of the disease — a discharge from the eyes. (Unations.)

90 per cent of the victims, while at other times the death-rate may be as low as 20 per cent.

Duration of immunity Cattle were immunised with a single dose of a rinderpest cell culture vaccine and maintained in a rinderpest-free environment for 6 to 11 years. They were then challenged by either parenteral or intranasal inoculation of virulent virus or by contact exposure to reacting cattle. None of the vaccinates reacted clinically and a rinderpest viraemia was never detected.

Cross-immunity Infection of dogs with the rinderpest virus apparently confers immunity against distemper.

Ring-Bones

A term used for any bony exostosis affecting the interphalangeal joints of the horse's foot, or indeed any bony enlargement in the same region: (1) high ring-bone, where the pastern joint (i.e. between the long and short pastern bones) is the seat of the disease; (2) low ring-bone, where the deposit occurs round the coffin-joint, between the short pastern bone and the coffin-bone; and (3) false ring-bone, where the enlargement occurs upon the shaft of one of the bones and does not involve the edges of a joint surface (though it may do so later). From the point of view of etymology it would appear that the term 'ring-bone' should be restricted to conditions in which a partial or complete ring of bone is formed round one or other of the joints, and that all other bony enlargements affecting the surface of the shaft of the bones, but not involving the edges of the joint surfaces, should be called exostoses. Difficulty arises, however, when examining a horse's foot, in determining exactly whether the joint surfaces are affected, or are likely to become affected, in any particular given case.

Causes Injury, inflammation of the periosteum or of the bone – sometimes following infection, possibly a vitamin D deficiency.

Signs In the early stages nothing more than a fleeting lameness is seen. Eventually the horse will go lame all day if it is worked, or becomes too lame to take out of the stable. After a time one or other of the joints becomes enlarged, and the cause of the lameness becomes obvious. It is only in the case of high ring-bones (around the pastern joint) that the exostosis can be felt; when the lower (coffin) joint is affected there is at first no outward visible or palpable sign; but after a time the hoof alters in shape, becomes distinctly bulged or 'buttressed' at the coronet. This latter effect is due to the fact that in low ring-bone the extensor or pyramidal process of the coffin-bone is usually involved, and the deposit of bone upon it pushes the coronet, and the wall which grows from it, in an outward direction ('pyramidal disease'). At times the alteration in the outline of the hoof is not by any means regular; it may be bulged at any point from one heel to the other, denoting a deposit of bone wherever there is a bulge.

In 'true ring-bone' the joint that is affected almost always ends by becoming stiff (ankylosed), owing to fusion between its complementary bones and obliteration of the joint having occurred. In this state the horse may become fairly sound, because the pain occasioned by movement at the joint has disappeared, but the gait will always be stiff.

Treatment Prolonged rest in a loose-box or, preferably, at grass is indicated. More harm than good results when blistering is carried out. Corticosteroids may be used.

Ringer's Solution

Ringer's solution is a sterile liquid for the irrigation of wounds, etc. It consists of sodium chloride, 9 grams; calcium chloride, 0.25 g; potassium chloride, 0.42 g per litre. Lactated Ringer's Solution is isotonic with blood, for parenteral use.

'Ring Eyed'

A name given to the iris where there is an absence of pigment. Also known as WALL EYE. It is seen in horses, rarely in cattle but in some breeds of dogs (Collies and other sheepdogs). (See EYE - FRONT OF THE EYE; WALL EYE.)

Ring Vaccination

A disease-control process by which susceptible animals in a prescribed area surrounding an outbreak are vaccinated. It is used, for example, in the control of foot-and-mouth disease where there is no slaughter and eradication policy. Vaccination is begun at the perimeter of the areas, progressing inwards towards the centre. For success, diagnosis, typing of virus and the vaccination itself must all be speedy. It has been used, for example, in the control of FOOT-AND-MOUTH DISEASE where there is no slaughter and eradication policy. However it may be integrated with a slaughter and eradication policy in the UK and EU.

'Ringwomb'

This is the colloquial name for a condition which sometimes complicates lambing, and is due to failure of the cervix to dilate. Usually, the *os uteri* will admit 1 or 2 fingers, which can feel what seems like a firm ring.

The shepherd may recognise the condition on seeing a small portion of fetal membrane

protruding from the vulva. The ewe remains in good health (but does not lamb) until death and decomposition of the fetus occur.

Manual dilation of the cervix is practised by some veterinary surgeons. Should this prove impossible, Caesarean operation is the only alternative. (See UTERUS and PARTURITION.)

Ringworm

A contagious skin disease caused by the growth of certain fungi, which live either upon the surface of the skin or in the hairs of the areas affected. It also occurs in birds, but the crusty, flaky lesions are normally limited to the skin and do not appear to affect the feathers. Ringworm may affect any of the domesticated animals, but it is probably commonest in young store cattle when they are enclosed in buildings during winter, and in pet cats and kittens. Dogs and horses are also frequently affected, but the disease is not often seen in the sheep and pig in the UK.

Ringworm and favus (see below) in the domesticated animals are caused by parasitic fungi which belong to the family Gymnoascidae.

Lesions generally Ringworm appears in the form of patches of dry, raised, crusty skin, from the surface of which the hairs have fallen and upon the surface of which there are scales or scabs. The patches are often more or less circular, but in bad cases large irregular areas may be produced, which result from the coalescence of adjacent areas. Favus is a type of ringworm seen in birds due to *Trichophyton gallinae*. Favus also affects the dog and cat, the mouse and rat, rabbits sometimes, and fowls occasionally. The lesions have cup-shaped depressions which bear some similarity to a honeycomb, from which they get their name (*favus*, honeycomb). The lesions are usually crusty and flaky and are normally limited to the skin and possibly the feathering can become infected.

Horses Ringworm may be due to parasites belonging to the genera *Trichophyton* or *Microsporum*. In cases due to the former, the first affected areas are usually confined to the head, neck, withers and, sometimes, to the root of the tail. The hair becomes matted in patches about the size of a large coin, and in the centre of each patch appears a bare area from which the hair has fallen off; this gradually extends until the whole area is denuded. The skin becomes raised and scurfy, and greyish-white crusts are formed; at times there may be grey or yellow scales adherent to begin with, but becoming detached later. There is usually little or no itchiness, except when due to *T. mentagrophytes*.

When the horse is affected with ringworm due to *Microsporum* parasites, practically any part of the body may be attacked.

Cattle Ringworm is nearly always due to *T. verrucosum* infection. It is very common among young animals in autumn, winter, and early spring, especially if they are kept indoors. The head and neck are most often affected, especially the eyelids, lips, ears and above the jaws, but it may occur anywhere on the body. The lesion begins as a raised ring-like patch on which the hairs stand erect. In a day or so the hairs fall off, and the surface of the skin becomes covered with masses of scales heaped up into a greyish-white or greyish-yellow crust. The areas are usually very numerous and often become confluent, so that large areas become bare of hair and present roughened, crusty, hard, dry surfaces with a tendency towards pronounced wrinkling of the skin around and between them. Where calves are extensively affected with ringworm there is always a good deal of loss of condition and itchiness.

Ringworm.

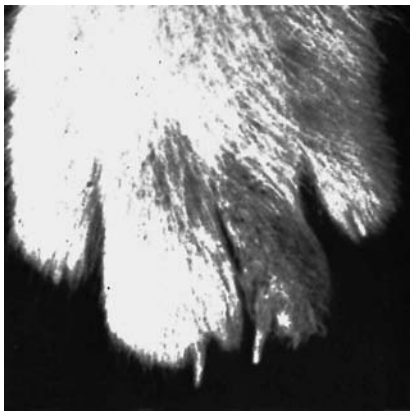
Sheep When they are affected the fleece becomes matted, and falls out in circular patches over the shoulders, neck and chest. *T. verrucosum* is one cause. Control is by isolating affected animals and disinfecting troughs, etc.

Dogs Ringworm may be caused by one of four genera: *Trichophyton, Microsporum, Oidmella*, or *Oospora*, the last-named causing favus. The lesions produced by the first three of these are very similar in all respects to those seen in horses and cattle. In favus caused by *Oospora canina* the lesion appears as a raised circular patch upon whose surface there is a pale yellow crust with little depressions (honeycomb) scattered through it. The skin in such cases is often very much thickened.

Hedgehogs Caused by *T. erinacei*, this infection may cause lesions on the face of dogs where the skin has been damaged by the hedgehog's spines.

VetBooks.ir

VetBooks.ir



The roughened appearance of an infected claw. *Microsporum canis* Bodin was responsible.

Cats Ringworm is of three kinds: due to *Trichophyton, Microsporum* and *Achorion*, the latter producing favus. When due to the first two of these, the signs and lesions can be similar to those seen in other animals although often there are no obvious lesions. Wood's lamp is of use but only indicates about half of the infections. (See ONYCHOMYCOSIS.)

Cats become infected from mice with mouse favus (*A. quickeanum* or *A. arlongi*), although it may also be due to *A. schoenleinii* – the favus of man. The lesions are chiefly confined to the forepaws and the head and the neck, though they may spread to other parts of the body. Itchiness is usually absent. The areas affected vary in size from that of a pin's head up to a 5p piece or so, and are not always regular in outline. The skin is thickened and the edges are raised. When newly formed, the covering crust is yellow and soft to the touch, but when old it is grey and powdery. The characteristic cup-shaped depressions are seen in most cases, but when affecting the claws they may be absent.

Ringworm due to *M. canis* Bodin is of public-health importance. It is often overlooked by owners, but children are readily affected.

A bare scaly patch on a kitten's toe due to ringworm.

Cats, especially Persians and other longhairs, may be 'carriers' of ringworm fungus. In a survey involving 200 selected cats seen at a veterinary clinic, none of them showed any sign of ringworm. Fur samples taken with a brush showed that 39 per cent of the 200 were carrying spores of ringworm

Ringworm in the cat: whitish, scaly lesion can be seen to the right of the ear, above the white fur.

fungi. (In 72 samples the spores were those of *M. canis*.) A survey in England of fur samples taken at four cat shows revealed that, overall, 35 per cent of longhairs were carrying *M. canis* spores.

Decontamination of households is important for human health after ringworm has been diagnosed. Hypochlorite, benzalkonium chloride, and glutaraldehyde-based compounds are recommended.

Favus in the fowl (honey comb ringworm), is due to *T. gallinae*, affects the comb, wattles and other parts of the fowl's head.

If the condition spreads down to feathered parts, the feathers become dry and brittle, and break off at the surface of the skin, leaving large bare areas. There is always a most disagreeable odour from fowl favus.

Treatment Oral administration of griseofulvin is by far the simplest method. Cattle and horses can be given a supplemented feed. This makes possible group treatment, and avoids handling of infected animals – thus reducing the risk of infection being transferred to man. However, it is inadvisable not to use griseofulvin in pregnant animals. In a cat itraconazole is available as an oral suspension, and thiabendazole (see ANTHELMINTICS) dip was successfully used.

Natamycin and enilconazole which are used as a wash or spray can be applied to infected cattle and horses with a knapsack sprayer. Ketaconazole, applied as a shampoo, may be used to treat dogs (not in the UK).

Otherwise, treatment consists, in the first place, of removing the hair from around the lesions, collecting it and burning it. There are many suitable dressings to choose from: e.g. gentian violet solution; undecylenate ointment; and copper naphthenate lotion, which has given rapid and good results in the treatment of ringworm in cattle. A vaccine for use in cattle is available.

Dressing should be carried out twice a week for a fortnight for cattle and horses, and by then most of the fungus will be killed. The cases should not be considered cured until there is a level crop of new hair over each of the areas. For the smaller animals it is better to use the dressing once every second day.

In all instances it is very important to remember that ringworm spreads from the centre outwards, and edges and margins of the areas should be especially well dressed.

Vaccination of calves against *T. verrucosum* involves two intramuscular doses, 10 to 14 days apart.

In Russia the vaccination of racehorses, and other horses taking part in competitive events, is compulsory.

Public health Ringworm is readily transmissible to human beings, so precautions such as handwashing and disinfection after contact with known infected animals should not be neglected. Dettol is useful for these purposes.

Diagnosis Microscopic examination or culture methods. (See also WOOD'S LAMP.)

RINSE
(See REDUCING THE IMPACT OF NON-NATIVE SPECIES IN EUROPE.)

Risk Determinant
(See DETERMINANT.)

Risk Factor
A term used in epidemiology to denote an increase (more susceptible) or decrease (less susceptible) in risk of developing a disease, infection or illness. The term DETERMINANT may also be used.

Ritual Slaughter
(See RELIGIOUS SLAUGHTER.)

RMS
(See RECYCLED MANURE SOLIDS.)

RNA
(See RIBONUCLEIC ACID.)

Road Accidents
Dogs and cats struck by cars may suffer chest injuries in addition to limb injuries. (See FRACTURES; ACCIDENTS; DIAPHRAGMATOCELE; HYDROTHORAX; PNEUMOTHORAX.)

Road Transport
In horses, heart rate and behaviour indicated that it was more stressful than air transport. (See TRANSPORT STRESS.)

Roaming
Roaming is a behavioural habit in certain male dogs and cats. If the animal does not respond to training from an animal behaviourist, it may be castrated – although there is no guarantee that this will stop the habit.

'Roaring' in Horses
An abnormal sound made when the horse breathes in; the usual cause has for long been regarded as vibration of the slackened vocal folds on one or both sides of the larynx, due to paralysis of the muscles which move the arytenoid cartilages outwards. (For treatment and further details, see LARYNGEAL PARALYSIS IN HORSES.)

Robenacoxib
A non-steroidal anti-inflammatory agent for dogs and cats given orally or by injection. It targets the

VetBooks.ir

pain-causing COX-2 enzymes whilst sparing the protective actions of COX-1 enzymes. It quickly leaves the bloodstream and then persists at the point or area of inflammation. It is used to provide pain relief and reducing inflammation caused by musculoskeletal disorders in cats and to relieve pain and inflammation in OSTEOARTHRITIS in dogs.

Robenidine

A coccidiostat used in poultry, turkeys and rabbits in the prevention of intestinal coccidiosis. It has no effect on hepatic or renal coccidosis.

Rock Salt

(See SALT - SALT LICKS.)

Rocky Mountain Fever

Also called Rocky Mountain spotted fever, this is a disease of man caused by *Rickettsia rickettsii*. Wild animals provide a reservoir of infection.

Rocky Mountain fever affects human beings usually between March and July. The onset of fever is sudden, and in two to five days a rash appears over the whole body, including the palms of the hands. The rash changes to a sort of mottling – petechiae, scattered over the skin, which gives the condition its name of 'spotted fever'. The infection is transmitted by ticks, especially *Dermacentor andersoni,* the Rocky Mountain wood tick.

Dogs The infection causes fever, abdominal pain, depression, loss of appetite, nystagmus, with sometimes conjunctivitis and petechial haemorrhages in the mouth. Oedema of a limb(s) is common, and the scrotum and prepuce may be similarly affected. Over 30 cases are confirmed serologically each year, with many more being diagnosed, in Long Island, New York.

Diagnosis is most reliably confirmed by the immunofluorescent test. Treatment is by antibiotics.

Precautions There is a risk to veterinarians taking a blood sample or carrying out a post-mortem examination, as the rickettsia is present in the blood during the acute phase.

Rodents

Rodents (see CHINCHILLAS, CHIPMUNKS, DEGUS, GUINEA-PIGS, HAMSTERS, MICE, RATS) form an order of mammals with a special adaptation of their teeth that allows them to gnaw hard objects. This is achieved by a rostro-caudal movement of the mandible. The constantly growing incisors withstand this use. Many species are kept as pets and many are important from a veterinary point of view on account of the diseases which they may transmit to domestic animals. For examples, see AUJESZKY'S DISEASE; SALMONELLOSIS; LEPTOSPIROSIS; RINGWORM; FOOT-AND-MOUTH DISEASE. In countries where the disease is present, rodents may transmit RABIES.

Zoonoses Members of the family Muridae (Old World rats and mice) can infect man with BUBONIC PLAGUE, TULARAEMIA, LISTERIOSIS, YERSINIOSIS, LEPTOSPIROSIS, BRUCELLOSIS, ERYSIPELAS, SWINE, MELIOIDOSIS, MURINE TYPHUS, Q FEVER, SCRUB TYPHUS and other rickettsioses, HISTOPLASMOSIS, LYMPHOCYTIC CHORIOMENINGITIS, LASSA FEVER, RABIES rickettsioses, and other viral infections, Asian SCHISTOSOMIASIS, CHAGAS DISEASE, RAT-BITE FEVER and HANTAVIRUS.

Rodenticides Substances used to kill rats and mice, etc. They are of two types: anticoagulants, e.g. warfarin, brodifacoum; and toxic agents, e.g. alphachloralose. The anticoagulant brodifacoum is widely used. It is highly toxic in low doses to mammals and fish: the manufacturers' precautions must be followed. Vitamin K is the antidote.

(See also WARFARIN.) ALPHACHLORALOSE and difenacoum are used for the same purpose.

Accidental poisoning of domestic animals has occurred from some of the above, and also from others banned in the UK, e.g. RED SQUILL; THALLIUM; ANTU; THIOUREA; PHOSPHORUS; FLUOROACETATE POISONING; barium salts; zinc phosphide; STRYCHNINE.

Rodent Ulcer

In human medicine this term is reserved for carcinoma of the skin, but is sometimes misapplied by animal-owners to EOSINOPHILIC GRANULOMA or LICK GRANULOMA.

Romagnola

An Italian breed of cattle, white in colour, and reared for beef. Romagnolas have been imported into the UK.

Romifidine

An α-adrenergic agonist used in horses as a sedative, alone or in conjunction with ketamine or thiopentone. Kicking and other struggling movements may be reduced by the simultaneous administration of butorphanol. It must never be used in an animal receiving potentiated sulfonamide treatment. It cannot be given in the last month of pregnancy.

Romney Marsh Sheep, Romney Sheep

A breed developed in Kent, England (and known locally as Kents), in about 1800. It has fleece and body shape improved by crossing with Robert Bakewell's Leicesters. They were exported to many countries especially New Zealand and in about 2000 they made up about 58 per cent of the sheep

population with Coopworths (originally Border Leicester on Romney ewes) and Perendales (originally Cheviots on Romney crosses) making up another 16.6 per cent of the population. They have a wide head and are polled with white wool over the poll but with a white face without wool, pink skin, black nose, and hooves. Rams weigh about 110 kg (240 lb) and ewes 85 kg (110 lb). They are not a prolific ewe but have a lambing percentage of up to 170 per cent and are said to be resistant to FOOT-ROT OF SHEEP.

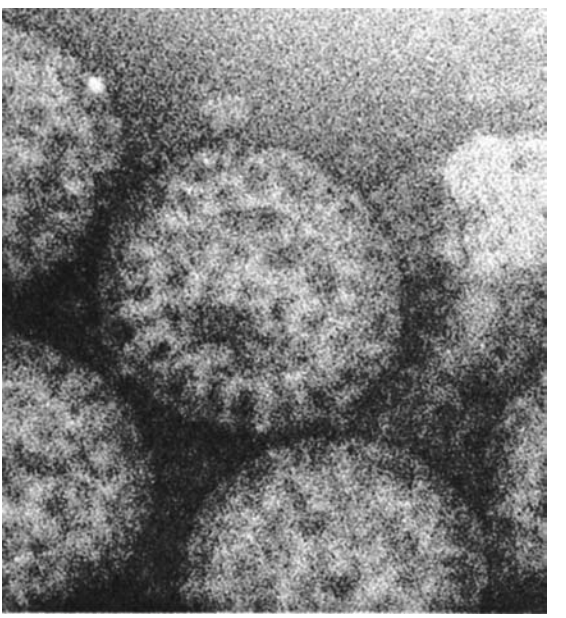
Rompun
Proprietary name for XYLAZINE.

Ropivacaine Hydrochloride
A local anaesthetic which lasts 3.5 to eight hours in horses after a 10 to 30-minute onset. It is not licensed for the horse in the UK.

Roscommon Longwool Sheep
Longwool sheep bred in the 1870s and recognised by the Royal Dublin Society in 1896 when a breeders' association was formed. The sheep are large white, full bodied and with long curly wool. They were exported all over Europe. A smaller version is the GALWAY SHEEP.

Rose Bengal Plate Test
A simple and quick screening test used in the diagnosis of brucellosis in cattle. Sera giving positive results may then be tested by means of the SERUM AGGLUTINATION TEST and COMPLEMENT FIXATION TEST.

Rostral
Towards the nose or front end of the body.



Rostral teeth are the incisors and canines.

Rotavirus
So-called because of its resemblance to a wheel. Responsible for causing diarrhoea in the young of many species – humans, foals, calves and piglets. It has been shown that, in piglets, only the pig and calf rotaviruses cause diarrhoea, although the human and foal rotaviruses can replicate in the pig.

Research at the Moredun Institute led to a method of diagnosis based on the direct detection of the viral nucleic acid, which comprises 11 molecules of double-stranded DNA. This method is 'rapid and as sensitive as ELISA'.

A vaccine Rotavec K99 (Schering-Plough) was introduced in 1986, following research at Moredun, to protect calves against rotavirus (and also K99 *E. coli*). The vaccine is used to immunise cows in late pregnancy, producing enhanced antibody levels in the colostrum; this is given to calves at the rate of 2.5 litres to 3.5 litres daily for the first two weeks of life.

Rotenone
The insecticidal principle of derris root. Rotenone is highly poisonous to fish and is used deliberately

The rotavirus. (By courtesy of the AFRC.)

for removing coarse fish from enclosed waters before establishing trout fisheries.

Rothera's Test

A test for ketones in milk or urine; a modified version requires the following reagent: ammonium sulphate, 100 g; anhydrous sodium carbonate, 50 g; sodium nitroprusside, 3 g.

If the bottom 1.25 cm of a test-tube is filled with this powder, and a little of the fluid to be tested runs down the side of the tube, a red colour will develop after three or four minutes if ketones are present, as with ACETONAEMIA.

Rottweiler

A large powerful breed developed as a guard dog in Germany: some are 'one man dogs'. The breed is prone to DEAFNESS and RETINAL DYSPLASIA; HIP DYSPLASIA may also be a problem. OSTEOCHONDRITIS DISSECANS is found in the breed but the mechanism of inheritance is unknown. The breed is also prone to CRUCIATE LIGAMENT RUPTURE; whether this is due to inheritance or the structure of the body is unknown. PERSISTENT PUPILLARY MEMBRANE (PUPILLARY MEMBRANE, PERSISTENT) and SPINAL MUSCULAR ATROPHY are recorded. They are susceptible to INFLAMMATORY BOWEL DISEASE.

Roughage

By this is meant food of a bulky and fibrous nature, such as hay and straw. These have a low water-content, and are in a sense the opposite of succulents, e.g. kale, silage. (See also DIET AND DIETETICS – Fibre.)

Rough Collie

A rough-coated medium-sized dog with an elongated face and nose, originally developed as a sheep-dog and also called the SCOTCH COLLIE. The breed is prone to cleft palate, corneal dystrophy, deafness, epilepsy and umbilical hernia. CENTRAL PROGRESSIVE RETINAL ATROPHY (RETINAL PIGMENT EPITHELIAL DYSTROPHY) is a dominant trait; COLLIE EYE ANOMALY is a recessive trait. PATENT DUCTUS ARTERIOSUS may be inherited, as may cyclic neutropenia. DISTICHIASIS is an autosomal dominant trait. The breed also has a fibrinogen deficiency which may be inherited as an incomplete dominant trait and CORNEAL LIPIDOSIS is recorded. CANINE MULTIDRUG SENSITIVITY (DNA test available) – IVERMECTIN toxicity is found in the breed.

Rouleaux

Rouleaux is the term applied to the columns into which red blood cells collect as seen under the microscope. The appearance somewhat resembles a pile of stacked coins.

Round Heart Disease

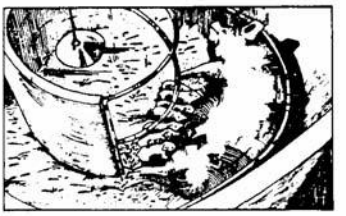
In chickens, this occurs only on some types of deep litter. The cause is not known, but litter from affected houses can transmit the disease to healthy chickens. Sudden death occurs; on post-mortem examination, the heart is firm, bright pink in colour, barrel shaped and with a dimple at the apex. Replacement of the litter stops mortality.

In turkeys, the disease is more common in the small white strains. It causes sudden death in birds in apparently good condition. There appears to be a genetic factor.

Roundhouse

A type of circular farrowing pen devised in New Zealand. It consists of a circle of hardboard, about 2.4 m (8 ft) in diameter and 1.2 m (4 ft) high, bolted to a light iron framework and fitted with an internal creep rail. A smaller circle, about 1 m (3 ft) in diameter, made partly of hardboard and partly of tubular rails, is fitted eccentrically within the larger one, and the whole is fastened with bolts to the concrete floor of the piggery. The smaller circle, which is warmed by an infra-red lamp, acts as a creep for the piglets, while the sow is kept in the space between the two circles. Because of the shape of this space, the sow invariably lies in the same position, with her udder towards the piglet's creep. This gives the piglets the maximum degree of safety. (See illustrations on next page).

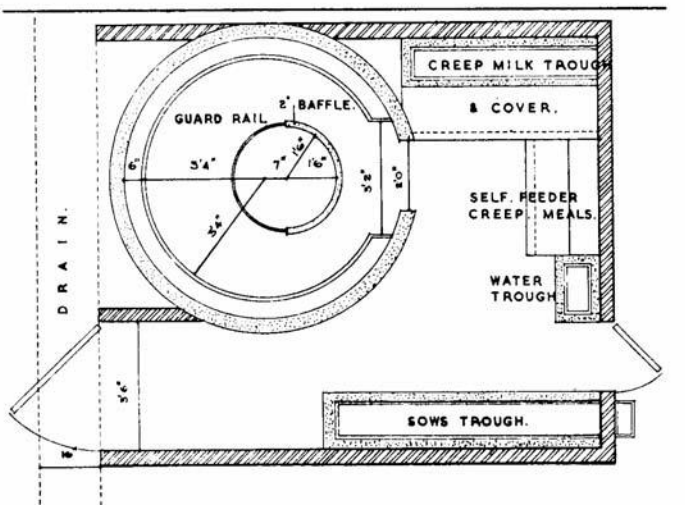
Roundworms, Nematoda



Most nematodes lay eggs, but some produce living larvae. The life-history may be direct or indirect, i.e. an intermediate host may be necessary.

Nematodes can be the cause of anaemia, wasting, gastroenteritis, bronchitis and pneumonia, aneurism, convulsions and blockage of the intestine. Some are of public health importance. (See TRICHINOSIS; *Toxocara*.)

Horses



1. Stomach Two species of *Habronema* (*H. muscae* and *H. microstoma*), and *Draschia megastoma*, inhabit the stomach of Equidae in various parts of the world.

The worm larvae are passed in the horse's faeces; swallowed by maggots, and continue through the pupal and adult stages of the stable-fly or house-fly; finally the larvae become located in the fly's proboscis. When the fly settles near a horse's mouth, the larvae enter it, and reach the stomach. However, if the horse has a wound, some of the larvae will be attracted to that, and give rise to the cutaneous or orbital form of habronemiasis, 'summer sores' or 'bursati'.

Roundhouse

The New Zealand pen: a drawing showing the position in which the sow volunatily assumes, and, below, a plan for the pen's construction.

Habronemiasis is common in the tropics and subtropics, but has also been seen in the UK. Hard nodules or granulomas may form on the skin or at the inner canthus of the eye.

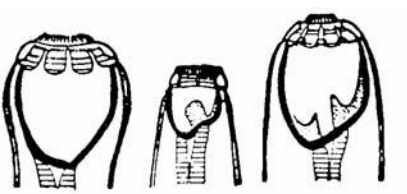
D. megastoma forms nodules, in which it lives, in the stomach. *Habronema* worms may penetrate the gastric mucosa and become embedded causing gastritis, thirst, colic and pica.

Trichostrongylus axei, seldom more than 8 mm long, also causes gastritis. This worm also inhabits the duodenum.

2. Small intestine *Parascaris equorum* is the common large roundworm of the horse. The female may be up to 50 cm long. Pica, colic and unthriftiness may result from heavy infections, which may also lead to partial blockage of the intestine.

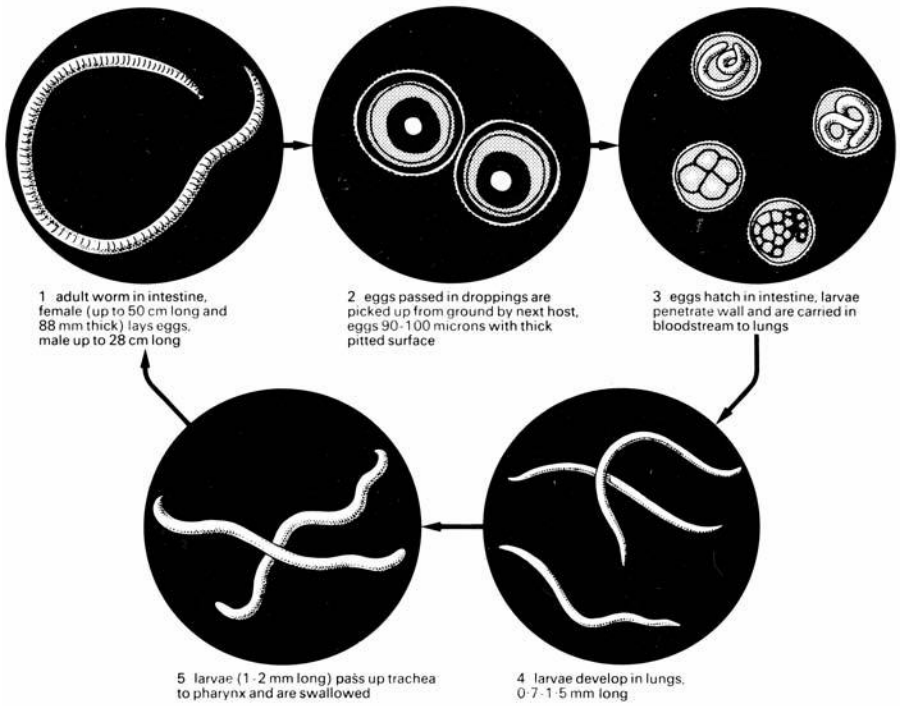
The larvae, which migrate to the lungs after hatching in the stomach, are capable of causing a catarrhal bronchitis or broncho-pneumonia; and possibly some damage to the liver also, during their migration through that organ.

Strongyloides westeri is another worm found in the duodenum, and a cause of diarrhoea in foals. This and other worms of this genus may also cause broncho-pneumonia.



3. Caecum and colon *Strongylus*. Three species are important.

S. (Delafontia) vulgaris is a cause of verminous arteritis, or thrombosis, affecting the cranial mesenteric artery. (See EQUINE VERMINOUS ARTERITIS.)



S. (Alfortia) edentatus produces nodules in the peritoneum. If very numerous, the larvae may cause peritonitis, bleeding, and anaemia. After two or three months they return to the large intestine and become adult worms.

S. equinus. The larvae of this large worm also produce nodules in the caecum and colon, and later migrate to the liver and pancreas.

Oxyuris equi. The female worm comes to the end of the rectum to deposit its eggs, which are ejected as a yellowish or greenish mass surrounding the anus. Resulting pruritus can lead to emaciation in severe cases, and more usually to unsightly bare patches on the tail and hindquarters.

Strongylus (head). (Left to right) *S. edentatus*, *S. vulgaris*, *S. equinus*.

Life-cycle of the large roundworm of the horse, *Parascaris equorum*. (Reproduced with permission from H. T. B. Hall, *Diseases and Parasites of Livestock in the Tropics*, Longman.)

4. Lungs *Dictyocaulus arnfieldi* is the cause of a verminous bronchitis which may be recognised by a cough and, if the worms are numerous, by loss of appetite and emaciation.

'Demonstration of the presence of larvae in the faeces is sufficient to confirm the presence of infection in donkeys, but even if respiratory symptoms are present, this finding should not be allowed to obscure the more likely possibility that other causal agents are involved. Diagnosis of infection in horses may be very difficult. Recovery of larvae from faeces will identify the "silent carriers" but most horses have very low larval output and several examinations may be necessary. Most cases of clinical disease, in horses, are seen during the pre-patent phase and larvae will not therefore be present in the faeces. Most infected horses, although showing respiratory signs, do not develop patent infections. It is therefore important not to exclude lungworm as a possibility just because it is not possible to recover larvae from the faeces. Naturally acquired infections are known in which larvae were not recovered from horses with clinical respiratory signs extending for more than a year. Complete recovery followed specific lungworm therapy. While an association with donkeys is added circumstantial evidence on which diagnosis can be based, infection may be transmitted from horse to horse in the absence of a donkey contact. This frequently occurs on thoroughbred studs.'

The efficacy of orally administered ivermectin against induced *D. arnfieldi* infection was evaluated in a controlled study comprising 12 yearling ponies. Treatment with ivermectin paste, orally once, was 100 per cent effective against both adult and immature or inhibited stages of the horse lungworm.

5. Connective tissue *Onchocerca. O. reticulata* is found in the horse, especially in tendons. It is common near the suspensory ligament, but is also reported in the withers. They may cause no signs, or may induce hypertrophy of the tendon or may cause fistulous withers. *O. cervicalis* occurs in the *ligamentum nuchae* of equines, and is often associated with poll-evil.

6. Skin *Parafilaria multi-papillosa* (*Filaria haemorrhagica*) is found in intermuscular tissue or under the skin. The female worms penetrate the latter to lay their eggs on the surface, where hard nodules subsequently develop, and these open and bleed.

Haematobia flies in Russia, and *Drosophila* in tropical regions, transmit the worm larvae.

VetBooks.ir

7. Nervous system The larvae of *Setaria equina* invade the central nervous system of horses in Asia, causing epizootic cerebrospinal nematodiasis. This is characterised by paralysis, and the disease may prove fatal.

The adult worm, milky-white, lives in the peritoneal cavity. Transmission is by mosquitoes.

8. Eyes *Thelazia lachrymalis* causes conjunctivitis (and sometimes keratitis too). (See EYEWORMS.)

Cattle, sheep and goats

1. Oesophagus and stomach *Gongylonema*. Two species occur in ruminants and one in pigs. They are found just below the epithelium in the thoracic third of the oesophagus. The intermediate hosts are various species of dung-beetles.

Haemonchus contortus. This is the large stomach worm or 'barber's pole' worm of ruminants, so-called because of the female's spiral red and white stripes. The male is red. It is a trichostrongyle, with a length of about 30 mm and the thickness of a pin. It is a voracious blood-sucker, and inhabits the abomasum. It can cause serious anaemia and unthriftiness, especially in lambs.

H. placei is another of several species.

Ostertagia worms, which are of considerable economic importance, are peculiar in that while most infective larvae living in the abomasum moult twice to become adults, some – especially perhaps those ingested by the calf during late summer and autumn – moult only once and remain as fourth-stage larvae in a dormant state. These dormant larvae are unaffected by many anthelmintics but are usually, though not always, susceptible to ivermectin, fenbendazole and albendazole. Later they develop into adults causing a winter outbreak of gastroenteritis. Calves should therefore be dosed in September and moved to 'clean' pasture.

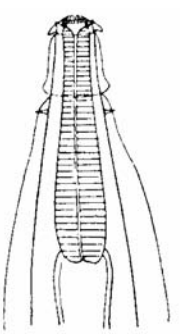
Also known as the small brown stomach worm, *Ostertagia* cause severe irritation of the mucous membrane by the formation of nodules. Infested animals may lose weight, scour, and become anaemic.

2. Small intestine *Ascaris vitulorum*. This large round worm of cattle is generally of little importance, but it may be a frequent and fatal parasite of calves in certain localities.

Nematodirus. This is a common trichostrongyle genus found in large numbers in the small intestine of sheep. It is a very slender form under 2.5 cm long. In recent years nematodirus infestation has caused severe losses.

The infestation is a 'lamb-to-lamb' one, and can be avoided – where practicable – by confining lambs to pasture which carried no lambs in the previous two seasons. *Nematodirus* species found in Britain are *N. filicollis, N. helvetianus, N. spathiges*, and *N. battus. N. helvetianus* and *N. battus* are parasites of calves. (See PASTURE, CONTAMINATION OF.)

Cooperia species are important. They are usually present in association with other species of worms, e.g. *Ostertagia, Trichostrongylus*. They seldom cause anaemia, but are responsible for weight loss and scouring. *Trichostrongylus* worms are very small (only 2 mm to 7 mm long) and inhabit the abomasum and duodenum.



Bunestomum (hookworms) live in the small intestine. The larvae may either enter their host via the mouth or penetrate the skin. They suck blood and accordingly cause anaemia and sometimes oedema under the throat. (See HOOKWORMS.)

Oesophagostomum. This is a genus of strongyle worms related to the horse forms, and found in ruminants and pigs. They are about 2.5 cm (1 in) long. They are the cause of nodular disease of the intestine ('pimply gut'). If present in small numbers, the only result is to render the intestine unfit for sausage skins. If in large numbers, the signs are anaemia, emaciation, diarrhoea and oedema. The disease in this case often has a fatal termination.

Trichuris. This genus of whip-worm occurs in the caecum of various animals, but is usually of little importance. The worms have very slender necks with stoutish bodies. The necks are threaded through the mucous membrane of their host.

They may cause inflammation at the point of insertion of the head and may admit bacteria.

Strongyloides worms are found in the small intestine, often deep in the mucosa. Scouring is caused in heavy infestations. The worm larvae can enter the body via the skin.

Oesophagostomum (head-end).

3. Lungs *Dictyocaulus*. Three species are known in cattle, but only one is important – *D. viviparus,* which causes a form of bronchitis. The male is about 4 cm long and the female about 7 cm. Eggs hatch in the lung and the larvae climbing up the trachea are swallowed, passing to the exterior with the faeces. After moulting twice, they reach the

resistant infective stage, and can live thus on pasture through the winter. When swallowed, they continue their development.

The signs and treatment are described under PARASITIC BRONCHITIS.

Parasitic bronchitis ('husk') Several species of roundworm occur in sheep and goats.

Dictyocaulus filaria is the largest and most common species. The male is about 5 cm long and the female 8 cm. The infective stage is reached in about 10 days. Apparently lambs can be infected prenatally. This worm is cosmopolitan in its distribution. Its life-history is direct.

The signs are those of a verminous bronchitis, sometimes complicated by bacterial infection, but otherwise similar to those in cattle.

Protostrongylus (Synthetocaulus) rufescens is a red and much smaller form. The male is about 2 cm and the female 3 cm long. It is found mainly in Europe. These worms live in the bronchioles and in the pulmonary parenchyma, and cause a verminous lobular pneumonia. The eggs cause a diffuse nodular pneumonia. Cough is less prominent than in the above form, but breathing is difficult.

4. Connective tissues *Onchocerca*. Several species occur in cattle in various parts of the world. They are the cause of 'worm nodules'.

The nodules are found mainly in the brisket, but also occur in the flank and forequarters. They appear to cause little harm to their host, but as the capsule is a product of inflammation, beef containing worm nodules is condemned and, in Australia, they have caused considerable loss in the export trade.

Dracunculus. Only one species of this worm is found in the domestic animals, *D. medinensis*, the 'guinea worm'. It is found in India, Africa and South America. The female is of considerable length, but is generally recovered from the host in small pieces. It is milky white in colour, smooth and without markings. Nearly the whole of the worm is occupied by the uterus, packed with coiled-up embryos. The worm occupies a subcuticular site, as a rule in the extremities, with the head-end projecting to the exterior. The larvae are released by a prolapse of the uterus through the cuticle of the worm. They escape into the water, and are swallowed by a cyclops in which they develop. The cyclops is in due course swallowed in the drinking water by a suitable host – practically any of the domestic animals will do – and larvae are released by the digestive juices and proceed to their adult habitats. The worm may give rise to local abscesses, and sometimes affects the feet of dogs.

5. Eye *Thelazia*. (See EYEWORMS.)

Pigs

1. Stomach The most important worm here is *Hyostrongylus rubidus*. Its life-cycle is direct. (See also THIN SOW SYNDROME.) The latter may sometimes be due to various species of *Oesophagostomum* worms. (See OESOPHAGOSTOMIOSIS.)

2. Small intestine *Ascaris suum*. This worm is a very common parasite of pigs in all countries.

The eggs have a remarkable vitality, and have been kept alive for as long as five years. The egg, in a few weeks after passing to the ground, develops an embryo, but this does not hatch until the egg is swallowed. When this happens, the larva, which is about 0.25 mm long, bores through the intestine, reaches the bloodstream, and is carried through the liver and heart to the lungs. Here it remains for some days, but it finally climbs up the trachea and is swallowed. The larva which leaves the lung has grown to about 2.5 mm in length. In the intestine it continues its development, taking about 2½ months to do so.

In passing through the lungs a certain amount of bleeding is caused, and if the larvae are numerous, pneumonia results. During this period the animal shows the signs known as 'thumps'. If it survives the lung signs, it often fails to grow properly and remains small and stunted.

Macrocantorhynchus hirudinaceus is found in the small intestine of pigs. It is a whitish worm, the male being 5 cm to 10 cm long, while the female is 20 cm to 35 cm long. The neck is thin and the posterior region stout. The intermediate stages are found in beetles.

The parasite may cause a catarrhal enteritis or even actual perforation with peritonitis.

Trichuris suis, the pig whip-worm, causes mainly subclinical disease in temperate climates, but in the tropics it may cause dysentery, anaemia, and even death. In the Americas up to 85 per cent of pigs may be infested; in some areas of the UK, from 75 per cent. *Trichuris* occurs in the caecum.

Treatment in the pig includes oxibendazole, fenbendazole and thiophanate.

3. Lungs In pigs two species are common, both belonging to the genus *Metastrongylus*. The male is about 2 cm and the female about 4 cm long. Both species are common in Europe and America, and may occur in the same pig. They cause a verminous bronchitis and sometimes pneumonia. Young animals are more susceptible and may die from it. Both species are carried by earthworms.

4. Muscles *Trichinella spiralis*. This is a small worm found in the intestine. The female produces living larvae (0.1 mm to 0.16 mm long) which

VetBooks.ir

migrate through the mucosa, reach the bloodstream, and are carried to various muscles. Here they pass into a cystic stage (the cyst being formed by the host), in which they remain until they are swallowed by some flesh-eating host or until they calcify and degenerate. In the intestine of the new host they reach sexual maturity and produce a new lot of larvae, which in turn migrate to the muscles.

The normal hosts are carnivores (dogs and cats). Rodents may be infected and rats can be a source of infection to pigs. Man may be infected from the pig. (See under TRICHINOSIS.)

5. Kidney *Stephanurus dentatus* is a thickish worm of fair size, the male being nearly 3 cm long and the female a little larger. It is found as a rule in the kidney fat of pigs, but also occurs in the liver and other locations in these animals and in ruminants. It is found in America and Australia, and is responsible for considerable damage. Its life-cycle is similar to that of the hookworms. Thiabendazole, fenbendazole and ivermectin have proved effective in controlling this parasite.

Dogs and cats

1. Oesophagus *Spirocerca lupi* is found in nodules in the oesophagus and, less frequently, the stomach of the dog, in all hot countries and in Europe.

It is a reddish worm. The male is 3 cm to 5 cm long. The intermediate hosts are various beetles and cockroaches.

The disease is often undiagnosed during life, but in countries where it is common the presence of the worm may be suspected from a frequent cough followed by repeated vomiting. Death from exhaustion may result.

Damage to the carotid artery by *S. lupi* worms (three in each of two nodules attached to the oesophagus) led to the death in the UK of an Alsatian from internal haemorrhage. This parasite appears also to be closely associated with sarcoma of the oseophagus.

2. Stomach A microscopic gastric nematode of cats, *Ollulanus tricuspis*, has been found in the Americas, Australasia and Europe. The worm causes unthriftiness and vomiting in kittens.

3. Small intestine

Ascarids include several species that occur in dogs and cats. In cats the species seem to be *Ascaris tubaeforme* and *A. braziliense*.

Hookworms in dogs Two species of hookworm are found in dogs: *Ancylostoma caninum* and *Uncinaria stenocephala*. The latter is found in Britain. These are smallish worms, about 2.5 cm long, found in the small intestine.

Eggs are passed to the exterior in the faeces and hatch in the soil or water. After several moults, the resulting larva becomes infective, and is able to gain access to the host either in the food or by penetrating the unbroken skin. It enters the bloodstream and is carried to the lungs. It then passes up the trachea and is swallowed. It completes its development in the small intestine, where it becomes mature.

4. Caecum The whip-worm *Trichuris vulpis* occurs in the UK, and gives rise to diarrhoea/dysentery, loss of condition and a harsh, staring coat.

5. Heart *Dirofilaria*. There are two species occurring in dogs and cats. *D. immitis* occurs in the heart of the dog and occasionally the cat. The female may reach a length of 30 cm, but the male is little more than half this size. It is found in Asia and, of recent years, in Britain. The embryos are hatched in the body of the female, and the young larvae, passed into the bloodstream, are sucked up by a mosquito in which they develop. After a certain period they escape from the fly, when it attacks another dog, and entering the blood are carried to the heart, where they complete their development.

The worms interfere to a greater or lesser extent with the circulation. No signs may be shown; or the dog may suddenly die. Other signs include anaemia, respiratory troubles, ascites, etc. Various complications may be due to emboli, such as cough, dyspnoea, etc. Diagnosis is by demonstration of the microfilaria in the blood.

Another heartworm of the dog is *Angiostrongylus vasorum*, which has, as intermediate hosts, slugs and snails. This worm, which has caused an outbreak of infestation in kennels in Ireland, lives in the pulmonary artery and the right ventricle of the heart. Signs include malaise, stiffness on running, and subcutaneous swellings (due to suppression of normal blood clotting by the parasites). Some lung damage may be caused; likewise anaemia.

(See also under HEARTWORM.)

6. Kidney *Dioctophyme renale*. The kidney worm of dogs and wild carnivores is very large, reaching 1 m in length, and is a blood-red colour. It is found in Europe and the USA. It occurs in the pelvis of the kidney, and occasionally destroys the kidney tissue, to leave only the wall as a cyst filled with a purulent fluid. The other kidney usually shows a compensatory hypertrophy. It is occasionally found in the bladder. Infestation follows the eating of raw fish.

The worm's eggs are barrel-shaped and may be seen in the urine, under the microscope.

VetBooks.ir

7. Bladder In the UK the bladder-worm *Capillaria plica* is rare, and seldom gives rise to obvious signs. A severe infestation can lead to inflammation of the bladder and a mucoid discharge from vagina or prepuce. In cats cystitis may, rarely, be caused by *C. feliscati*.

8. Trachea *Oslerus (Filaroides) osleri* occurs in the UK and gives rise to a sporadic but persistent cough, especially on exercise or if the dog is excited. Retching may be caused. Severe infestation can give rise to emaciation despite a fair appetite, laboured breathing, sleeping standing, and death in young dogs. For control, thiabendazole has given promising results.

Another tracheal worm, *Capillaria aerophilia,* seldom gives rise to obvious signs.

9. Lungs A minute worm lives in the lungs of cats in Britain and elsewhere in Europe and America. It may cause a fatal form of parasitic pneumonia. The parasite (*Aelurostrongylus abstrusus*) is transmitted to cats by mice. In Africa, *Bronchostrongylus subcrenatus* is found.

Lung lesions found at the autopsy of five out of a batch of 20 beagles were due to *Filaroides* species, 'probably *F. milksi* rather than *F. hirthi*'. The lungs had the appearance of being peppered with black spots. Signs of larval migration were seen microscopically in the liver, mesenteric lymph nodes, and gastrointestinal tract.

Poultry Roundworms more commonly occur in free-range systems where it is also difficult to ensure that all birds can be treated. There may be no obvious clinical signs but breeding flocks (chickens and turkeys) often show reduced hatchability.

Public health aspects (See under *Toxocara*.)

Roup

A term commonly used to describe birds with infections of the nasal chambers and CORYZA. (See TRITRICHOMONIASIS - AVIAN TRITRICHOMONIASIS.)

Rous Sarcoma of Chickens

This is produced by a virus. (See under CANCER.)

Royal Army Veterinary Corps (RAVC)

It has a long and honourable history. An Army Veterinary Service was established in 1796; this became the Army Veterinary Corps in 1906, the title of 'Royal' being bestowed in 1918.

A History of the RAVC 1796–1919 was compiled by Major-General Sir Frederick Smith KCMG, CB, a former Director-General, Army Veterinary Services, and published by Baillière, Tindall & Cox. A second volume, by Brigadier J. Clabby, was published in 1963 by J. A. Allen & Co.

Royal College of Veterinary Surgeons (RCVS)

Address: Belgravia House, 62–64 Horseferry Road, London SW1P 2AF. Telephone: 0207 2222001. The governing body of the veterinary profession in the UK. (See also REGISTER OF VETERINARY SURGEONS.)

Royal Society for the Prevention of Cruelty to Animals (RSPCA)

Address: RSPCA, The Causeway, Horsham, West Sussex RH 12 1HG. Telephone: 01403 264181; website: www.rspca.org.uk.

RPED

(See also RETINAL PIGMENT EPITHELIAL DYSTROPHY.)

-rhaphy

-rrhaphy is a suffix meaning an operation in which some opening or tear is closed by stitches.

RSPCA

(See ROYAL SOCIETY FOR THE PREVENTION OF CRUELTY TO ANIMALS.)

RSV

(See RESPIRATORY SYNCYTIAL VIRUS.)

RT-PCR

(See REAL-TIME POLYMERASE CHAIN REACTION; REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION.)

Rubarth's Disease, Hepatitis Contagiosa Canis

This is named after the Swedish scientist Rubarth who, in 1947, described for the first time a disease in dogs which he called, on account of its contagious nature and the damage caused to the liver, *Hepatitis contagiosa canis*. This is now commonly known as CANINE VIRAL HEPATITIS. He regarded this disease, on the basis of the microscopical findings, as identical with fox encephalitis, which had been known in America for some 17 years previously. Vaccination is routinely used against the disease.

Rubber Bands

These sometimes get, or are put, on to the legs of cats (and possibly dogs), where they may remain unnoticed until the continual pressure has destroyed the skin beneath the band and caused damage to the underlying structures. Gangrene or loss of use of the limb results.

A successful prosecution has followed the application of rubber bands to cows' teats in the UK.

Rubber rings have been used for castration of lambs and calves, and for the docking of lambs. (See ELASTRATOR, etc.)

'Rubber Jaw'

A condition seen in the dog in some cases of chronic nephritis. It may be associated with enlargement of the parathyroid glands. Softening of the bones of the skull, particularly the jaw, occurs, and at post-mortem examination in a severely affected part the bone can be cut with a scalpel. There is resorption of bone and its replacement by vascular fibrous tissue. 'Rubber jaw' is not, of course, seen in all cases of chronic nephritis, though some changes may be detected microscopically after death.

Rumen

The first stomach of ruminants. It lies on the left side of the body, occupying the whole of the left side of the abdomen and even stretching across the median plane of the body to the right side. It is a capacious sac which is subdivided into an upper or dorsal sac and a lower or ventral sac, each of which has a blind sac, at its posterior extremity. These divisions are defined by the presence of grooves on the outside of the organ and by pillars or ridges internally. The whole organ is lined by mucous membrane which possesses a papillated, stratified, squamous epithelium containing no digestive glands, but mucus-secreting glands are present in large numbers. Its entrance is through the oesophagus, and its exit is into the reticulum or second stomach through the rumeno-reticular orifice.

Coarse, partially chewed food is stored and churned in the rumen until such time as the animal finds circumstances convenient for rumination. When this occurs, little balls of food are regurgitated through the oesophagus into the mouth, and are subjected to a second, more thorough mastication. Each bolus is chewed 30 to 60 times and mixed with copious amounts of saliva, to be swallowed and passed onwards into other parts of the compound stomach.

In rare instances, the rumen may be situated on the right-hand side.

Rumen, Ulceration of

In calves, ulcers in the rumen may be associated with lesions of the liver caused by *Bacteroides* (*Fusiformis necrophorus*), or with BVD infection. (See also STOMACH, DISEASES OF.)

Rumen Flukes

Belonging to the genus *Paramphistomum*, these are found in both the tropics and North America. In the British Isles they have been found to be *Calicophoron daubneyi*.

Conical in shape, round in cross-section, they inhabit not only the rumen but also the reticulum, and – when immature – the duodenum. They are also found occasionally in the bile ducts and urinary bladder.

Little damage is caused to the rumen, but in young animals a severe enteritis is the important aspect of the disease, resulting in diarrhoea, unthriftiness, anaemia, and sometimes death.

Paramphistomum flukes have a life-history similar to that of the common liver-fluke *Fasciola hepatica*; several species of snails being the intermediate hosts.

Rumenotomy

Opening the rumen via the left upper flank for the purpose of emptying the contents.

Ruminal Digestion

In the rumen, bacteria break down the cellulose (which forms the structural materials of plants), and starch by means of enzymes, and convert them into fatty acids. The bacteria fall a prey to the protozoa which, besides digesting starch, thus perform the useful task of converting plant protein into animal protein. This becomes available to the cow when the protozoa are, in their turn, destroyed further down the digestive tract and themselves digested.

A sample taken from the rumen, at the Hannah Research Institute, contained 100 million protozoa and 5 million bacteria (giving some idea of the proportion of the two). Examples of protozoa included *Entodiniomorph* species, which feed on plant material, bacteria, and each other; and *Holotrich* species, which ferment soluble sugars from plants and feed on bacteria. (See also under, DIET AND DIETETICS – Fibre; LACTIC ACID.)

Ruminal Tympany

(See BLOAT.)

Rumination, 'Cudding'

Rumination ('cudding') is the process whereby food taken into the stomachs of ruminants is returned to the mouth, subjected to a second, more thorough chewing, and is again swallowed.

The act occurs at intervals of from six to eight hours, and occupies a longer or shorter time according to the nature of the food and the amount taken at the last meal. It usually commences about half an hour after feeding ceases, and probably continues until all the coarser constituents have been re-chewed, or at least until the animal is disturbed. This fact is of considerable importance practically; cattle and sheep should be allowed at least 2 hours' rest after feeding before they are

VetBooks.ir

subjected to any severe exertion. Disregard of this is a fruitful contributory cause of stomach disorders in both cattle and sheep. (See also under RUMEN.)

The act of regurgitation appears to be in reality a complex one, but it may be briefly summarised as follows:

1. The tension of the oesophagus relaxes, partly by dilatation, and partly through an inspiratory movement of the diaphragm (the glottis being temporarily closed), which reduces pressure in the thorax.
2. The rumen and the reticulum powerfully contract and squeeze upon their contents.
3. The abdominal muscles contract and raise the intra-abdominal pressure.

The direct result is that ingested foodstuffs are forced from the area of high pressure (i.e. the rumen and reticulum) through the open oesophagus into an area of lower pressure (i.e. into the thoracic portion of the oesophagus). When a small quantity, sufficient to form a bolus or 'cud', has entered the oesophagus, the lips of the oesophageal groove and the muscles in the vicinity close the terminal part of the oesophagus, and there commences an antiperistaltic movement which conveys the 'cud' upwards past the closed glottis, underneath the soft palate, and so into the mouth. Excess fluid is immediately squeezed from the mass and swallowed, and chewing movements commence at once. Each bolus is chewed 30 to 60 times according to its consistency, size, and to the nature of its constituents; coarse straw or hay fodder requiring the longest time. The chewing occupies from 30 to 90 seconds, and then the bolus is rolled up by the dorsum of the tongue and again swallowed. In from three to six seconds another bolus has reached the mouth, and so the process is continued.

Ruminomics

A word coined to describe the study of increasing feed efficiency of, and decreasing environmental impact from, farming ruminant livestock.

Runch

(See CHARLOCK POISONING.)

'Runners'

This is an old, popular term for hounds unable to gallop properly. 'Runners' are usually recognised as such when they return to hunt kennels at about seven months old after being walked; and they are then often culled from the pack. Technically, the condition is known as osteochondrosis of the spine. Signs include poor muscular development in the spinal region, poor bodily condition, an unnatural gait, and often inability to jump a fence successfully negotiated by the rest of the pack. Some curvature and rigidity of the spine may also be observed. It seems that this is, in part at least, an inherited defect of foxhounds.

The term is also applied to young budgerigars affected by French moult.

Runting and Stunting Syndrome

A condition of economic importance in poultry production. It is probably due to a virus associated with environmental, management and nutritional factors. Several viruses have been suggested to be involved including REOVIRUSES, ROTAVIRUSES, ENTEROVIRUSES, PARVOVIRUSES and RETROVIRUSES. In the Netherlands it has been suggested that anaerobic bacteria are involved. Clinical signs include pallor of the skin, especially of the legs, decreased skeletal density, lameness, late development of plumage, distortion and bending of quills or primary feathers ('helicopter syndrome'), lack of co-ordination, lateral recumbency, orange-coloured mucus in the droppings, along with particles of undigested food. The problem occurs sporadically and tends to last for about a year on the farm before any improvement is seen. Affected flocks show a variation in live weight from seven to 10 days of age and at 21 days up to 20 per cent of the flock can show runting and stunting. Disappearance of the syndrome over much of the USA coincided with the use of reovirus vaccines.

Runt Pigs

Runt piglets are defined as being less than 1 kg in weight. If they are born after number seven in the litter the mortality is estimated to be 75 per cent due to the lack of immunoglobulins in the blood, most likely through failure to obtain enough colostrum. Those at the same weight and born earlier are more likely to have a teat with a richer colostrum supply and so they survive. Runt pigs can be reared in special nursing units designed for runts and excess piglets in a litter. Runt pigs and underweight babies have similar biochemical and physiological abnormalities.

Rupture

Rupture is a popular name for HERNIA. The term is also applied to the tearing across of a muscle, tendon, ligament, artery, nerve, etc. Rupture of the aorta is a cause of death in male turkeys at 5 to 22 weeks old.

Rural Economy and Land Use (RELU)

This involves a multidisciplinary approach to sustainable agriculture. It involves collaboration of

three research councils to investigate the social, economic, environmental and technological experience in rural communities and areas.

Russian Black Terrier

A large terrier; in outline like an Airedale but black. The male weighs 50 kg to 60 kg (110 lb to 130 lb) and the female 45 kg to 50 kg (100 lb to 110 lb). The breed can suffer from HYPERURICOSURIA (DNA test available).

Russian Gad-Fly

(*Rhinoestrus purpureus*.) This attacks horses in Europe and North Africa.

Russian Spring-Summer Virus

Russian spring-summer virus causes an encephalitis of man and goat, caused by a virus and transmitted by the tick *Ixodes ricinus* in Russia, Poland, the Czech Republic and Slovakia.

Rut

(See MUSTH.)

Rye, *Secale cereale*

This is a cereal crop used for humans and in animal feeds, particularly livestock. It has a high energy level (higher than BARLEY, MAIZE, OATS, WHEAT) and low protein content. The high soluble fibre content makes it of most use in ruminant diets. It is susceptible to the fungus CLAVICEPS species. (See ERGOT, FUNGAL; ERGOT OF RYE.)

Rye-Grass

Rye-grass poisoning has caused the death of cattle and horses restricted to grazing rye-grass pasture (*Lolium perenne*). In New Zealand and Australia, a fungus present on the rye-grass may cause facial eczema. A staggering gait – and convulsions – may occur in cattle and sheep on rye-grass pasture giving rise to the colloquial name 'rye-grass staggers'. In a UK outbreak in sheep, they had 'a rocking-horse gait, and when chased fell down and trembled violently'. (Veterinary Investigation Service report.) Fungal toxins are the cause of 'rye-grass staggers' in both the UK and New Zealand. The rye grass is infected with a seed-borne enfophytic fungus, *Acremonium lolii*, containing the alkaloid loitrem B. (See also CEREBROCORTICAL NECROSIS.)

Ryeland Sheep

The breed has short wool and produces good quality meat.

S

Saanen Goats
The breed is a white goat with fine coats, originating from the Saanen Valley of Switzerland. They are used for milk, producing 4.3 kg (9.5 lb) milk at 3.6 per cent butterfat and 2.7 per cent protein. Their numbers in Britain are few but they have been used to improve the BRITISH SAANEN.

Sabulous
Gritty, sandy.

SAC
Originally the acronym of SCOTTISH AGRICULTURAL COLLEGES but later just called SAC. It is the official consultancy, veterinary services and research organisation with centres throughout Scotland and amongst other things, undertaking post mortem and laboratory examinations. Its veterinary services address is SAC Consulting, Veterinary Services, Allan Watt Building, Bush Estate, Penicuik EH26 0QE; telephone 0131 535 3130.

Saccharide Polymers
Compounds such as OLIGOSACCHARIDES made by combining saccharides.

Saccharides
These are carbohydrates, which include the sugars and depending on the number of saccharide groups present they are called MONOSACCHARIDES, DISACCHARIDES, TRISACCHARIDES or POLYSACCHARIDES.

Sacks
Sacks may be a means of passing infection from one farm to another, for when empty they are put to many uses. Poisoning has occurred through contamination of feeding-stuffs by sacks previously used for sheep-dip. For these reasons, non-returnable paper or plastic sacks have advantages over jute sacks.

Sacrum
(adjective, Sacral)
The part of the spinal column lying between the lumbar region and the tail. It consists of five vertebrae in the horse and cattle, four in the sheep and pig, and three in the dog and cat, fused together in each case. It is roughly triangular in shape in all animals, and forms the roof of the pelvic cavity, lying midway between the two 'points of the hip' or 'haunch bones'.

Saddle Slip
The tendency of a saddle to slip to one side while the horse is being ridden. In the past it has been blamed on poor saddle fit or 'crooked' riders. The most common cause is probably lameness, especially of the hind-limbs; often it is subclinical and not seen. Saddles with uniform flocking that had even contact along the horse's back were found to be 15 times more likely to slip compared with other saddles. Poorly-fitting saddles are found to increase the risk of abnormal hair wear, focal pain beneath the saddle and tenderness/stiffness of the longissimus dorsi muscles of the back.

Saddle-Sores
Saddle-sores are formed through uneven pressure upon the back by some part of the saddle. They may be found in the middle line, immediately over the upper ends of the spinous processes; they may occur on either side of the middle line where the fore-arch of the saddle-tree presses; or they may be found just behind the elbow, when they are caused by badly fastened girths, and are often called 'girthgalls'.

The injuries consist of raw areas from which the hair has been rubbed or chafed off and, later, ulcers. Alternatively, patches of the skin, varying in size from 2.5 cm in diameter to almost 7 cm, may become hard and leathery, pus being formed underneath. These are known as 'sitfasts'.

Treatment Attention must first of all be paid to the saddles. They should fit evenly all over the back, and the stuffing or padding should be adequate to protect the skin from pressure by the rigid framework of the saddle-tree. The hollow of the arch of the saddle should never press upon the middle line of the back, and the girth should never be fastened with the skin folded under it. Rest from work will be necessary. (See ULCER; WOUNDS.)

Sagittal
A structure or section running parallel to the median plane of the body or a limb.

Sainfoin
(*Onobrychis sativa*) A leguminous forage crop which fixes its own nitrogen; it contains tannins, so its rumen protein degradability is low (this means that the protein is used more efficiently); and it does not cause bloat. Voluntary intake by animals is high – intakes of sainfoin can be 25 per cent higher than that of ryegrass. Furthermore, it is drought-resistant.

Unfortunately, sainfoin does not grow as well as bred strains of grasses, clovers and lucerne; 30 per cent less yield than lucerne is quoted.

St Bernard
A very large dog with a massive head and drooping ears, traditionally used for mountain rescue work in the Swiss Alps; the rough-coated variety is commoner. The breed is prone to 'diamond eye' – a combination of ENTROPION and ectropion. 'WOBBLER' SYNDROME (cervical spondylolithesis) is inherited as a recessive trait and haemophilia B is a sex-linked recessive trait. Other inheritable conditions include ununited ANCONEAL PROCESS and a progressive posterior paralysis (STOCKARD'S DISEASE).

St John's Wort
This plant, *Hypericum perforatum*, which may be present in hay, does not lose its poisonous character when dried. It causes LIGHT SENSITISATION in cattle, sheep, and pigs, especially in Australia.

St Louis Encephalitis
Transmitted by mosquitoes, and caused by a flavivirus, this disease occurs in North and South America, affecting wild birds, bats, horses and man (in which it may cause encephalitis and death in the elderly, although only fever in other people).

Salamanders
These are lizard-like amphibians with a wet skin and without scales as reptiles. Some are purely aquatic, some semi-aquatic and some terrestrial. They are in the Order *Caudata* and include newts. They can suffer from a fatal fungal dermatitis caused by *Batrachochytrium dendrobatidis*.

Saler Cattle
A French breed known as Rae de Salers or la Salers (plural les Salers), bred in the Massif Central region and seen in many parts of Europe. One of the oldest cattle breeds, they are known to have existed 7,000 to 10,000 years ago, and appeared in cave paintings. They are a dark red colour, with light coloured horns. The cows weigh 700 kg to 750 kg (1,540 lb to 1,650 lb) and produce 3,000 kg milk, used for cheese making, but are mainly used for beef. They are able to survive just on forage.

Salicylic Acid and Salicylates
Originally derived from the willow (genus *Salix*), salicylic acid and its salts have long been used in pain relief. ASPIRIN, which is acetylsalicylic acid, largely replaced the other salicylates as pain relievers (see ANALGESICS), and has been given in fevers. It should not normally be used in cats, which metabolise aspirin very slowly. A standard 300 mg tablet given daily to a cat may prove fatal in 12 days. (See also NON-STEROIDAL ANTI-INFLAMMATION DRUGS (NSAID).)

Salicylate poisoning has occurred in young animals following overdosage. Signs include depression, loss of appetite and vomiting. Treatment involves the use of an emetic or gastric lavage and respiratory stimulants.

Saline
(See under NORMAL SALINE.)

Salinomycin
An IONOPHORE used as a coccidiostat in chickens, and also (outside the EU) as a growth-promoting feed additive for pigs. Its use was phased out within the EU by January 2006.

Salinomycin poisoning Turkeys have died within a week after the introduction of a diet containing 50 ppm salinomycin.

In horses the signs of poisoning are eyelid-swelling, anorexia, colic, weakness, ataxia.

Saliva
The liquid excretion of the SALIVARY GLANDS. It contains minerals and some enzymes, including LYSOZYME.

Salivary Glands
Salivary glands include the parotid gland, lying in the space below the ear and behind the border of the lower jaw; the submaxillary gland, lying just within the angle of the lower jaw, under the lower part of the parotid; and the sublingual gland, which lies at the side of the root of the tongue. Each of these glands is paired, so that actually there are six glands, not all of which function at the same time.

Salivary Glands, Diseases of
Calculi and tumours may occur. In rabies, the salivary glands must become infected before transmission of the virus to another host can occur through a bite. (See also MUMPS.) A foreign body, such as a grass seed, may cause an obstruction to one of the ducts, particularly in the dog.

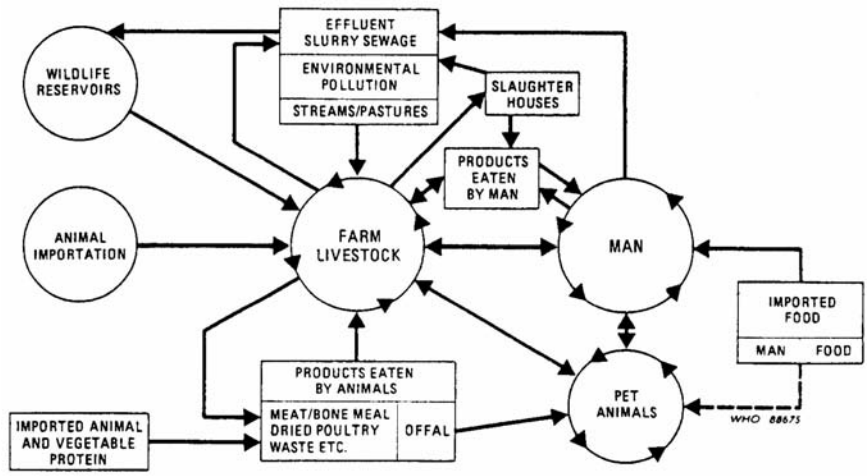
Salivary-gland tumours in dogs and cats are rare. The majority of 138 tumours in dogs (81) and cats (57) involved animals of 10 years of age or more, were malignant and of epithelial origin (84 per cent). Local recurrence after excision occurs frequently, and metastasis to regional lymph nodes and beyond is common.

Salivation
'Foaming at the mouth', to use a colloquial but apt expression, is seen in the dog, e.g. in an epileptic or other fit (see FITS). 'Drooling of saliva' is seen in

the dog with a bone wedged across the roof of its mouth, or in a cat with a needle embedded in its tongue – or in cases of RABIES in all species.

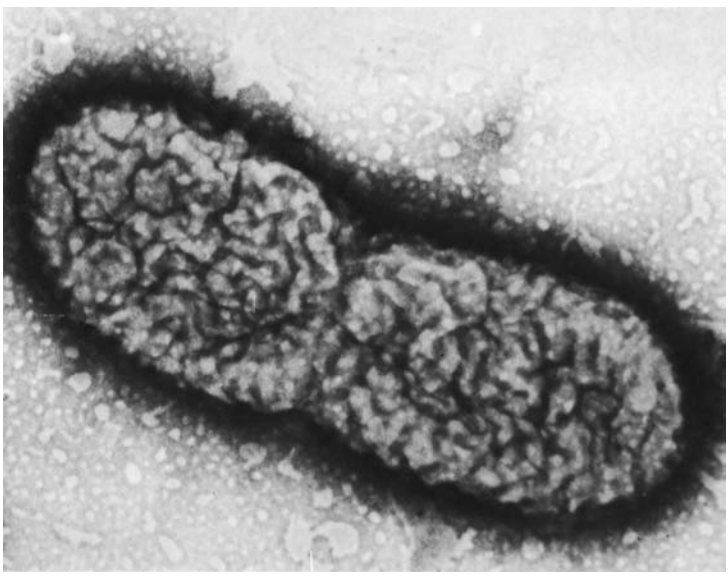
Salivation is a clinical sign of 'CHOKING', of almost any painful condition of the mouth or tongue, and of poisoning (e.g. by benzoic acid in the cat), arsenic, lead, phosphorus and organophosphorus compounds; see also TOADS.

Salivation is also an important sign of FOOT-AND-MOUTH DISEASE, and of other diseases and conditions mentioned under MOUTH, DISEASES OF. Excessive salivation may also be the first sign of epilepsy.



Salmincola

Parasites on the gills of salmonid fish which affect respiration. Affected fish show reduced growth and delayed sexual maturity.



Salmonellosis

Infection with organisms of the salmonella group is of importance from two distinct aspects: (1) food poisoning in man; and (2) disease in domestic animals.

Salmonella poisoning – routes of infection (See diagram below.)

Salmonella poisoning – routes of infection. (With acknowledgements to World Health Organisation, Technical Report No. 774.)

An electron-micrograph of Salmonella dublin. (Magnification × 50,000.) (Reproduced by courtesy of the Department of Veterinary Preventive Medicine. University of Liverpool.)

VetBooks.ir

In cattle and calves Salmonellosis and brucellosis have four points in common – both diseases are important from the public health point of view; both can lead to abortion in cattle, to a carrier state likely to perpetuate infection on the farm, and to considerable financial loss to the farmer.

While the salmonella group of bacteria includes more than 1,000 different serotypes, the two of most importance to the dairy farmer are *Salmonella dublin* and *S. typhimurium*. Either can produce acute or subacute illness in adult cattle and in calves.

S. typhimurium infection is of greater public-health importance, and is a notorious cause of outbreaks of food poisoning in man. *S. typhimurium* type 204C used to be a major source of problems in calves bought from markets and is highly resistant to antibiotics; it is now uncommon.

S. typhimurium 104 also has a relatively high resistance to antibiotics. It can result in severe illness and deaths in small groups of cows or calves; it is the second most common salmonella in food poisoning.

S. dublin infection may be associated with abortion, sometimes without any other signs being observed. Animals which recover may excrete the organisms for years. Besides this carrier state, which may keep infection on the farm, there is also a latent carrier state in which the organism remains dormant within the animal until it is subjected to some stress or superimposed disease, when excretion of the organism occurs and fellow members of the herd become infected.

Signs The two infections are usually very similar and can be distinguished only by laboratory tests. In the acute form of the disease, the cow becomes dull, feverish, goes off her food, and the milk yield suddenly drops. Scouring is usually severe, and the animal may pass blood and even shreds of mucous membrane from the intestine. Death may occur within a week. If treatment is delayed, mortality may rise to 70 per cent or so; whereas early treatment can bring the death rate down to 10 per cent. In animals which recover, scouring may persist for a fortnight, and it may be several weeks before the cow is fit again.

The subacute form in adult cattle runs a milder course and, indeed, the infection may exist without any signs being shown. A latent infection may become an overt one following stress of any kind or when another disease becomes superimposed – sometimes masking the signs of salmonellosis itself. A liver-fluke infestation may be a precipitating factor.

Salmonellosis may run through eight calves out of a batch of 10, and kill four of them. Some calves collapse and die without ever scouring; others become very emaciated as a result of persistent scouring. Pneumonia, arthritis, and jaundice may be among the complications; occasionally the brain is involved, giving rise to nervous signs.

S. typhimurium infection seldom persists from one season to another on any particular farm because there are fewer 'carrier' animals than there are with *S. dublin*; it is often brought on to the farm by calves bought in from markets and suffering from the effects of stress, rough travelling conditions, lack of food or a change of diet. The infection occurs in many species of animal including, as the name suggests, mice.

S. dublin infection arises mostly from other cattle. It can be spread from farm to farm via slurry and streams. Infection may enter even a closed herd if it is grazing flooded pasture land.

Lack of shelter, overcrowding, dirty surroundings and faulty feeding have all been implicated in outbreaks. In adult cattle, the fortnight after calving is regarded as a danger period, especially where the calving has been a difficult one.

S. dublin can survive in slurry for at least 12 weeks.

Salmonella organisms can survive for six months or so in dung and litter, and *S. dublin* can survive for over 307 days, on dung splashes on a wall, so that thorough cleaning and disinfection of buildings are necessary, and reliance must not be placed on a simple 'resting period' between batches of calves.

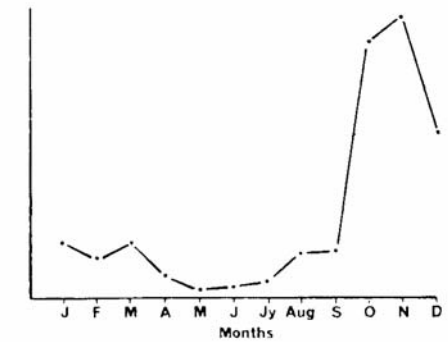
Salmonella organisms may be present in domestic sewage, and river pollution from this source has led to outbreaks of salmonellosis in cattle.

Preventive measures include trying to keep rats and mice off cattle feed, avoiding pig and poultry effluent for organic irrigation, having piped drinking water for cattle, and not buying in through markets or dealers but rather from farms with a known health record. The earlier housing of cattle in the autumn may help, and it is important not to neglect liver-fluke infestation which can sometimes act as a 'trigger' to outbreaks of salmonellosis in which the infection was hitherto latent.

Treatment Drugs used include antibiotics, potentiated sulfonamides and sulfadimidine. A vaccine is available for prophylaxis and therapy.

In sheep *S. typhimurium* has caused diarrhoea and abortion. *S. agona* has caused abortion, death of ewes from septicaemia, death of lambs within a week of birth, and sometimes diarrhoea. *S. dublin* is likewise a cause of abortion and diarrhoea.

Outbreaks in sheep flocks may be characterised by rapid spread and heavy mortality in ewes and young lambs. Clinical signs included diarrhoea and abortion. Abomasitis (inflammation of the abomasum) can be a striking post-mortem lesion. Vaccination is often the only successful control method. Infection can also spread to any cattle, farm personnel and dogs also present on the farm.



(See also ABORTION - EWES.)

VetBooks.ir

In pigs The term 'salmonellosis' is now usually reserved for a severe septicaemia. *S. cholerae suis* causes this; signs include fever, huddling together, purple discoloration of ears, unsteady gait and sometimes scouring. The same organism may give rise to a chronic infection with scouring. The organism can infect man.

Infection with *S. dublin* sometimes occurs in pigs, and may give rise to dysentery.

More common is infection with *S. typhimurium*. This causes fever, scouring, vomiting and unsteady gait – usually in younger pigs than the first-named organism. Sulfadimidine has proved useful in treatment. Supplementing the diet of piglets with fructan showed benefits in countering *Salmonella* spp. infection.

Seasonal incidence of salmonellosis. (With acknowledgements to the *British Veterinary Journal*.)

In horses *S. typhimurium* has caused serious outbreaks of illness in young horses. Horses may also be symptomless carriers of this infection. In 1976 an outbreak of *S. newport* infection caused the death of many horses in the UK. (See also FOALS, DISEASES OF.) Outside the UK, *S. abortus equi* is a cause of abortion in mares.

Stress, associated with the hospitalisation of horses, is said to have led to acute enteritis, often from *S. senftenberg*.

In dogs Illness may be mild, with fever and malaise; or there may be severe gastroenteritis and death. Many salmonella serotypes infect dogs. It is possible for a dog to become a symptomless carrier of *S. typhimurium* and to infect man.

Feeding raw offal to dogs had been suspected as an important source of salmonellosis. A German study of 408 samples of edible offal (liver, lungs, heart, bovine rumen and porcine oesophagus) found that 231 samples (57 per cent) were infected with salmonella. *S. typhimurium* was the most prevalent of 24 serotypes. Feeding puppies with 1 per cent fructo-oligosaccharides reduced enterocyte sloughing and may protect weanling puppies from *Salmonella* spp. infection.

In cats Infection with *S. enteritidis* and *S. typhimurium* may be set up following the catching of infected rats and mice. For this reason cats should not be allowed to lie on animal feeds or to gain access to surfaces on which food is prepared for human consumption. Cats may also become infected through eating contaminated meat.

In poultry As a specific disease, salmonellosis is rare except in broilers, although it is involved in numerous other disease conditions. Over 50 members of the salmonella group have been isolated from poultry in the UK, and several have caused outbreaks of disease in broiler plants. (See PULLORUM DISEASE OF CHICKS; FOWL TYPHOID.)

Arthritis, due to a variant strain of *S. pullorum*, gives rise to a mortality of 5 per cent or so, but it can be 20 per cent. Apart from lameness and swelling of the foot and hock joints, signs include poor feathering and under-development. Death can be expected between the ages of 10 days and 5 weeks.

Survivors may not react to a blood test carried out with standard *S. pullorum* antigen, but react strongly to antigen prepared from the variant strain. This probably accounts for carrier birds having remained undetected in the past.

During a five-year period, birds in 144 flocks in Sweden were given cultures of caecal contents as a means of controlling salmonella infection by the competitive exclusion technique. In all, 2.86 million birds were treated and it was concluded that this treatment was associated with a reduction in salmonella infections. No adverse effects were reported.

Salmonellae will remain alive for periods of up to six months or more in dung and litter. Potentially infected material should be stacked so that heating occurs; no animals should have access to the heap.

S. enteritidis is a serious pathogen carried by poultry. It has been found that this *Salmonella* spp. has a greater ability to adhere to the wall of the reproductive tract than any other *Salmonella* species.

A vaccine prepared from *S. enteritidis* phage type 4 is available (Salenvac; Intervet). Eggs from vaccinated hens carry the 'lion' mark. Rodents (especially mice) and beetles play a significant role in maintaining *S. enteriditis* infection in flocks. Rodent control and disinfection of housing may be effective in dealing with the problem.

In ducks Salmonella species sometimes cause a high mortality in ducklings. Fatal cases of human food poisoning have occurred as a result of infected ducks' eggs.

In geese *S. typhimurium* may be found in goslings, affecting only the eye, the vitreous body being totally destroyed.

VetBooks.ir

Public health As already mentioned, salmonellosis is an important cause of food-poisoning in man, often leading to serious illness. In 2010, there was a continuing fall to 9,685 cases of laboratory confirmed human cases, which was a fall of 8 percent from 2009. In the USA, it is estimated that there are 29 human cases undiagnosed for every one reported. Numerous instances linking food-processing with outbreaks have been investigated. *S. seftenberg* has been linked with isolates from human beings and a poultry processing plant. *S. kiambu* and *S. enteritidis* have been isolated from frozen turkeys from the same batches which caused illness in people. *S. panama* and *S. brandenburg* have been similarly isolated from abattoirs/processing plants and human beings.

S. agona is a public-health problem in the USA, the UK, the Netherlands and Israel. In each country the original source of the infection was linked to Peruvian fish meal used in animal feeds. It has been demonstrated that animal feeds can play an important role in the transmission of salmonellosis to man.

Unpasteurised milk is another source of human salmonellosis.

Viable salmonellae have been found in the meat fraction of domestic refuse. This source could provide a reservoir of infection accessible to wild animals. Tipping should be carefully controlled, and refuse covered immediately.

A pustular dermatitis has been recorded in veterinary surgeons involved in obstetrical manoeuvres in infected animals with pure growth of *Salmonella* species being recovered.

(See also under SAUSAGE.)

'Salmon Poisoning' in Dogs

'Salmon poisoning' in dogs occurs on the Pacific coast of the USA, and is the result of eating salmon or trout infested with the fluke *Troglotrema salmincola*, containing a rickettsia. The latter, *Neorickettsia helminthoeca*, produces a haemorrhagic gastroenteritis which is usually fatal unless antibiotics are used in time.

Salpingectomy

An operation in which the oviduct of birds or reptiles is removed surgically.

Salpingitis

Salpingitis is inflammation in the Fallopian tubes or oviducts, sometimes the cause of sterility in cattle. (See INFERTILITY.)

Salpingotomy

An operation in which the oviduct of birds or reptiles is opened to remove the contents, usually a retained egg or egg material.

Salpinx

The oviduct of birds and reptiles.

Salt

A chemical substance in which a metal is substituted for the hydrogen of an acid.

Sodium chloride (common salt) (NaCl) is an essential ingredient of body fluids. Sodium depletion results, ultimately, in circulatory collapse.

Salt is an appetiser, and commonly incorporated in animal feeds in carefully measured proportions. Ruminants will avidly consume salt; any excess is harmlessly excreted in the urine and faeces.

Salt licks It has been suggested that a 500 kg (10 cwt) cow needs 30 g (1 oz) of salt a day for maintenance and a further 3.5 g (⅛ oz) for 4.5 litres (1 gallon) of milk produced. Therefore, a 3,200 litres (700 gallons) cow requires about 14 kg (30 lb) of salt yearly.

On some pastures, or under some systems of management, cattle may not obtain sufficient salt. To obviate this danger, salt licks are commonly provided. In some salt licks traces of iodine are incorporated, together with other trace elements such as copper, manganese, cobalt and magnesium. (See 'LICKING SYNDROME'.)

Salt Poisoning

Salt poisoning has been reported in both pigs and poultry. It is essential that pigs are not kept short of water, or given food that is too salted.

An outbreak, reported from Scotland, involved piglets aged six weeks brought indoors from field arks at weaning. A proprietary meal was fed dry. The water bowls in the house were not very accessible, and some of the piglets were not strong enough to depress the levers. Two days after being housed, 23 out of the 32 piglets were showing signs of salt poisoning, and some died.

Signs Often a number of pigs are found dead without signs having been observed, the remainder being weak and very thirsty. Vomiting and diarrhoea may occur. (For other signs, see under MENINGOENCEPHALITIS.)

In poultry, adult birds show excessive thirst and diarrhoea, with sometimes cyanosis of the wattles, somnolence, and sudden death. In young birds gasping and ascites may occur.

Saluki Dogs

A medium-sized hound which is one of the oldest domesticated breeds; their type was found in Egyptian tombs of around 2134 BC. They are slight-boned animals weighing about 25 kg (55 lb) and can be smooth-coated or the more popular feathered; feathering occurs on the ears, tail and

back of the legs. The colours are white, cream, fawn, red, grizzle and tan, black and tan, and tricoloured (white, black and tan). It is a fast dog and used for hunting.

Samoyed Dogs

A medium-sized breed of dog characterised by thick straight cream or white hair. Like the CHOW CHOW, they tend to be 'one-person' dogs. Haemophilia A (Factor VIII deficiency) is inherited as a sex-linked recessive and PULMONARY STENOSIS appears to be inherited polygenically. The breed appears to be prone to develop DIABETES MELLITUS, but whether or not this is inherited is open to debate. CORNEAL LIPIDOSIS is also recorded.

Sand

Horses on the seashore or along tidal mud flats learn that the sand contains salt, and may lick up large quantities of it in their endeavour to get the salt. The signs set up are chiefly those of COLIC with impaction.

Cattle feeding on the seashore take in quantities of sand, which in some cases may be so great as to hinder the movements of the rumen (where the sand always collects), and, by upsetting digestion, may cause unthriftiness and even emaciation.

Some rodents (CHINCHILLAS and DEGUS) and birds require sand baths in order to keep their PELAGE and PLUMAGE respectively in good condition.

Sandcrack

Sandcrack is a pathological condition affecting horses' feet, in which a deep fissure or crack forms at some part of the wall of the hoof, extending downwards from the coronet, and usually involving the whole of the thickness of the wall.

Causes Anything which interferes with the proper nutrition of the horn at the coronet predisposes to sandcrack, the actual splitting of the horn occurring as the result of the strains put upon the foot. Treads on the inside of the coronet, occasioned by hurried turning when at work, are frequent causes in the fore-feet, and continual pressure on the coronary matrix by the second phalanx, especially when the toes have been allowed to grow too long, appears to be the commonest cause in the hind-feet. A predisposition to sandcrack may be inherited.

With all cases it is advisable to place the animal under veterinary care. (See HOOF REPAIR WITH PLASTICS)

'Sandflies'

(See under FLIES.)

Sand Tampan, *Ornithodorus savignyi*

(See TICKS - FAMILY ARGASIDAE.)

Sanguineous

Sanguineous means containing blood.

Santa Gertrudi

This breed of cattle are ⅝ Shorthorn and ⅜ Brahman in origin.

Saponins

These are natural detergents, present in some plants such as corncockle and soapwort. Saponins contain a sugar and a steroid-like compound, and with water form a lather. Poisoning by them results in gastroenteritis. The central nervous system may also be affected, with consequent paralysis. Saponins break down red blood cells. In the USA the leaves and nuts of the tung tree, grown for the sake of its oil, can cause fatal poisoning.

Saprolegnia

A fungus that can infect fish and amphibians. It is sometimes found as a secondary infection to another condition such as ulcerative dermal necrosis in salmonids, and autumn aeromonad disease in adult brown trout. The infection can be controlled by bathing the fish in zinc-free malachite green but the healing process is prolonged. In a salmon hatchery, it is important to remove dead and infertile eggs as these can be invaded by the fungus and passed on to healthy eggs.

In amphibia it can invade the spawn and destroy the embryos; it has been associated with environmental die-outs. Treatment of infected amphibia is by spraying with a solution of MICONAZOLE (following instructions to avoid a toxic overdose); BENZALKONIUM CHLORIDE may be used as an alternative. ITRACONAZOLE and KETOCONAZOLE may be given systemically; AMPHOTERICIN B may be used with care as it can be nephrotoxic.

SARA

Acronym for SUBACUTE RUMINAL ACIDOSIS.

Sarafloxacin

A quinolone antibiotic used in treatment of FURUNCULOSIS in Atlantic Salmon while in seawater pens. There is a relatively long withdrawal time of 150 degree days.

Sarcina

Bacterial group which are GRAM-POSITIVE and MICROCOCCI. They are found in the CAECA of some animals, especially poultry, and their significance is not fully known. They have caused caecal disease in poultry, abomasal bloat in calves

VetBooks.ir

and lambs and gastro-enteritis in humans. Since 2012, *Sarcina* have been increasingly reported in pheasants, often with other alimentary infections, management and environmental problems.

Sarco-
Sarco- is a prefix signifying flesh or fleshy.

Sarcolemma The membrane covering each voluntary (striated) muscle fibre.

Sarcocystis
A genus of protozoal, coccidian parasites having a two-host life-cycle. Carnivorous animals such as dogs, cats and foxes ingest the cysts when eating infected flesh of cattle, sheep, pigs and horses. Human infection also occurs, and sarcocystis is a ZOONOSIS.

While the cysts in the intermediate host's muscles may not have any serious effect upon health, the second-generation schizonts are certainly harmful – damaging the endothelium of blood vessels, and causing serious illness in many cases.

Signs Cattle showed loss of appetite, fever, anaemia and wasting, after ingesting sporocysts from canine faeces, and some cattle died within 33 days. Sarcocystis has also killed sheep. In horses, signs of central nervous system damage may be seen, as well as signs of muscle inflammation, resulting in lameness.

Prevalence In Europe 61 per cent of slaughtered cattle have been found to be infected. In Germany a prevalence rate of 5 per cent in pigs has been recorded.

Human sarcocystosis may give rise to abdominal pain, diarrhoea, fever, tachycardia and an increased respiratory rate.

'Sarcoid'
A tumour which resembles histologically a sarcoma (see CANCER), but which is regressive in character, disappearing within a matter of months. It has the appearance of a reddish button, raised about 30 mm (⅛ in) above the surrounding skin. It affects the dog.

A fibroma-like sarcoid is perhaps the most common tumour of equines, especially older ones, occurring on limbs or head. Believed to be caused by a virus, the equine sarcoid commonly ulcerates and recurs following surgery. Cryosurgery may be tried, or a BCG VACCINE; the latter may be more successful in donkeys. A guarded prognosis should be given.

Bovine papillomavirus is involved in the process by which sarcoids develop from normal equine fibrous tissue.

Sarcoma
(See CANCER.)

Sarcoptes
Sarcoptes are members of a class of parasitic acari, which cause MANGE in animals and man.

Sarcoptic mange occurs in cattle, horses, sheep, pigs, and dogs – also in man, when it is called scabies – and is caused by the parasitic mite *S. scabiei*. (See MANGE.) Cats are only very rarely infected.

Sarcosporidia, Sarcosporidiosis
(See SARCOCYSTIS.)

SARDS
(See SUDDEN ACUTE RETINAL DEGENERATION SYNDROME.)

SARS
Severe Acute Respiratory Syndrome (SARS) is a form of AVIAN INFLUENZA that is transmissible to man, often with fatal results. It is thought to have originated in bats. Outbreaks occurred in several Far Eastern countries in 2004; many poultry flocks were destroyed in an attempt to prevent the disease from spreading.

SAT
(See SERUM AGGLUTINATION TEST.)

Satiation
A condition in which an animal is fully satisfied with feed and water and thus without any desire to eat or drink.

Satiety
A condition in which an animal is replete, i.e. has had sufficient feed and water.

Satiety Centre
An area located in the brain in the medial part of the hypothalamic nucleus.

Sausage
Discarded portions of sausage, or sausage-skin, can be a source of infection when fed, unboiled, to pigs, etc. FOOT-AND-MOUTH DISEASE has been transmitted in this way. AFRICAN SWINE FEVER and swine fever could similarly be spread by this means. (See SWILL.)

The incidence of salmonella-contamination of pork and beef and pork sausages during production was 65 per cent and 55 per cent respectively. The salmonella serotypes isolated (in descending order of incidence) included *Salmonella derby*, *S. dublin*, *S. newport*, *S. stanley*, *S. typhimurium*, *S. heidelberg*, *S. infantis* and *S. agona*.

VetBooks.ir

Savaging of Litters by Sows
Various causes of this have been suggested, including: an inherited tendency; absence of any straw for nesting purposes; a painful udder; insufficient time to have become used to her farrowing quarters; and fright resulting from the use of a farrowing crate. (See PIGS, SEDATION OF.)

Sawdust
(See under BEDDING AND BEDDING MATERIALS and MASTITIS.)

Sawflies
Four-winged insects which have a saw-like ovipositor. The larvae can cause poisoning if swallowed.

Sawfly poisoning This affects both sheep and goats.

Cause The larvae of the birch sawfly (*Arge pullata*).

Signs Depression, anorexia, muscular incoordination with a difficulty in rising to their feet.

Autopsy Findings Liver necrosis, petechial haemorrhages, and sometimes degeneration of the kidney tubules.

Saw Palmetto
A plant (*Serenoa repens*) used as a traditional herbal remedy for a variety of conditions. Said to be of value for lack of stamina and alertness in dogs.

SBV
(See SCHMALLENBERG VIRUS.)

Scabies
A common name for sarcoptic mange. (See under MANGE – Sarcoptic mange.)

'Scad'
A colloquial name for a transitory lameness, in sheep, which may follow frost. (See 'SCALD'.)

'Scald'
Inflammation between the digits of young sheep resulting from infection by *Bacteroides nodosus*; it causes acute lameness. Its onset is said to be associated with frosts and moisture. Recovery may occur spontaneously under dry conditions. The term is vague, however, and has been used to include the non-progressive 'benign' form of footrot. It has to be differentiated from foot-and-mouth disease. (See also 'SCAD'; OVINE INTERDIGITAL DERMATITIS.)

Scalds
(See BURNS AND SCALDS.)

'Scaly Beak', 'Scaly Face'
(See KNEMIDOCOPTIASIS.)

Scaly Foot
KNEMIDOCOPTIASIS of the foot in birds.

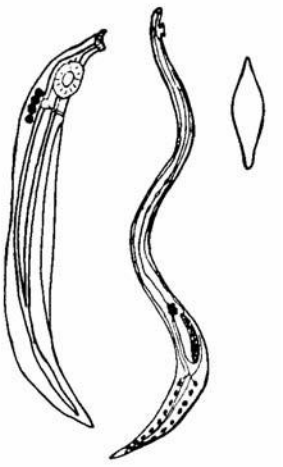
'Scaly Leg'
(See MANGE - MANGE IN FOWLS.)

Scanner, Body
A device utilising computer tomography to produce an image of a section of the whole body. (See X-RAYS.)

Scanning
(See RADIOISOTOPES.)

Scaphoid
The name given in human anatomy to a small bone present in the carpus and tarsus. In the racing greyhound, fracture of the right hind scaphoid is a common accident. Treatment has included the removal of bone fragments and the successful insertion of a plastic 'scaphoid'.

Scapula
The scapula is the shoulder blade – the large, triangular, flat bone that lies on the outside of the front of the chest, to which are attached many of the muscles that unite the fore-limb to the trunk.



SCC, scc
(See SOMATIC CELL COUNT.)

Scheduled Diseases
This is similar to a NOTIFIABLE DISEASE except that it may not be suspected on clinical examination, but only after laboratory examination e.g. BRUCELLOSIS. Once there is confirmation, the origin and spread are investigated by the animal health authorities and appropriate action undertaken. (See also NOTIFIABLE DISEASES.)

Schipperkes
A Belgian breed of small shepherd dog developed in the 16th century but considered by others to be spitz. It has erect ears and a thick black double coat. They are about 32.5 cm (13 in) high and weigh about 3 kg to 9 kg (6 lb to 20 lb). They can suffer from MUCOPOLYSACCHARIDOSIS VI and epilepsy is seen in some strains. They live about 13 years but require exercise.

Schistosomiasis
Infestation with *Schistosoma* worms or flukes, which are also known as bilharzia worms. They inhabit the portal and mesenteric veins mostly, one species preferring veins of the urinary bladder, and

VetBooks.ir

Schistosoma, ♂, ♀, and egg.

another the veins of the nose. Cattle and sheep and virtually all domestic animals, and man, may become infested.

Several species have been reported from mammals in India, Africa and Europe. *S. bovis* may cause anaemia, emaciation and death of cattle in Africa, or the infestation may be subclinical. In India *S. nasalis* may produce a nasal discharge and difficulty in breathing, with sometimes the formation of a granuloma. In the Far East *S. japonicum* occurs in water-buffalo and infests man, in which the disease is very serious.

The life-cycle differs from the typical case, in that the free cercaria may pierce the skin of its host instead of being swallowed.

The sexes are separate, and are usually found with the female lying in a groove formed by the incurved edges of the male.

Control Provision of clean drinking water and treatment of pasture with molluscicides such as copper sulphate to kill the intermediate host will reduce infection. However, such measures are rarely practicable in affected areas. Drugs such as PRAZIQUANTEL may be effective in treatment.

Schistosomus Reflexus

A deformity of the bovine fetus, in which the spine is bent, so that head and tail curve towards each other, causing dystokia. Fetal intestine may be visible at the vulva, or located in the vagina.

Schmallenberg Virus (SBV)

An orthobunyavirus infecting cattle, sheep and goats (and possibly camelids), originally found in Schmallenberg (a small town in Germany), Belgium, France and the Netherlands in 2011 and tentatively given the name 'Schmallenberg virus'. Disease has spread and in January 2012, it was reported in Great Britain, and has continued. The virus is related to AKABANE VIRUS and spread by arthropods, including *Culicoides obsoletus*, *C. dewulfi* and *C. pulicaris* all of which are biting midges MIDGES, BITING). It has been associated with transient disease of milk drop, diarrhoea and fever in adult cattle in August to October. It has been seen in at-term ovine and bovine fetuses with ARTHROGRYPOSIS and HYDRANENCEPHALY. There can be stillbirths, weakness or profound congenital nervous signs (OBTUNDATION – 'DUMMY Syndrome signs' –, blindness or marked paresis/paralysis). It is thought that fetal problems mainly result from dam infection in the second month of gestation in sheep and the second and third months in cattle. An RT-PCR test can be used to detect virus in the fetus; serological and bulk milk ELISA tests are available. A vaccine has been produced.

Schmorl's Disease

Schmorl's disease is a disease of rabbits, involving areas of necrosis of skin or mucous membrane, and caused by *Bacteroides necrophorus* (often after the animal's resistance has been lowered by some other pathogen).

Schnauzer

A German breed of dog with wiry coat that forms characteristic eyebrows, mouth and chin whiskers. There are miniature, standard and giant forms. The standard has fewer defects than the miniature, which is predisposed to cataracts and progressive retinal atrophy. PULMONARY STENOSIS occurs and may be polygenically inherited.

Schradan

An organophosphorus insecticide used in agriculture and a potential danger to farm livestock. (See also PARATHION) Signs of poisoning may include vomiting, lachrymation, salivation, straining, twitching, distressed breathing, and coma.

SCI

(See SPECIFIC CHEMICAL INJECTION.)

Sciatica

Sciatica means pain connected with the sciatic nerve which runs down the thigh.

Scintigraphy

The application of nuclear medicine to the diagnosis of bone pathology and lameness. It has applications for dogs and horses. (See NUCLEAR MEDICINE.)

Scirrhous Cord

Scirrhous cord is a condition in which there is a chronic fibrous enlargement of the cut end of the

spermatic cord following castration of a horse. In most cases the castration wound does not completely heal, but a small sinus discharging a thick white pus persists. The discharge may later cease, but the swelling of the cord goes on increasing slowly in size, until eventually it may be nearly as large as a man's head. In extreme cases the swelling extends upwards through the inguinal canal and into the abdomen and a mass weighing as much as 45 kg (100 lb) has occasionally been encountered in the horse on post-mortem examination. Treatment is entirely surgical.

Scirrhus
Scirrhus is a term applied to a growth or to other hard fibrous conditions of various organs.

Sclera, Sclerotic Coat
Sclera (sclerotic coat) is the outermost hard fibrous coat of the EYE. It is sometimes called the 'white of the eye'.

Scleritis
Scleritis means inflammation of the sclerotic coat of the eye.

Scleroderma
(See CHANCRE.)

Sclerosis
Sclerosis means hardening of tissues.

Scolecobasidium
A soil-dwelling fungus which may infect salmonids, causing swelling of the skin and, if it penetrates the body, in the kidney.

Scoliosis
Lateral curvature of the spine.

Scombiotoxic Poisoning
Scombiotoxic poisoning is a type of food-poisoning which occurs as a result of eating fish that contains large amounts of histamine. The histamine is produced by bacterial degradation of histadine when the fish – particularly tuna, bonito and mackerel, and also sardines, pilchards and herrings – are stored for prolonged periods at elevated temperatures. The signs commonly found are rash, diarrhoea, flushing and headache.

SCOPS
(See SUSTAINABLE CONTROL OF PARASITES IN SHEEP.)

Scorpions
Their venom affects the nervous system, causing pain, salivation, erection of hair, dilated pupils, increased blood pressure, and muscular spasm.

Scotch Collie
(See ROUGH COLLIE.)

Scotland's Rural College (SRUC)
A name change from the SCOTTISH AGRICULTURAL COLLEGES. SAC is part of this grouping. Address: Ferguson Building, Craibstone Estate, Bucksburn, Aberdeen AB21 9YA.

Scotophobin
A protein in the body which appears to be associated with the ability to learn. It has been suggested that this might explain why some animals that have been on a protein-deficient diet in infancy are difficult to train or teach.

'Scottie Cramp'
A condition apparently confined to the Scottish terrier, and occurring usually for the first time at 4 to 8 months of age. There is cramp following exercise. In mild cases the animal may be seen to be in difficulties when negotiating steps; in severe cases 100 metres' (330 ft) brisk trot will cause the animal to double up and collapse, and in a few instances excitement without exertion will give rise to cramp. Mild attacks often become worse, reaching a maximum severity at 12 or 15 months of age. At around 2 years of age the dog may have outgrown 'Scottie cramp'. The cause is unknown. Intravenous injections of calcium borogluconate, or administration of parathyroid extract, have been recommended. The condition could be eliminated by breeders being selective in choice of breeding stock.

Scotties
A popular name for SCOTTISH TERRIER DOGS.

Scottish Agricultural Colleges (SAC)
The former name for SCOTLAND'S RURAL COLLEGE. (See SAC.)

Scottish Blackface Sheep
The most common breed of sheep in Britain. It originates in Scotland and the Border region of England, being recorded as far back as 1503. They are hardy and can survive in harsh conditions. They have a black face and legs. Fleeces weigh 2.5 kg to 3 kg (5.5 lb to 6.5 lb), mainly long and coarse, used in upholstery and carpets and the finest is used in Harris Tweed. The condition of 'REDFOOT' is seen in some lambs and is believed to be inherited.

Scottish Fold
A breed of droop-eared cat. Although no major problems should be seen, owners are advised to check regularly for ear mites and infection. Some

VetBooks.ir

individuals may have a thickening and shortening of the tail that may be accompanied by thickening of the limbs and overgrowth of cartilage at the joints.

Scottish Government

It is responsible for matters concerning animal health and welfare in Scotland.

Scottish Society for the Prevention of Cruelty to Animals (SSPCA)

Address: Kingseat Road, Dunfermline, Fife KY11 8RY. Telephone Hotline: 0300 0999 999

Scottish Terrier Dogs

A small wiry dog, black, white or brindled. VON WILLEBRAND'S DISEASE may be inherited as an autosomal recessive gene, and the breed is prone to CRANIOMANDIBULAR OSTEOPATHY, PATELLAR LUXATION, DEAFNESS and LEGG-CALVÉ-PERTHES DISEASE. INTERVERTEBRAL DISC PROTRUSION may be found in the neck region; it may possibly be due to the weight of the head in relation to the body in some individuals. There is also seen a platelet defect which may be inherited as an autosomal dominant trait. They are prone to INTERDIGITAL CYSTS.

Scours, Scouring

(See DIARRHOEA.)

Scrapie

Scrapie is a disease of sheep and occasionally goats that has been known for nearly 300 years in the UK, although now is very rare. It is a NOTIFIABLE DISEASE with compulsory slaughter of affected animals. It has been seen in Europe including Spain, France and Germany. Sheep imported into Australia, New Zealand, Canada and the USA have brought the disease with them. Australia and New Zealand quickly eradicated the disease.

Scrapie, BSE and other 'prion' diseases are in a disease group which includes the human diseases kuru, Creutzfeldt-Jakob disease and Gerstmann-Straussler-Scheinker syndrome. (See BOVINE SPONGIFORM ENCEPHALOPATHY.) Scrapie is not usually considered to be a zoonosis.

Diagnosis One method is to detect scrapie-associated fibrillar protein (PrP) by means of a rabbit-anti-sheep PrP polyclonal antibody by Western blot analysis, which allows most cases to be differentiated from BSE. However, mouse assay is required to be certain. Rapid tests include immunohistochemistry analysis of third eyelid tissue, and the RAMALT test that detects pathognomonic build-up of lymphoid tissue in the rectum which can be found up to 12 months before clinical signs of scrapie. Recent work has shown scrapie to be present in the saliva and milk of sheep several months before clinical signs.

Experimentally, scrapie has been transmitted to goats, mice, rats and hamsters.

Cause An infective agent, possibly a prion. Research at the joint AFRC and MRC Neuropathogenesis Unit, Edinburgh, found that crude extracts of scrapie-infected brain contained accumulations of material known as scrapie-associated fibrils (SAF), which were also found in scrapie-like diseases.

Infection is spread from ewe to lamb and, possibly, to other sheep, by contact with fetal fluids. Signs take from about 2 to 5 years to appear.

A long-term DEFRA research project is investigating the causes, disease process and epidemiology of scrapie, and the genetic factors making some sheep more susceptible than others. The aim is eradication of the disease from the UK. (See NATIONAL SCRAPIE PLAN.)

Signs The most striking and easily seen sign of sheep scrapie is the torn, ruffled, and untidy appearance of the fleece, and when very severe, the bruised or scratched condition of the skin. In many cases, especially those occurring during the late spring, the fleece may be almost entirely rubbed off against fences, posts and trees or may be greatly removed by the mouth. Pruritus is less common in goats. In addition, the condition of the sheep is noteworthy; whereas the remainder of the flock may be in fair bodily condition, the scrapie sheep are thin, gaunt and apt to become weak on their legs, lagging behind when going uphill, and losing their foothold when descending. Muscular tremors are often seen, and later there is evidence of intense itching.

Occasionally, when startled – as, for instance, when being moved by dogs, or when a gun is fired near the unwary scrapie sheep – convulsive seizures are seen, usually lasting from 3 to 5 minutes, and leaving the animal temporarily dazed.

Control Scrapie is a NOTIFIABLE DISEASE. Clinically suspect animals are slaughtered and examined post mortem. Some strains of sheep carried a gene that made them resistant to scrapie and this has allowed the creation of scrapie-resistant flocks. A similar gene has been detected in Damascus goats. The test involved an analysis of DNA from a blood sample where presence of AA RR or AA QR confers resistance and where VV QQ, AV QQ, or AA QQ are highly susceptible. The letters stand for the amino acid sequence on the gene at the critical point (codon 171) for a pair of genes (A is Alanine, R is Arginine, Q is Glutamine and V is Valine).

Scrapie.

Eradication programmes are present in many countries including the USA. They involve breeding resistant strains of sheep, avoiding breeding from susceptible strains, rigorous culling of susceptible sheep and their families, and of lambs which might be exposed to infection soon after birth.

Screw-Worm Flies

These include *Chrysomyia bezziana* in Australia, *Cochliomyia hominivorax*, *C. Americana*.

The screw-worm (*C. hominivorax*), a significant parasite of both humans and animals, had not been recorded outside the New World until its accidental introduction into Libya, probably in 1988–9. Hundreds of cases of wound myiasis including many fatalities were recorded in various species of domestic animals during 1989 and 1990.

An international campaign to eradicate the American screw-worm fly from North Africa was begun in December 1990 and involved the release of sterile male flies imported from Mexico, where they are commercially produced. The flies were dispersed by air at densities of 500 to 1200 per km² over an area of 40,000 km². More than 745 million flies have been used and 40 million a week were dispersed during the campaign. (See FLIES; MYIASIS; STRIKE.)

Scrotal

Relating to the scrotum.

Scrub Typhus, Japanese River Fever

A disease caused by *Rickettsia tsutsugamushi*, and transmitted by mites.

Scruff

A colloquial term for the loose skin over the neck of dogs, cats and ferrets, and over the withers in rabbits, mice and hamsters. It is a useful area to grasp for restraint of those animals, but not rats or hamsters and never without supporting the weight of the animal under the rump.

Scur

A loose, horny growth, not attached to the skull, at the site normally occupied by a horn in a horned breed of cattle.

A bull calf with a scur, or with a bony protuberance beneath the skin at the horn site, is not a pure polled animal. Without these, a bull can be expected to breed true as regards the poll character; this can be checked by a progeny test of the bull mated to horned cows – the result should be polled heifer calves or bull calves with scurs or bony protuberances, but no calves with horns.

Sea Lice

Farmed Atlantic salmon, and sea trout, are subject to infestation by sea lice (*Lepeophtheirus salmonis* and *Caligus elongatus*) with serious economic consequences. Treatment with parasiticides including hydrogen peroxide and synthetic pyrethroids such as cypermethrin is effective, but must be repeated at intervals depending on circumstances.

Seals

A common marine mammal found around the coasts of Britain and many parts of the world, favouring colder climates. True, or earless, seals are members of the family *Phocidae*. They are susceptible to infection by a morbillivirus similar to that causing canine distemper, which results in PHOCINE DISTEMPER causing outbreaks of infection, often with high mortality. In polluted areas, they are liable to suffer mercury poisoning.

VetBooks.ir

Sealyham Terriers
A short-legged breed with a wiry, often white, coat. PROGRESSIVE RETINAL ATROPHY is inherited and the breed is prone to DEAFNESS, INTERVERTEBRAL DISC PROTRUSION and LENS LUXATION (DNA test available). They are prone to INTERDIGITAL CYSTS.

Season
(See OESTRUS.)

Seat-Worm
(See OXYURIS.)

Seaweed
A source of AGAR; a food grazed by sheep on the seashore, and sometimes fed to horses and cattle. A source of iodine and other trace elements and (in the case of brown seaweeds) of vitamins A, B_1, B_2, C and D. Animals do not take readily to seaweed as a rule, nor are they able to digest it well at first, but after a few days it usually proves an acceptable supplement to the ration.

The ruminal microflora of sheep feeding almost entirely on seaweed were devoid of cellulolytic bacteria and anaerobic bacteria which are so numerous in sheep-grazing pasture. An extract of kelp seaweed is available dogs and cats in the UK. (See FUCUS.)

Sebaceous Glands
Sebaceous glands are found in the skin (see diagram under SKIN), and secrete the oily sebum which prevents excessive dryness of hair and skin. The glands are liable to become invaded during some parasitic diseases; sometimes a blocked duct leads to a retention cyst.

Seborrhea
American spelling of SEBORRHOEA.

S

Seborrhoea
An abnormal, excessive secretion by the sebaceous glands. (See SKIN.)

Seborrhoeic, Seborrheic (US)
Related to or caused by SEBORRHOEA. (See MALASSEZIA.)

Sebright Bantam Chickens
This is a true British BANTAM breed with no corresponding large chicken breed. It was developed by Sir John Sebright. A popular, mainly ornamental, breed; they lay small eggs and are not used for meat. The male weighs 625 g (1.4 lb) and the female 570 g (1.25 lb). The breed has plumage laced with a border of black on a base of either dark gold or silver.

Sebum
The oily section of a SEBACEOUS GLAND. (See SKIN - GLANDS OF THE SKIN.)

Secale cereale
(See RYE.)

Secondary Case, Secondary Infection, Secondary Disease
A case of infection where the date of onset is greater than the incubation time for the PRIMARY CASE or where the risk factor is most probably that of exposure to the primary case. It is thus considered that the infection has been caught from the primary case or another infected animal. (See also CO-PRIMARY CASE, INDEX CASE, PRIMARY CASE.)

Secondary Intention
A way of describing healing of a wound in which there is exposure of the underlying tissues. The wound fills with granulation tissue and is then covered from the sides with epithelium. (See INTENTION.)

Secretin
A hormone secreted by the mucous membrane near the beginning of the small intestine when food comes into contact with it. On reaching the pancreas via the bloodstream, the hormone stimulates the flow of pancreatic juice.

Secretory IgA
It has been shown that in some infections, especially those of the respiratory and digestive tracts, immunity is conferred by antibody found in the local secretions – and not by the antibody circulating in the bloodstream. For example, the IgA found in secretions is quite different from that found in serum. Secretory IgA is relatively resistant to breakdown by digestive enzymes and has an affinity for mucus. (See IMMUNE RESPONSE, IgA.)

-sectomy
A word-ending meaning 'surgical removal of'.

Sedation
The state of reduced or complete reduction in excitement or irritability, often following administration of a SEDATIVE.

Sedative
A compound inducing SEDATION, thereby reducing nervousness, irritability and excitement and often acting by depression of the CENTRAL NERVOUS SYSTEM.

Seed, Impregnated
This is used to administer medication to aviary birds. Seed can be TOP DRESSED or the kernels of

VetBooks.ir

dehusked seeds can be impregnated with medication. Top-dressing runs the risk of the medication being discarded when the birds (e.g. parrots) dehusk the seed.

Seed Corn, dressed

A number of substances with which seed corn may be dressed may be toxic to animals. For example, corn with a mercury dressing has been fed to pigs with fatal results.

Dieldrin seed dressings lead to poisoning in wild birds and, indirectly, have killed dogs, cats, and foxes which have eaten poisoned birds. (See also under GAME BIRDS, MORTALITY.)

Seedy Toe

A condition affecting the hoof of the horse, in which there is a separation of the wall from the laminar matrix below, and the formation in the space so produced of a dry, crumbly, friable variety of horn, which bears some resemblance to pumice-stone. It may occur at any part of the wall of the foot. The cause is uncertain.

Signs In most cases the condition is generally first noticed by the farrier when paring down the wall prior to fitting a new shoe. Lameness is only seen when the extent of the separation is large, or when foreign matter becomes forced up into the space, and causes pressure upon the sensitive matrix.

When struck with a hammer the affected part of the foot gives out a hollow resonating note, and the margins of the separated area can usually be fairly well determined by this means.

Treatment All the soft friable horn should be cleared away and an antibiotic applied within. A suitable shoe should be fitted to cover the base of the cavity. (See HOOF REPAIR WITH PLASTICS.)

Seizure

A sudden attack of a disease or illness or a recurrence. It also refers to a period of disturbed brain activity resulting in FITS or CONVULSIONS and it occurs in EPILEPSY.

Selamectin

A derivative of ivermectin licensed for use in the treatment and prevention of heartworm infestation in dogs in the UK. (See HEARTWORMS; IVERMECTIN.)

Selegiline

A drug used in the treatment of certain behavioural conditions in the dog. Clinical improvement may occur within two months but some dogs require treatment for much longer.

Selenium (Se)

A TRACE ELEMENT essential in minute quantities for nutrition, but toxic if fed in excess. In some parts of Britain home-grown animal feeds may not contain enough selenium, and unless concentrates are fed as well, nutritional muscular dystrophy (see MUSCLES, DISEASES OF) may result. The organic form conjugated to the amino acid METHIONINE is more easily utilised by animals than inorganic salts such as sodium selenite. In other areas the soil may contain an excess of selenium. The normal level in animal feeds should be around 0.2 ppm; the maximum level of selenium allowed in pig diets without a veterinary prescription is 0.5 mg/kg, this level being specified under the Feeding-Stuffs Regulations 2000.

Supplements of selenium can be given not only in the feed, but also in drinking water, by subcutaneous injection, by BOLUS and, for lambs by an oral dose.

Sodium selenate is used by horticulturists as an insecticide, and accordingly there is a possibility of toxic effect occurring in animals. Sterility results and also loss of hair. These signs are also observed in parts of the USA and Eire where the soil contains an excess of selenium. In the acute form of poisoning, animals may be found wandering aimlessly or in circles. Paralysis precedes death.

Externally, selenium sulphide is used in wet shampoos for dogs and cats infested with FLEAS, harvest mites, or *Cheyletiella* mites. (See also VITAMIN E; LATHYRISM; MUSCLES, DISEASES OF; IONOPHORES.)

Retention of placentas in a dairy herd in the north of England was associated with a selenium deficiency; this also lowers an animal's ability to fight infection. Selenium enhances phagocytic activity and increases leukocyte, lymphocyte and neutrophil numbers.

Sella Turcica

Sella turcica is the name applied to the deep hollow on the upper surface of the sphenoid bone in which the pituitary gland rests.

Semen, Seminal Fluid

Semen (seminal fluid) consists of the secretions of the accessory sex glands, in which is found the mature spermatozoa (or sperms) from the epididymis. A single ejaculation by a bull may produce semen containing millions of sperms.

The secretions of the accessory sex glands act as a vehicle for the sperms, probably as a nutrient, and neutralise any acidity in the female genital passages.

The accessory glands are the prostate; the ampullae of the vasa deferens (absent in the boar); the seminal vesicles; and (except in the dog) the

bulbo-urethral (Cowper's) glands situated on either side of the urethra. (See also under SPERMATOZOA; ARTIFICIAL INSEMINATION.)

Imports of semen in Britain are subject to DEFRA regulations.

Semen Extenders
Fluids added to semen used in artificial insemination to increase volume without decreasing viability of the sperm. They provide nutrients for sperm, antibiotics to reduce infections, maintain suitable pH and osmotic pressure and protect the sperm during freezing and thawing.

Seminal Vesicles
(See under TESTICLE; ACTINOBACILLOSIS.)

Seminoma
A germ cell tumour of the testis. It is relatively common in dogs but rare in other species.

Sendai Virus
This causes respiratory disease in the mouse but is most noteworthy for its use in experimental cell fusion work.

Senkobo
Cutaneous streptothricosis, caused by *Dermatophilus congolensis*, occurring in tropical Africa in cattle, sheep, goats, and horses. The hair stands erect and matted on small patches along the back. Moist, raw areas are left, then crusts form, and eventually a 'crocodile-skin' effect is produced. The disease occurs in association with tick infestation, and can therefore be controlled by means of an ectoparasiticide. (See DERMATOPHILUS.)

Senna
A standardised preparation of this household laxative has been recommended in treating or preventing constipation in pigs – especially in pregnant sows. A sublaxative dose of 3 g is recommended during the farrowing period.

Sensitisation
(See ALLERGY.)

Sensitivity
1. In a micro-organism, its degree of susceptibility to the killing or inhibiting effect of antibiotics.
2. In a diagnostic test, a measure of the test's ability to identify the condition under investigation. This is the indication of the number of animals that are falsely positive to the test, i.e. they do not have the condition. Ideally with all tests they should give a 100 per cent positive sensitivity and thus have no false positives (See SPECIFICITY).

SEP
Abbreviation for SWINE ENZOOTIC PNEUMONIA. (See ENZOOTIC PNEUMONIA OF PIGS.)

Sepsis
(See SUPPURATION; ANTISEPTICS.)

Septicaemia
A condition in which toxic bacteria invade the bloodstream. It is very serious because the organisms and the toxins they produce become widely distributed throughout the tissues, and practically every organ is affected by them. In many cases, septicaemia results in death if treatment is too late or if the bacterium is resistant to the antibiotic used. Examples are ANTHRAX; HAEMORRHAGIC SEPTICAEMIA.

Signs In many cases, especially when the animal is in a weakened state, sudden death, preceded by a very high temperature, may be the only sign of the presence of septicaemia.

Treatment Antibiotics and/or sulfonamides and antisera (where appropriate) are given. Supportive therapy (anti-inflammatory drugs, fluid therapy and PARENTERAL nutrition) is usually required.

Septum
A thin wall dividing two cavities or masses of tissue.

Sequelae
Clinical signs or effects which may follow disease or injury. Thus PNEUMONIA may follow a simple INFLUENZA, and CHOREA may follow DISTEMPER.

Sequestrum
A fragment of bone which, in the process of necrosis, has been cast off from the living bone and has died, but still remains in the tissues. It often leads to abscessation which does not resolve until the bone fragment is removed.

Serine
An essential amino acid, which is important in the storage of energy in organs and in the production of immunoglobulins.

Seroconversion
The appearance in the blood serum of antibodies following vaccination (or natural exposure to some infective agent).

Serosa
(See SEROUS MEMBRANES.)

Serosal Linings
(See SEROUS MEMBRANES.)

VetBooks.ir

VetBooks.ir

Serosal Surfaces
(See SEROUS MEMBRANES.)

Serotonin
A neurotransmitter which inhibits gastric secretion, stimulates smooth muscle and produces vasoconstriction. It is mainly found in the gastrointestinal tract, platelets, pineal gland, and in the central nervous system of both humans and animals. In man, it contributes to feelings of well-being. Also known as 5-hydroxytryptamine, it is derived from TRYPTOPHAN. It can be converted into MELATONIN.

Serous Membranes
Serous membranes are smooth, glistening, transparent membranes that line certain of the large cavities of the body and cover the organs that are contained in them. The chief serous membranes are: (1) the peritoneum, lining the cavity of the abdomen; (2) the pleurae, one of which lines each side of the chest and surrounds the corresponding lung; (3) the pericardium, in which the heart lies; (4) the tunica vaginalis, one on each side, enclosing a testicle; and (5) the mesentery supporting the small intestine.

Serpulina
A group of spirochaetes which includes *Serpulina hyodysenteriae*, the cause of swine dysentery. (See SWINE DYSENTERY; TREPONEMA.)

Sertoli Cells
Cells in the testicular tubules to which spermatids become attached. Their function is believed to be the nourishment of spermatids. (See diagram under SPERMATOZOA.)

Sertoli-Cell Tumour
This may be associated in the dog with feminisation, urethral bleeding, and urinary obstruction. (See also SPERMATIC CORD, TORSION OF.)

Serum
Serum is the fluid which separates from blood when clotting takes place. It is, in effect, defibrinated plasma without the red cells, platelets or white cells. (For a description of plasma, see BLOOD.) (See also ANTISERUM.)

Serum Agglutination Test, Standard Agglutination Test (SAT)
It is used to detect antibodies and involves clumping of the antibody with an antigen. The test often used is the microagglutination test. It has been used to detect *Brucella abortus*, *B. melitensis* and *B. suis*.

Serum Glutamic Oxalo-Acetate Aminotransferase (SGOT)
(See ASPARTATE TRANSFERASE.)

Serum Glutamine-Pyruvic Transaminase (SGPT)
(See ALANINE AMINOTRANSFERASE.)

Serum Gonadotrophin
(See HORMONES.)

Serum Sickness
In human medicine this term is applied to the fever, glandular enlargements, oedema, and pain in the joints, which may occur 8 to 12 days after the injection of a 'foreign' serum. Immediate reaction, denoting sensitisation by a previous injection of the same kind of serum, is regarded as anaphylactic shock. (See HYPERSENSITIVITY.)

Serum Therapy
(See ANTISERUM.)

Service Period
This is usually taken to mean the interval between giving birth and subsequent service leading to conception. In cattle, an 85-day service period would appear to be the optimum number of days between calving and successful service. If the trend of heat periods after calving is detected at about 6 weeks, and checked again around 9 weeks, the herdsman can, with a fair degree of accuracy, be on the look-out for bulling at or about the twelfth week (or 84 to 85 days). In practice, most farmers will serve at nine weeks to try to maintain a 365-day calving interval. Very early service may produce prolonged infertility.

Sesamoid Bone
A bone which lies within a tendon; it help to minimise friction where the tendon passes around another bone. The largest example is the PATELLA or the kneecap.

Setae
Stiff hairs. (See CATERPILLARS; SPIDERS.)

'Set-Fast'
(See EQUINE MYOGLOBINURIA; EQUINE RHABDOMYOLYSIS).

Severe Acute Respiratory Syndrome
(See SARS.)

Severe Combined Immunodeficiency (SCID)
An autosomal recessive disease characterised by immunodeficiency involving many factors including immunoglobulin synthesis failure, cell mediated immunity failure, thymic hypoplasia and lymphocyte deficiency. It is seen as susceptibility and eventual

death following cessation of maternally-acquired immunity. It is seen in BASSET HOUNDS, CORGIS and ARAB foals.

Sevoflurane
An inhalation anaesthetic licensed for use in dogs (except for pregnant and lactating bitches). The dose must be carefully monitored in geriatric, debilitated animals or those suspected to have a tendency towards malignant hyperthermia. It is similar to ISOFLURANE but with a quicker onset of action and recovery, and popular for the use in small mammals, birds and reptiles. (See ANAESTHESIA, GENERAL.)

Sewage Sludge
Sewage sludge is often contaminated by heavy metals (cadmium, copper, lead) and should not be used for manuring pasture unless these have been removed. The heavy metals are present as harmless sulphide complexes when first applied to the soil: however, passage through earthworms breaks down the complexes, which can then be absorbed by animals. The process may take several years. Horses on pasture were fatally poisoned by cadmium, lead and copper five years after sewage sludge was applied. More rarely, the eggs of *Taenia saginata*, which pass through the filters in some sewage, may be present on pasture and lead to cysticercosis in cattle. (See also SALMONELLOSIS; SLURRY; COPPER, POISONING BY in sheep.)

Sex, Predetermined, of Calves
(See PREDETERMINED SEX OF CALVES.)

Sex Differentiation
Sex differentiation in the fetus is briefly described under EMBRYOLOGY. (See also under GENETICS, HEREDITY AND BREEDING; CYTOGENETICS; FREEMARTIN.)

S

Sex-Hormones
(See HORMONES.)

Sex-Inversion
Animals which at birth, and for a variable period afterwards, are of normal sexual structure and function, but which later in life acquire properties of the opposite sex, are said to undergo sex-inversion. This has been seen in Ayrshire cows permanently kept indoors. In domestic poultry, the reverse can sometimes occur, where a hen will lay eggs for part of a laying season, moult and then grow cockerel feathers and crow. In the Middle Ages, these birds were burnt at the stake for witchcraft. (See also FEMINISATION.)

Sex Pilus
(See PLASMIDS.)

Sexual Cycle
(See OESTRUS.)

Sexually Transmitted Diseases
(See VENEREAL DISEASES.)

SGOT
Abbreviation of SERUM GLUTAMIC OXALOACETATE AMINOTRANSFERASE. (See ASPARTATE TRANSFERASE.)

SGPT
Abbreviation of SERUM GLUTAMINE-PYRUVIC TRANSAMINASE. (See ALANINE AMINOTRANSFERASE.)

Shar-Pei
A medium-sized breed of dog originally from China which is characterised by very loose, infolded skin. In the folds, dermatitis may develop (INTERTRIGO), if the care of the dog is less than good. ENTROPION, MEGAOESOPHAGUS and PATELLAR LUXATION may also be inherited but the mechanisms are unknown. They are prone to SUNBURN.

Shavings
(See under BEDDING AND BEDDING MATERIALS.)

Shearing
In Britain, the usual time for shearing is May in the southern counties, early June on upland semi-arable farms, and during July in mountain flocks.

The newly shorn sheep is very sensitive to cold. This is particularly so with machine shearing which leaves a fleece of about 6 mm depth compared with about 12 mm after hand shearing. In Australia, late-winter and early-spring shearing of ewes has led to a high mortality, so that the practice is being abandoned or the usual shears replaced by 'snow combs' which leave a longer fleece. In Britain, losses of weight or poor gains in lambs shorn during the summer can largely be attributed to an effect of cold.

Chemical 'shearing' Certain drugs, for example cyclophosphamide and mimozone, cause the wool to loosen so that it can easily be plucked. It has been suggested that this could be an economical way of defleecing sheep. However, the sheep is left naked and unprotected against cold. It does not seem that the system has gained wide usage.

Shechita
The Jewish method of slaughtering animals and birds for food. Animals must be alive, uninjured and healthy and are not stunned before killing. They are slaughtered by a suitably trained and licensed person – a schochet. The meat is known as

kosher. The hindquarters are required to have their veins removed (porging), which is difficult and costly, and so only the front of cattle and sheep is eaten.

Sheep, Abortion and Infertility in

(See ABORTION.)

Sheep, Breeds of

Introduction Sheep are maintained, generally speaking, with the object of producing both wool and meat. In some countries' ewe's milk is valued for cheese-making. In the UK the importance of the fleece tends to be disregarded.

Hardiness, prolificacy, milking capacity of the females and activity are all important. What will constitute the most profitable type must be carefully considered in relation to local conditions.

British breeds of sheep British breeds – some 40 are registered – offer a wide choice of types, adapted to almost every conceivable set of conditions under which sheep are maintained in the country, from the highest mountain grazings in Scotland and Wales to the richest lowland pastures, or the dry arable farms of the Wolds. However, crossbreeds are increasingly popular.

Cambridge This breed was developed at the University of Cambridge by Professor John Owen in collaboration with Alun Davies. The breed is now regarded as one of the most prolific in the world with litter sizes of 1.7, 2.5 and 2.9 for 1-, 2- and 3-year-old females respectively. Both sexes are polled, ewes weighing 70 kg (154 lb) and rams 90 kg (198 lb). (See also TEXEL SHEEP; COOPWORTH SHEEP.)

The British breeds are commonly classified as Longwools, Downs, other Shortwools, and Mountain breeds.

Longwool breeds include DEVON LONGWOOL, BORDER LEICESTER, KENT or ROMNEY MARSH, LEICESTER, LINCOLN LONGWOOL, ROSCOMMON LONGWOOL, SOUTH DEVON and WENSLEYDALE.

Downs breeds include Southdown, Suffolk, Hampshire, Dorset Down, Shropshire and Oxford.

Other Shortwool breeds include DEVON CLOSEWOOL, DORSET HORN, KERRY HILL, RYELAND and WILTSHIRE HORN.

Mountain breeds include SCOTTISH BLACKFACE, CHEVIOT, SWALEDALE, HERDWICK, LONK, WELSH SHEEP, EXMOOR and DARTMOOR.

UK sheep population A rapid rise in sheep numbers followed the imposition of dairy milk quotas, plus the granting of various subsidy payments. At December 1994, MAFF recorded 29.5 million of which 20.1 million represented ewes in the breeding flock. The summer census annually lists the population at 35 to 40 million. However, the virtual collapse of the sheep market in the later 1990s led to a drop in numbers. A further fall followed the foot-and-mouth diseases outbreaks of 2001, since when restocking has revived numbers. In 2007, there were about 16 million breeding ewes, with a peak population of 33.5 million after the lambing season.

Sheep, Names Given According to Age, Sex, etc.

There are probably more names for any given class of sheep than is the case among any of the other domesticated animals, and it is almost impossible to give a list that will include all the various designations that are used, but the table gives a list of commoner terms.

Sheep, Winter Coats for

(See SHEARING.)

Sheep Breeding and Management

The use of hybrids, referred to under SHEEP, BREEDS OF (British), is a relatively new trend. Another is the housing of ewes for part of the winter before lambing. The number of sheep per flock has increased and a full-time shepherd will be looking after more than 10,000 breeding ewes.

Economic factors have dictated many changes in traditional sheep management. The sheep market has altered greatly and demand is mainly for lamb, not mutton. However, sheep are still sold through markets on a liveweight basis and are classed as light (25.5 kg [56 lb]), standard (32.1 kg to 39 kg [70.12 lb to 85 lb]), medium (39.1 kg to 45.5 kg [86.3 lb to 100 lb]) and heavy (45.6 kg to 52 kg [100 lb to 114 lb]). Wool is now of relatively low value because of reduced demand.

Efficient sheep production depends on raising the productivity of grassland by improving the quality and quantity of the grazing, and improving the growth characteristics of the sheep. Worming

NAMES OF SHEEP GIVEN ACCORDING TO AGE, SEX, ETC.

Periods	Male		Female	Remarks
	Uncastrated	Castrated		
Birth to weaning	Tub lamb Ram lamb Pur lamb Heeder	Hogg lamb	Ewe lamb Gimmer lamb	A sheep until weaning is a lamb
Weaning to Shearing	Hogg (also used for the female) Hogget (also used for the female) Haggerel or hoggerel Tup teg Ram hogg Tup hogg	Wether hogg Wedder hogg He teg	Gimmer hogg Ewe hogg Sheeder ewe Ewe teg	Hogget wool is wool of the first shearing
First to second shearing	Shearing, or shearling, or shear hogg Diamond ram Dinmond ram Dinmont ram tup One-shear tup	Shearing wether Shear hogg Wether hogg Wedder hogg Two-toothed wether	Shearing ewe Shearling gimmer Theave Double-toothed ewe Double-toothed gimmer Gimmer	'Ewe', if in-lamb or with lamb; if not a 'barren gimmer'; if not put to a ram is a 'yield gimmer' (Scotland)
Second to third shearing	Two-shear ram Two-shear tup	Four-toothed wether Two-shear	Two-shear ewe	A ewe which has ceased to give milk is a 'yeld ewe'; taken from the breeding flock she is a 'draft ewe' or a 'draft gimmer'
Third to fourth shearing	Three-shear ram Three-shear tup	Six-toothed wether Three-shear wether	Three-shear ewe Winter ewe (Scotland)	
Afterwards	Aged tup or ram	Full-mouthed, full-marked or aged wether or wedder	Ewe Ewe	After fourth shearing 'aged' or 'three-winter'

VetBooks.ir

regimes must be established to deal with the infestations that affect all grassland used for growing young sheep. Feed available to the lactating ewe must be of sufficient quality to allow a good supply of milk for twin or triplet lambs, and limit initial grass uptake.

Direct and indirect feed costs (including fertilisers, fuel and labour), can account for 60 per cent of the cost of sheep production. This emphasises the importance of the efficiency of feed conversion. In lowland flocks, most food is consumed by the ewes, so the number of lambs weaned per ewe per year is of critical importance. Ideally, the aim is for a relatively small ewe, with good milking potential, which can be crossed with a larger, meat-producing breed to produce several offspring that grow fast and economically.

While artificial rearing systems for lambs are used, they are not favoured by most breeders except for orphan lambs or those from large litters. Most farmers aim to produce two viable lambs that can be naturally reared.

Housing of sheep (In-wintering) Sheep are frequently housed for part of the year, usually before and after lambing. The duration of housing depends on the area and other management considerations. In Scotland, in-wintering of ewes lambing between December and April revives a practice traditional in hill areas until a change was made to wintering them on lowland pastures. That policy proved too costly and led to the flocks being kept on the farms and provided with shelter. Winter housing is also now common on lowland farms. The ewes are kept in groups of 50 to 70, lambing at the same time.

Housing permits greater attention to feeding and care at lambing, and leads to less culling as the sheep are not subjected to the stress of exposure to severe weather and finding their own food. However, the risk of disease and mismothering is higher.

Portable feeding troughs and racks in sheep houses can be used as partitions and leave an unobstructed floor so that pen sizes can be altered according to requirements. The two main types of feeder are a hay rack, with sloping sides so that seeds do not drop into the sheep's eyes, with a concentrate trough below (preferred for upland sheep); and a box type with a barrier in front which prevents the ewes from wasting the forage. Troughs should allow a length per ewe of 23 to 25 cm (9 to 10 in) for hill breeds and 30 to 35 cm (12 to 14 in) for lowland breeds. A supply of fresh (i.e. running) water must be provided; sheep will not drink water that is even slightly fouled, or warm. A raised trough fed from a slow running tap, with drainage to the outside, is suitable. About 30 cm (12 in) of trough per sheep should suffice for 40 sheep.

Adequate ventilation is essential. Yorkshire boarding to walls is suitable. If slatted flooring is used, care must be taken that updrafts do not chill sheep and, especially, lambs. The slats must be laid parallel to the door openings.

Lamb survival Lambs have the highest post-natal mortality of all the main farm species. This is partly because they are very susceptible to hypothermia caused by exposure, or lack of food. Problems arise when the environment is colder than the critical temperature of the lamb in the first few hours after birth. This is 32° C (89.5° F) for heavy lambs and 37° C (98.5° F) for light lambs. As most lambs are born at ambient temperatures well below this, they have to increase their metabolic rate to maintain body temperature. Wind-chill factor can reduce the effective temperature considerably. A wind speed of 20 km/h (12 mph) can have a cooling effect of up to 20° C (68° F) or more if there is rain. Even when a lamb survives such conditions, it will have suffered a major drain on its bodily reserves, mainly in the form of fat. In bad conditions these may be used up in between 5 and 17 hours.

While a lamb will normally begin to replenish its store of energy within an hour of birth by sucking, work in Australia has shown that the urge to do so is reduced if its body temperature falls below 37° C [98.5° F]. In some breeds of sheep, such temperatures occur in weather not unusually severe for March and April in Scotland. So cold not only increases the demand for energy, but may prevent that demand from being met.

Starvation exaggerates the effect of cold by reducing heat-production capability, so increasing the risk of death from hypothermia.

It may be possible to breed for greater ability to survive under harsh conditions. Experiments suggest that there are significant differences between breeds in their tolerance of body cooling; and within breeds, some individual sheep have a cold-resistance several times greater than that of other individuals. Preliminary trials have indicated that this character is moderately well inherited.

Lambs require between 180 ml and 210 ml of colostrum per kg bodyweight during the first 18 hours after birth, to provide sufficient fuel for heat production, and immunoglobulins for protection against infections.

Ewes which are well fed during late pregnancy produce more colostrum than their lambs need; those with singletons have enough for a second lamb. By contrast, most underfed ewes do not produce enough colostrum.

Colostrum can be readily obtained by hand milking and stored for subsequent use. Yields are markedly increased when milking is preceded by an oxytocin injection.

VetBooks.ir

Life-saving techniques The following recommendations have been made by the Moredun Institute, Edinburgh. Two danger periods should be recognised: (1) from birth to five hours afterwards; and (2) 10 hours to 3 days after birth.

During the first period, moderate hypothermia (a body temperature of 37° C to 39° C [98.5°F to 102° F]) usually responds to drying the lamb, feeding it colostrum by stomach tube, and moving it to shelter along with the ewe. Serious hypothermia (below 37° C [98.5° F]) requires in addition that the lamb be warmed in air at 37° C to 40° C (98.5° F to 104° F) until its body temperature has reached 37° C (98.5° F). When removed from the Moredun-type bale-warmer (heated by a domestic fan-heater), the lamb is then given colostrum and, if strong enough to suck vigorously, can be reunited with the ewe. If not strong enough, the lamb must be housed for a day or two in its own cardboard box in an intensive care unit. There, colostrum is given 3 times daily, and warmth provided by an overhead infra-red lamp.

During the second danger period, when serious hypothermia is then usually due to depressed heat production as a result of starvation, and often complicated by low glucose levels in the blood, treatment consists of drying the lamb, the injection of glucose, and warming – in that order.

Further details of bale-warmers, lamb warming boxes, the Moredun lamb thermometer (which indicates by flashing, coloured lights whether a lamb has hypothermia and, if so, how badly) and life-saving techniques can be obtained from the Moredun Research Institute, Pentlands Scientific Park, Bush Loan, Penicuik, Midlothian EH26 QPZ.

Worm control Most sheep at pasture are infected with roundworms. These, if numerous, can cause outbreaks of scouring and obvious unthriftiness. Subclinical infestations of the stomach or intestine can reduce the weight gain of growing lambs by 20 per cent to 50 per cent. (See WORMS, FARM TREATMENT AGAINST.)

Winter feeding Research has indicated the wisdom of hand feeding with starchy concentrates (rather than high-protein or high-roughage rations) to obviate the hill ewe burning up her own tissues in order to keep warm and alive during very cold weather. (See under ABORTION, FEED BLOCKS.)

For other aspects of sheep husbandry, and related health and disease problems, see ABORTION; BARLEY POISONING; BRACKEN POISONING; 'BROKEN MOUTH'; CASTRATION; CLOTHING OF ANIMALS; COBALT; COLOSTRUM; CONTROLLED BREEDING; COPPER; COPPER, POISONING BY; DIET AND DIETETICS; DIPS AND DIPPING; DOCKING; DRENCHING; EXPOSURE; FEED BLOCKS; FLEECE; FLUSHING OF EWES; GENETICS, HEREDITY AND BREEDING; HOUSING OF ANIMALS; INFECTION; INFERTILITY; ISOLATION; LIGHTNING STRIKE; LUMPY WOOL; NOTIFIABLE DISEASES; OESTRUS; PARASITES; PARTURITION, DRUG-INDUCED; PASTURE, CONTAMINATION OF; PASTURE MANAGEMENT; POISONING; SEAWEED; SHEARING; SHEEP, DISEASES OF; SHEEPDOGS; SOIL-CONTAMINATED HERBAGE; STELL; STOCKING RATES; STRESS; TRACE ELEMENTS; TROPICS, LIVESTOCK PRODUCTION IN THE; VAGINA – Rupture; VITAMINS; WATER AND WATERING OF ANIMALS; WEANING; WOOL BALLS IN LAMBS; WORMS, FARM TREATMENT AGAINST.

Clipping (See SHEARING; CLOTHING OF ANIMALS; WOOL SLIP.)

Sheep Dipping

(See DIPS AND DIPPING.)

Sheepdogs

There are three different types. Most in Britain are used to gather sheep; other types drive sheep or cattle (so-called 'huntaway' breeds) and those that act as guard dogs against predators. (See BEARDED COLLIES, BELGIAN SHEPHERD DOGS, BORDER COLLIES, COLLIE DOGS, HUNTAWAY DOGS, KELPIE DOGS, KOMONDOR DOGS, SHETLAND SHEEPDOGS, WELSH SHEEPDOGS).

Sheepdogs are popularly regarded as exceptionally healthy, but a survey in Scotland showed that at least 11 per cent were suffering from 'BLACK TONGUE' as a result of an inadequate diet.

Sheepdogs may walk or run 90 miles per day at lambing time and must have an adequate diet if stamina and health are to be maintained. (See also under GID; RICKETS.)

Sheepdogs may become infected with brucellosis as a result of eating infected cattle afterbirths; through eating dead sheep they may become infested with the tapeworm causing HYDATID DISEASE. Regular worming is essential. (See also ORF; ANTHRAX; BOTULISM.)

Sheep Genome

The genetic code of domestic sheep was first determined in 2014. It showed that they became distinct from goats about four million years ago.

Sheep Health Scheme

A preventive medicine and productivity monitoring scheme for maintaining herd health; it is operated by Scottish Agricultural College (SAC). A Premium Health scheme is operated for flocks seeking accreditation as free from chlamydial abortion. A maedi/visna accreditation scheme is also available; it involves certification by a veterinary surgeon that movement records have been checked, flock security rules obeyed and blood samples taken.

The SAC Scrapie Monitoring Scheme is also available. (See under NATIONAL SCRAPIE PLAN.)

Sheep Ked, *Melophagus ovinus*

Sheep ked (*Melophagus ovinus*) is a wingless blood-sucking parasite. (See KED.)

Sheep Pox

(See POX.)

Sheep Scab

The popular name for psoroptic mange. Sheep scab was formerly a notifiable disease in the UK, from where it was eradicated in 1952. It reappeared in 1973 and, following the abolition of compulsory dipping, has again become a serious problem. In the late 1990s, as many as 25 per cent of sheep pelts showed evidence of damage associated with scab. Although sheep scab is no longer a notifiable disease in most of the UK, control is exercised through local authorities (**NB** It is still a NOTIFIABLE DISEASE in Scotland under the Sheep Scab [Scotland] Order 2010). It is an offence under the Protection of Animals Acts and the Welfare of Animals (Northern Ireland) Act 1972 and 2001 to expose an infected sheep for sale; the charge would be one of causing unnecessary suffering. (See MANGE - MANGE IN SHEEP.)

Shelters, Need for

(See under EXPOSURE, TROPICS, LIVESTOCK PRODUCTION IN THE; also STELL.)

Shelties

(See SHETLAND SHEEPDOG.)

Shepherds

Occupational hazards include the following diseases: CAMPYLOBACTER INFECTIONS; CHLAMYDOPHILA; HYDATID DISEASE; LISTERIOSIS; LOUPING-ILL; ORF; PASTEURELLOSIS IN SHEEP; Q FEVER; SALMONELLOSIS; TOXOPLASMOSIS. (See also ZOONOSES.)

Shepherdesses, if pregnant, are at risk when helping with lambing. (See CHLAMYDOPHILA.)

Shetland Ponies

Small sturdy and robust ponies with long coats, originating from the Shetland Islands. Officially they should be less than 11 HANDS (1.1 m) high. They are strong-willed but when suitably trained they make a good child's first pony. Because of their origin they have a tendency to become overweight. PATELLAR LUXATION is relatively common in the breed.

Shetland Sheepdog

A small breed resembling a toy rough collie; often called 'shelties'. PROGRESSIVE RETINAL ATROPHY, RETINAL PIGMENT EPITHELIAL DYSTROPHY and DISTICHIASIS are recessive traits. Haemophilia A (Factor VIII deficiency) is a sex-linked recessive trait. DEAFNESS may be inherited but the mechanism is unknown and PATENT DUCTUS ARTERIOSUS appears to be polygenic in origin. CORNEAL LIPIDOSIS has also been recorded. (See HEART DISEASES). They are also prone to SUPERFICIAL PYODERMA, CANINE MULTIDRUG SENSITIVITY, VON WILLEBRAND'S DISEASE (DNA test available).

Shigellosis

Infection by one of the Gram-negative *Shigella* bacteria. (See Sleepy foal under FOALS, DISEASES OF - SEPTICAEMIA.)

Shih Tzu

A small dog with short muzzle and long-flowing hair; it originates from Tibet. The breed is prone to CLEFT PALATE and INTERVERTEBRAL DISC PROTRUSION and RENAL DYSPLASIA (DNA test available). They are also prone to KERATOCONJUNCTIVITIS SICCA.

'Shipping Fever'

A disease of cattle caused by a virus and/or *Pasteurella multocida* or *P. haemolytica*. 'Shipping fever' is very common in American feedlots, among cattle six months to two years old, and often follows the stress of transport, castration, dehorning, winter weather, change of food, etc. In the USA the term 'bovine respiratory disease complex' is a synonym. (See PASTEURELLA.)

Signs include fever, loss of appetite, weakness, followed by nasal discharge, a discharge from the eyes, distressed breathing, coughing, and signs indicating bronchopneumonia. Mortality is usually 1 per cent to 2 per cent, but may exceed this if cases are neglected.

Treatment And Prevention Antibiotics and sulfa drugs are used. Immunisation has been tried using myxovirus parainfluenza-3 and *P. septica*, for example.

Shire Horses

These HEAVY HORSES are an old English breed that was bred as a draught horse. The shire is the largest of all horses and some stallions can reach over 20 HANDS high; normally they are between 17 and 19 HANDS. They are normally bay in colour with FEATHERED legs. They are quiet and normally of good temperament.

'Shivering'

A nervous disease of horses, particularly CLYDESDALES. It runs a slowly progressive course, and constitutes an unsoundness.

Cause This is unknown, though it seems that there may be a hereditary predisposition to it.

Signs In early stages backing the horse may be resented or there may be a slight tremor in one or both hind legs. In a well-marked case, the muscles of the hindquarters are seen to quiver or tremble. At the same time, the tail is usually elevated and also shows the quivering movements. In advanced cases it may be difficult or impossible to pick up either of the hind-feet, and shoeing is only accomplished with difficulty. When the hind-limb is raised from the ground during backing, in many cases it also quivers, or 'shivers', and in some instances one or both of the fore-limbs, or the muscles of the fore-quarter, exhibit the same feature.

Shivering in the dog may occur, especially in fox terriers, for no apparent reason and may be unconnected with either cold or fear. At the prospect of a walk the dog may suddenly cease trembling.

Shock

Shock is, clinically, an abrupt fall in blood pressure (acute hypotension; see HYPOVOLAEMIA).

Signs include weakness, pale and cold mucous membranes, subnormal temperature but no shivering; a weak and rapid pulse; shallow breathing at an increased rate; cold extremities.

Cause Shock may follow severe trauma, haemorrhage, surgical operations, a sudden decrease in the heart's pumping capacity, burns and scalds and toxaemia. (See also ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION; ANAPHYLACTIC SHOCK.) Pain, fright, and any airway obstruction may exacerbate the condition.

Treatment Although corticosteroids are often used, it has been stated that there is little or no evidence that they are effective. A blood transfusion, adrenalin, plasma substitutes based on gelatin and dextrans, and lactated Ringer's solution given intravenously, may each have a place in treatment, as appropriate.

The patient must be rested and kept warm.

Shoeing of Cattle

This may be undertaken to reduce weight-bearing on an injured claw, especially where there is a fracture of a phalanx. Draught cattle may also be shoed.

Shope Rabbit Fibroma

A fibroma is named after Dr. R. E. Shope, an American pathologist. It is caused by a pox virus which is only present in the lesions; the virus is closely related to that of MYXOMATOSIS. In domestic rabbits the infection is seen as one or a few subcutaneous tumours which rapidly grow but then regress. The virus has been used in the production of myxomatosis vaccine.

Shorthorn Cattle

The breed developed in the 18th century in Northern England from the Teeswater and Durham breeds. It was, until the 1940s, one of the most common breeds in the UK. It was coloured red, white or roan and was dual-purpose and could be used for milk or beef. The beef breed started its own herdbook in 1958 and is still used but is a minor breed. The Dairy Shorthorn has almost died out. (See BEEF SHORTHORN CATTLE; DAIRY SHORTHORN CATTLE) Shorthorn crosses with FRIESIANS can result in SPASTIC calves.

Shotgun Injuries

(See GUNSHOT INJURIES.)

Shoulder

Shoulder is the joint formed between the scapula and the upper end of the humerus. (See DISLOCATION.)

Shoulder-Blade

(See SCAPULA.)

Shovel Beak

A disease occurring in intensively reared chicks fed dry mash. It affects usually birds of 2 to 8 weeks old. The upper or lower beak (or both) may be deformed, with ulceration or necrosis. Infection with *Fusiformis necrophorus*, *Staphylococcus aureus*, or *Clostridium perfringens* (formerly *welchii*) may follow.

Shrimps

A popular small crustacean farmed in many countries. It is susceptible to 'white spot virus' (which is not related to 'white spot' of salmonids. Formulation of diet for shrimps is very specialised since they are particulate feeders and feed wastage can be high. Urea formaldehyde appears to be a suitable binder for shrimp feed. It is important to ensure that at least 0.5 per cent of the diet is cholesterol. The Animal Welfare Act 1999 of New Zealand covers all crustaceans including shrimps.

Shropshire Sheep

These originated in the hills of Shropshire and North Staffordshire in England during the 1840s by crossing local horned black face sheep with white faced sheep including the COTSWOLD, SOUTHDOWN and LEICESTER producing a polled medium-sized breed with a black woolless face, used for meat and wool. It was exported to the

VetBooks.ir

USA and also Australia, New Zealand, and South America. In the USA by the start of the 20th century it was the most popular breed; breeding made it smaller and more woolly and it fell out of favour. However, by importing from Britain some larger rams its popularity increased and it is again the most common breed in the USA. The rams weigh 100 kg to 115 kg (225 lb to 250 lb) and the ewes 70 kg to 80 kg (150 lb to 180 lb). It is used for meat production. It helped produce LLANWENOG SHEEP.

Shunt

There are several definitions. It can mean a bypass, diversion (PORTOSYSTEMIC SHUNT), a natural passage or anastomosis between two channels, often blood vessels. Shunts can either be:

1. structural abnormalities
2. physiological (e.g. a method of bypassing a thrombosis)
3. a surgical anastomosis such as between the intestines.

Shying

(See 'VICES' AND VICIOUSNESS.)

Sialocoeles

Cyst-like swellings, usually lined by granulation tissue rather than epithelium, containing saliva.

Sialogogues

Sialogogues are substances which produce a copious flow of saliva, e.g. pilocarpine and arecoline.

Sialoliths

These are CALCULI, found mainly in STENSON'S DUCT (parotid salivary duct) of horses.

Siamese Cats

A popular breed of foreign short-haired cat. Congenital Unilateral Peripheral Vestibular Disease may be seen in individuals soon after birth but many adapt and lead a reasonable life. It suffers from MUCOPOLYSACCHARIDOSIS VI (DNA test available) and PROGRESSIVE RETINAL ATROPHY.

Siberian Husky

A medium-sized, thick set muscular dog weighing 20 kg to 25 kg (45 lb to 55 lb). It has a thick double coat in various colours and dark markings on the head. It has erect ears, blue or brown eyes with often both eyes different colours. It suffers from PROGRESSIVE RETINAL ATROPHY (X-linked) and GM_1 GANGLIOSIDOSIS (DNA tests available). (See HUSKY.)

Sickness

(See VOMITING.)

Sidebones

Ossification of the LATERAL CARTILAGES of the horse's foot. When this occurs in a young animal, it is looked upon as an unsoundness. In old horses, all cartilages, not only in the foot, tend to become ossified as an almost natural course of events, and sidebones are accordingly not looked upon as so serious.

Causes Heredity is considered as a predisposing cause, but in many instances no such relationship can be shown. It has been suggested that a vitamin D deficiency in foalhood may be partly responsible.

Signs Ordinarily, the upper part of each cartilage can be felt at the coronet as a flexible ridge or edge, lying immediately below the skin, but when the cartilage has ossified, this ridge is no longer flexible, and is more or less thickened as well. In some instances the ossified cartilage can be easily seen when the feet are viewed from the front. The condition is more common by far in the fore-limbs, and may occur on the outside or inside, or in both places, on one or both of the fore-feet.

When sidebones have formed, there is no lameness, pain, heat, or other signs of inflammation, but when forming, there may be pain over the quarters involved, and lameness – characterised by the taking of a shorter step by the affected foot, and the tendency to do this may result in a peculiar short and long step.

Treatment As a rule, in horses with wide open feet and well-developed frogs, no treatment is required. The sidebone does not interfere with slow work of a regular nature. (See also RINGBONES.)

Side-Effects

The side-effects of a drug are those produced in addition to that for which purpose the drug is given. Examples: deafness in humans following the administration of streptomycin; moniliasis after the use of chlortetracycline; aplastic anaemia after the use of chloramphenicol. (See also IATROGENIC DISEASE.)

Silage, Ensilage

Silage (ensilage) is a succulent food. It has been classified as follows: Grade I containing 15 per cent and over crude protein, and made from young grasses, none in flower, clover, lucerne, or sainfoin in bud stage; Grade II containing 12 per cent to 14.9 per cent crude protein, and made from grasses in their flowering stage, late autumn grass, clover passed full flower, marrow stem kale, pea pods, cereal-legume crops cut when cereal is 'milky'; and Grade III containing less than 12 per cent crude protein, and made from seeding grasses,

VetBooks.ir

stemmy clover, maize, pea haulm and pods, sugar-beet tops, potatoes.

Grade I makes a substitute for cake, whereas Grade III is good enough only as a substitute for roots, straw, or low-grade hay.

Ensilage involves fermentation. Lactic, acetic and butyric acids are produced: in good silage, lactic acid predominates. Silage with a high butyric-acid content must be fed with caution, and may be recognised by its to unpleasant smell and lighter colour – yellowish-green instead of dark brown.

As with hay, there are extremes of quality in silage. At the Rowett Research Institute cows have maintained a yield of up to 23 litres (5 gallons) daily for 2 months while receiving no other feed. With the average quality silage it would, however, be unrealistic to expect to be able to dispense with supplements.

Acetonaemia is often seen in cattle receiving large quantities of silage of low quality. Hay should be made available as well; also 55 g (2 oz) per head of bone flour with salt added.

When self-feeding of silage is practised, care must be taken that conditions underfoot do not become dirty and slushy to an extent where softening of the horn of the hoof occurs and foot troubles develop.

MAIZE is also ensiled and often has higher dry matter and energy levels. It and grass silage often make up the bulk of feed for many dairy cattle in the south of England.

Silage must be free of ragwort. (See under RAGWORT POISONING; also TRAUMATIC RETICULITIS.)

Listeria in silage LISTERIOSIS in ruminants has often been associated with silage feeding. In a survey carried out in Scotland, *Listeria monocytogenes* was isolated from 2.5 per cent and 5.9 per cent of samples of clamp silage obtained in two successive years.

S

Silage Effluent

Silage effluent has been described as one of the strongest of all agricultural wastes and pollutants. Some 16,000 litres (3500 gallons) of clean water are needed to dilute 4.5 litres (1 gallons) of silage effluent to bring it to the recommended level for treated ('safe') effluents.

In a wet season a 400,000-kg (400-ton) silage clamp with grass at 1 to 15 per cent dry matter at ensiling may produce 182,000 litres (40,000 gallons) of effluent, most of which discharges in the first month. It takes only a little of this effluent to kill fish and other forms of aquatic life if it reaches a stream.

'Silent Heat'

(See under OESTRUS, DETECTION OF, IN COWS; INFERTILITY.)

Silicon

A non-metallic element. In the form of silicic acid or its derivatives, silicon is essential for growth, and is found mainly in connective tissue. It has been suggested that lack of sufficient silicon may be a factor in the cause of atherosclerosis in man.

Silicone implant repair A year-old Arabian filly had a depression over its right frontal sinus as the result of an injury sustained 6 months earlier when it ran into a steel pipe and the frontal bone had been broken. A heat-vulcanised silicone implant was used to repair the deformity and the normal facial contour was restored by suturing the sculpted implant to the periosteum over the defect.

Silicone Solution

An anti-coagulation solution used in connection with blood transfusion apparatus and syringes to prevent clotting.

Silkies Chickens

A small breed of chicken thought to be derived either from China or Southeast Asia, which has a fluffy plumage due to the absence of barbs on the feathers and feathered legs. Often they are white but they can be black, buff, blue, red and partridge. They are unusual in having black skin, flesh, bones and earlobes, and they have five toes on each foot. They are friendly and calm and tend to be good mothers. They tend to be very broody. The standard bantam size is 1.8 kg (4 lb) for cocks and 1.4 kg (3 lb) for hens. (See POULTRY AND POULTRY KEEPING - SILKIES.)

Silver (Ag)

This metal has antimicrobial properties and is included in a cream with sulphadiazine as the choice application for burns. It has caustic, astringent and antiseptic properties.

Simethicone

A potent and safe anti-frothing agent for use in ruminant frothy bloat. It can be given by mouth but, in severe cases, it can be placed directly into the rumen, using a trocar and cannula.

Simian Haemorrhagic Fever

(See MONKEYS, DISEASES OF; EBOLA VIRUS.)

Simmental

A dual-purpose (and also draught) breed of Swiss cattle, from the valley of the Simme river in the Bernese Oberland, now to be found throughout Europe and in the USA. It has been recorded since the Middle Ages. In Germany the Simmental has been developed with emphasis on beef production. It is credited as involved in the development of the Montbéliarde (France), Razzeta d'Oropa (Italy)

VetBooks.ir

and Fleckvieh (Germany). Simmental are dark red and golden brown have white faces with colour around the eyes.

Simple Fracture
A bone fracture which is closed; i.e. the bone has not penetrated the skin.

Simulium
(See under FLIES). In the UK, the gnat *S. ornatum*, which breeds in running water and is difficult to control, sometimes causes eye lesions in cattle.

Singleton
An animal born on its own and not as a twin or multiple birth. Usually cows and mares produce singletons.

Sinistrocardia
Displacement of the heart to the left of the medial line.

Sinus
Sinus is a term applied to narrow hollow cavities (especially in bones) occurring naturally in the body, or produced as the consequence of disease. (See SINUSES OF THE SKULL; also FISTULA.)

In pathology, a sinus refers to a blind infected tract, leading from a site of suppuration, necrosis or a foreign body to the surface of the skin or of a mucous membrane.

Sinuses, Diseases of the
The sinuses of the head are lined with a membrane which is continuous with that of the nasal cavities, and which acts as a PERIOSTEAL covering for the bone.

Causes Sinusitis may arise as a result of a spread of inflammation from that affecting the nasal mucous membrane. It may follow strangles in the horse. Occasionally the cause is a diseased tooth, the root of which has suppurated and the pus burrowed through the thin plate of bone that separates the tooth socket from the sinus cavity (see MALAR ABSCESS). In other cases, the cause is a penetrating injury from the outside, such as is occasioned by a blow on the forehead which fractures the external plate of bone and allows the ingress of infection. Animals living near the seashore or in sandy and windy localities are sometimes afflicted with collections of fine sand in the sinuses. In sheep, and sometimes in the horse, sheep-nostril fly larvae of the Oestrus family may be found in the sinuses, and are generally associated with pus formation. In dogs especially, but also in other animals, tumour formation is often accompanied by the presence of pus in the sinuses, and the condition may be complicated by a FUNGAL infection. In the dog, a foreign body such as a grass seed may give rise to the discharge from one nostril which is characteristic. Either cancer, or a fungal infection which may follow, can lead to distortion of the dog's or cat's face. (See also MITES, PARASITIC – *Linguatula serratus*; LEECHES.)

Signs The most prominent sign of the presence of any amount of pus in the sinuses is the usually slight, but continual, dribbling of discharge from one or both nostrils. This discharge is usually more marked when the animal lowers its head.

Treatment This consists of opening, under anaesthesia, the diseased sinus by TREPHINING the bone over the surface, and irrigation and evacuation of the cavity. When a tooth has been the primary cause of the condition it is extracted, and its cavity temporarily plugged with gauze until healthy tissue fills up the space between the tooth socket and the sinus. Parasitic inhabitants are removed, either by the injection of fluids that will kill them, or by picking each out separately with forceps. Chloroforming the animal was formerly done to kill such parasites.

Sinuses of the Skull
The sinuses of the skull, also called the paranasal sinuses, are directly or indirectly connected with the nose. There are four pairs: (1) maxillary; (2) frontal; (3) spheno-palatine, or sphenoid; and (4) ethmoidal.

Sinusitis
Inflammation of the sinuses.

Sinusitis, Infectious
A disease of turkeys, poultry and pheasants caused by *Mycoplasma gallisepticum*. The obvious sign is a swelling of the sinuses below the eyes, but the disease will also be present in the lower respiratory tract. While local treatment (e.g. draining the sinuses) is helpful, generally the administration of antibiotics is necessary. The disease is egg-transmitted and may spread from egg to egg in the hatcher. Infected birds always remain carriers. Eradication has been carried out in the commercial breeding stock of major suppliers.

Swollen sinuses may also be seen in certain paramyxovirus infections, from which infectious sinusitis must be differentiated.

Sinusitis is commonly seen in cage birds. An infection is often present and is best treated by means of an injection of suitable antibiotic directly into the sinus or sinuses. However, the condition can be due to lack of vitamin A. Infectious sinusitis is often mistaken for CONJUNCTIVITIS.

Sire Identification
(See DNA 'FINGER-PRINTING'.)

Sitfasts
(See SADDLE-SORES.)

SI Units
The *Système International d'Unités* was adopted by the *Conférence Générale des Poids et Mesures* in 1960. Based on seven units – metre, kilogram, second, ampere, degree kelvin, candela and mole – it admits only one unit for any one physical quantity. Derived units in any science or technology can be made up from the seven basic units by division or multiplication without numerical factors being involved. The SI unit joules replaces calories. The seven basic SI units and their symbols are as follows:

(length)	metre	m
(mass)	kilogram	kg
(time)	second	s
(electric current)	ampere	A
(thermodynamic temperature)	degree kelvin	°K
(luminous intensity)	candela	cd
(amount of substance)	mole	mol

(See under METABOLISABLE ENERGY.)

Skatole
A derivative of TRYPTOPHAN, which is formed by protein putrefaction and is partly responsible for the smell of faeces. It also contributes to BOAR TAINT.

Skeletal Hyperostosis
(See DISSEMINATED IDIOPATHIC SKELETAL HYPEROSTOSIS.)

Skeleton
(adjective, Skeletal)

The hardened structures which provide the form of an animal, usually consisting of bones. In vertebrates this is an endoskeleton. In invertebrates it is often an exoskeleton.

Skewbald
A coat colour usually used when referring to horses. Skewbalds have a mainly white coat with large irregular patches of any colour other than black. (See also PIEBALD.)

Skim Milk
This is a valuable food, retaining, as it does, the solids-not-fat after most of the fat has been removed. These solids include the valuable milk-protein, the sugar lactose, valuable minerals, and vitamins of the B group. It is poor in the fat-soluble vitamins A and D, and also in vitamin E; and if given along with cod-liver oil to beef stores, may lead to cod-liver oil poisoning or MUSCULAR DYSTROPHY.

Skim milk is a useful food supplement for pigs. It can be fed ad lib to suckling pigs; weaners may receive 3 litres (5 pints) per day; fatteners from 14 weeks to slaughter, about 3.5 litres (6 pints).

For sows and piglets, skim milk should be either fresh or completely sour; 0.1 per cent formalin is sometimes added to skim milk for fattening pigs.

Its main veterinary use is as a SEMEN EXTENDER.

Skin
Skin, the protective covering of the body of vertebrates, is continuous at the natural openings with the mucous membranes. It consists of three main layers, which differ in structure and origin. The outermost layer, the epidermis, beneath which lies the dermis, overlying the subcutis of loose CONNECTIVE TISSUE.

The epidermis This is a cellular layer of non-vascular, stratified epithelium of varying thickness depending on the animal. It covers the outer surface of the body, which presents the openings of the cutaneous glands and of the hair follicles in mammals, the feather follicles in birds and the scales of fish and reptiles. It is divisible into two layers, the outer, hard, dry stratum corneum, and the deeper, softer, moist stratum germinativum. The cells of the latter are pigmented, and by their growth compensate for the loss by exfoliation or shedding of the surface cells from the stratum corneum, which forms the scurfy deposit upon an ungroomed horse. This inner layer consists of the part of the skin which is living, and is formed by several layers of cells set upon the corium and nourished by it. The lowermost layer rests upon a basal membrane and consists of germinating cells of the epidermis. The cells continually multiply, and are slowly pushed upwards to the stratum corneum, becoming keratinised as they do so (see KERATIN; KERATINISATION). The germinating layer contains pigment-producing cells (melanocytes), which pass the pigment to the migrating cells (keratinocytes) above them. Keratinocytes migrate into and through the stratum corneum on the surface where they exfoliate, which is a continuous process. The exfoliated cells mix with sebum and sweat forming the characteristic scurf on the skin. They continually replace the constant wear and tear which occurs on the cells at the surface. There are no blood vessels in the epidermis, but there is a ramification of the surface sensory nerves which supply the skin with its delicate sense of perception. A blister is a collection of fluid separating the stratum corneum from the stratum germinativum.

In birds the epidermis is mainly similar, the main difference being that the epithelial cells

VetBooks.ir

contain lipid. They multiply as above and are shed as a waxy secretion on the outer surface. It has been calculated that 94 per cent of the lipid content of the skin of pigeons originates from the epidermal cells, the remaining 6 per cent coming from the UROPYGIAL GLAND - the only gland in the avian skin.

In amphibians the epidermis is far thinner than in other animals and functions primarily as a thermoregulatory organ with an additional role in the maintenance of hydration. Specialised glands in both the epidermis and dermis excrete mucus or lipids as part of the hydration maintenance and in some species, toxins and irritants as protection against predators.

In reptiles, the epidermis has three layers: the stratum corneum being of variable thickness, the thicker areas bearing scales; the intermediate layer which is rich in waterproofing lipids; and the stratum germinativum of cuboidal cells, which multiply to produce the other two layers.

In lizards the skin scales are modified to form crests, spines and shields.

In snakes the scales are situated ventrally and widened into GASTROPEGES, which assist in locomotion.

The epidermis of CHELONIA is specialised to form shields or scutes and keratinised externally to allow for shedding as the animal grows, the dermis being ossified in the deepest layers and fused with the vertebrae to form the CARAPACE.

The dermis (corium) consists of a network of collagen and elastic fibres. It is very vascular, and, in healthy skin, sparsely populated with cells. In mammals, the dermis contains the hair follicles, the sudoriferous (or sweat) glands and the sebaceous glands, as well as a certain amount of involuntary muscle (*Arrectoris pilae*). The most superficial part is known as the corpus papillare, on account of the presence of numbers of tiny papillae, which are received into corresponding depressions in the epidermis. These papillae contain loops of blood vessels, which nourish the epidermal cells, and numerous sensory nerves, which act as tactile organs, affording sensations of touch, pain, temperature, etc.

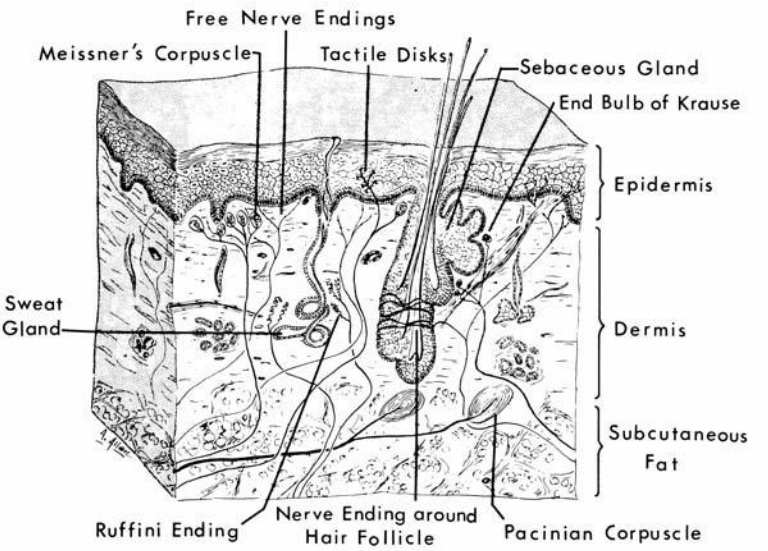
The mammalian sweat glands are situated partly in the deeper parts of the corium, known as the tunica propria, and partly below it in the layer of subcutaneous fibro-fatty tissue. In rodents and ferrets, sweat glands are absent and rabbits only possess them on the face.

In this deepest layer, which forms the bulk of the skin, or lying in the deeper part of the corium, there are certain tactile bodies, known as Pacinian corpuscles. The fibrous tissue of the skin consists of interlacing bundles of white fibrous tissue which form a dense felt-work. Here and there elastic fibres are mixed with them, and these serve to give the skin its pliability, and at the same time maintain its position and keep it stretched reasonably tightly.

In amphibians, the dermis can contain chromatophores, pigmentary cells giving the skin its colour.

In some lizards the dermis contains bony plates called OSTEODERMS to which epithelial scales are attached, providing added protection.

Subcutis This is the deepest and usually the thickest layer of the skin in mammals. It is a loose, fibrous, fatty formation assisting in heat insulation, acting as an energy reserve and providing protective padding.



In birds the fat of the subcutis is distributed mainly around the feather follicles. The insulating properties of the bird's skin are attributed more to the plumage than the fat content of the dermis. The fibrous element of the avian subcutis is more marked along the KEEL BONE.

Hair In mammals, practically the whole of the body of each domesticated animal is covered by hair, except in the pig. Portions of the skin which appear to be bare are found on close inspection to be covered with very fine hair of delicate texture. The hairs (and dead cells from the outer layer of the epidermis) are constantly being shed and replaced by others, while at certain periods of the year in the horse, and to a lesser extent in the other animals, they are cast off in great numbers, and constitute the 'shedding' or 'casting of the coat'. This normally occurs twice a year – once in the autumn, when it is more marked, and again in the spring with the first warm weather of the year.

In indoor pets, especially where the house has central heating, moulting can occur all the year round, without seasonal variation and is described as 'mosaic'. In contrast a 'wave moult' is described in mammals like rabbits in which the moult starts on the back of the neck and progresses caudally and ventrally.

Hairs grow from follicles in the epidermis. The number growing from each follicle varies between species, the higher the number, the finer the individual hair. Animals that are said to be furred have many more hairs per follicle than others – the CHINCHILLA (*Chinchilla laniger*) can have up to 60 hairs per follicle.

Hairs are of three kinds: in the first place there are the ordinary hairs — primary, or guard, hairs which, on account of the small amount of pigment that each carries, give the coat its characteristic colour or appearance of the animal. They are arranged in whorls, crests and partings and may be long and coarse, such as the mane (juba), the forelock or foretop (*cirrus capitis*), the tail (*cirrus*

The nerve supply to the skin. (In Muller, Christensen and Evans, *Anatomy of the Dog*, courtesy of W. B. Saunders Co.)

caudae) and the FEATHER of the fetlocks and cannons (*cirrus pedis*), which gave the name to this region (fetlock = feet-lock — a lock of hair on the foot).

There are different kinds of special hairs. Among these ordinary hairs scattered over almost the whole body are: tactile hairs which are thicker and longer than guard hairs. They are found on the lips, nostrils and eyes; cilia, or eyelashes, growing from the free rim of the eyelids; tragi, in the external ear; and vibrissae, round the nostrils. They are found on the caudal aspect of the forelimbs of rodents and other small mammals. The follicles of tactile hairs are associated with venous sinuses innervated to respond to mechanical stimulation.

Secondary or down hairs are more numerous, but more slender and shorter, than guard hairs and form the non-descript undercoat.

Each hair has a shaft, the part above the surface, and a root, embedded in the hair follicle. Below this is a little fibrous papilla possessing blood vessels, which is capped by the expanded end of the hair root, and known as the hair bulb. The follicles are set somewhat obliquely in the corium and at varying depths; the long tactile hairs reaching down to the underlying muscle. Most of the follicles have little bands of plain muscle attached to one side, known as the arrectores pilorum; these serve to erect the hairs during anger, fear, or extreme cold, and also to express from the sebaceous gland a small portion of sebaceous secretion.

Glands of the skin are of are of three kinds: sweat or SUDORIFEROUS, SEBACEOUS and specialised. Sweat glands are scattered over the body in nearly all mammals. They may open into the hair follicles or directly through the stratum corneum. Sweat glands have several functions: loss of heat (see PERSPIRATION), waste excretion and PHEROMONE production.

The sebaceous glands, except in certain places, open into the follicles of the hairs a little way below the surface. Each consists of a little bunch of small sacs, within which fatty or oily material SEBUM is produced. This secretion is forced from the sacs by the contractions of the arrectores pilorum muscles and during exercise it also escapes on to the shafts of the hairs. Its function is to keep these pliable and lubricated and prevent them from becoming brittle through drying. A copious secretion from the sebaceous glands results in a sleek shining coat, such as is associated with a well-fed and well-groomed horse.

Sweat glands are most numerous in the horse, and least in rodents and rabbits (which therefore are extremely susceptible to overheating). In dogs the largest sweat glands are found only on the pads of the feet. Each sweat gland consists of a long tube, usually greatly coiled in its inner part, which has a duct leading up to the surface of the skin.

The function of the sebaceous glands' secretion is to keep the hairs pliable and lubricated and prevent them from becoming brittle through drying; they also produce a scent (territorial marking), especially in cats, rodents and rabbits. A copious secretion from the sebaceous glands results in the sleek shining coat, Sebaceous glands can become invaded during parasitic diseases especially

VetBooks.ir

DEMODECTIC MANGE (see also MANGE) and sometimes a blocked gland gives rise to a RETENTION CYST.

Specialised sebaceous and sweat glands are modified to produce PHEROMONES and are grouped together in localised sites in mammals and birds.

Birds have very few glands in the skin; the LIPID or sebaceous content of the skin is supplied by the epidermal calls (as described above). As there are no sweat glands in bird skin, heat loss being regulated by elevation of the wings and feathers and by GULAR FLUTTERING.

Reptile skin generally contains no glands. The exceptions are the femoral and precloacal pores of some male lizards – the sites of PHEROMONE production.

In fish, glandular functions are supplied by cells in the epidermis, which secrete mucus and other exudates including PHEROMONES and 'alarm' substances.

Appendages of the skin In addition to hair, the skin possesses certain appendages, which in reality are modified hair only. Thus, horns, hoofs, claws, nails, ergots, chestnuts and other horny structures are closely packed epidermal cells which have undergone KERATINISATION or CORNIFICATION. Spurs of poultry are horny epidermal sheaths covering a centre of bony outgrowth from the TARSOMETATARSUS BONES. Feathers are highly-specialised scales produced by follicles: one feather per follicle. The down feathers of the chicken are simple, and consist of a brush of hair-like 'barbs' springing from a basal quill or 'calamus'. From the whole length of each barb a series of smaller 'barbules' comes off not unlike the branches of a shrub. The adult or 'contour feathers' are formed at the bottom of the same follicles that lodge the juvenile down feathers, which by the growth of the adult feathers are encouraged to fall out. Contour feathers develop according to their function. The calamus is extended into a shaft or rachis which supports the feather VANE. The vane is composed of barbs and barbules. The barbules are held against each other by hooks and comprise a smooth, flat surface. Body contour feathers, also called coverts, have hooks only on the barbules furthest from the skin so that the inner barbules are downy in appearance and give better insulating properties.

Flight The barbules, in the case of the large wing feathers ('remiges'; singular REMEX) and the tail feathers ('retrices'), are connected by minute hooks so that the feather 'vane' has a more resistant surface for flight than in the case of the breast feathers, for instance. Moulting in birds occurs periodically, when the bird casts off the old feathers and gets a complete new set. The timing of the moult varies from species to species and is associated with onset of maturity. Seasonal moulting is associated with breeding activity and/or camouflage.

Functions of the skin The skin has many functions, the main one being protective. It covers the underlying muscles, shielding them from injury, and by virtue of its padding of fat protects them from extremes of temperature. The hair, fur, wool, or feathers assist this heat-regulating mechanism still further, and the growth of the coat is usually determined by the temperature of the surroundings. For example, when horses are kept out of doors during winter they grow long thick coats, while when kept in warm stables and covered with rugs they assume a close sleek coat. The same applies to other animals.

Heat regulation is one of the most important functions of the skin. When cold air, water, or other cooling substances come into contact with a large area of the skin, the numerous blood vessels of the skin immediately contract, reducing the amount of blood circulating in them, inhibiting the cooling action from outside. On the other hand, when the surrounding medium is at a higher temperature than the normal – i.e. when it is approaching body heat, or rises above it – the blood vessels of the skin dilate, more blood is brought to the surface. This stimulates sweating. When the sweat evaporates, especially when the surrounding atmosphere is dry, considerable cooling of the skin surface occurs. (See TEMPERATURE, BODY; TROPICS, LIVESTOCK PRODUCTION IN THE; HYPOTHALAMUS.)

Seasonal variations in colour of hair, fur, feathers and other appendages play important roles in camouflage and breeding display, especially in birds. Other functions of the skin include IMMUNOLOGICAL activities and the production of PHEROMONES.

Skin, Diseases of

The majority of the commoner diseases of the skin in animals are due either to parasitic invasion, or to conditions of an allergic origin, e.g. eczema. These are treated under separate headings – e.g. mange, of all varieties, is dealt with under MITES, PARASITIC; ECZEMA; URTICARIA; RINGWORM; ACNE; see also TUMOURS; IMPETIGO; POX; BRIDLE INJURIES; SPOROTRICHOSIS; SWINE ERYSIPELAS; LIGHT SENSITISATION; DERMATOPHILUS; GRANULOMA; ABSCESS; HYPERKERATOSIS; LUPUS ERYTHEMATOSUS; AUTO-IMMUNE DISEASE; CUTANEOUS ASTHENIA.

Cats may suffer from cancer of the sweat glands.

Skin, Poisoning Through

(See under POISONING; HYPERKERATOSIS.)

VetBooks.ir

Skin Cancer

This is a not unusual finding in animals. Cancers tend to be more often seen in areas of the world where there is more exposure to ultra-violet light and sunlight. There are numerous types, dependent on the structures of the skin involved, whether the cancer is malignant or benign, and also the species of animal. Thus, squamous cell carcinomas tend to be common in all species with sparse or white hair which are exposed to much ultra-violet light. In such cases, often extremities like ear tips are involved. Cancer of the eye in cattle involve animals with white faces such as HEREFORDS when exposed to much sunlight and affects the eyelids and eye. BOXERS are prone to skin cancer.

Skin Disorders in Cattle

These include squamous cell carcinoma (which may also affect the eye), iodism, persistent BVD infection, vitamin E deficiency, vitamin A deficiency, papillomatosis, lice infestation, ringworm and the effect of a snake-bite.

Skin Fold Dermatitis

(See INTERTRIGO.)

Skin Grafting Transplantation

The surgical transplantation of skin to repair a damaged area. The pedicle technique, in which the transplant is attached at one end to adjacent skin, has been applied in cats and dogs. A broad flap of full thickness skin is formed by incision to cover the denuded area, with a narrow strip attached to the rest of the skin to form the pedicle or bridge to carry the blood supply to the broad flap or graft. The edges of the pedicle are sutured; the flap is sutured to adjacent skin.

In horses, skin grafting has also been carried out using free, whole-thickness grafts of skin taken from other sites in the same animal. Such grafts will give rise to normal hair growth.

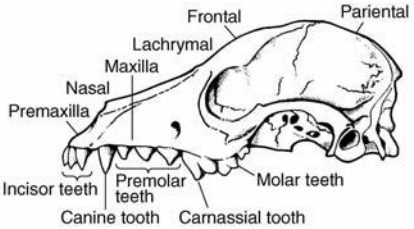
In a cat a badly damaged tail was used as a source of skin for a graft before tail amputation – extensive skin loss having resulted from a fan-belt accident.

'Skin Tuberculosis'

This is characterised by the appearance of swellings, varying in size from that of a pea to that of a tangerine, on the limbs and occasionally on the trunk of cattle. Lesions are often multiple and in the form of a chain, often along the lines of the lymphatic vessels. They are unsightly but appear to cause the cow no discomfort and their economic importance lies only in the fact that they apparently sensitise the animal to mammalian and/or avian tuberculin, thus complicating the interpretation of the tuberculin test. A re-test after an interval of 30 to 60 days will, however, in the absence of tuberculosis, usually give a reaction justifying retention of the animal within the herd.

Microscopically, the lesions of 'skin tuberculosis' closely resemble those of tuberculosis, and acid-fast bacilli resembling *Mycobacterium tuberculosis* are present in them.

(See CAT LEPROSY; MYCOBACTERIUM; TUBERCULOSIS.)



Skull

The bony structure of the head. Excavated in it there are large irregular spaces known as sinuses. (See illustration on next page, and SINUSES OF THE SKULL.)

General arrangement of the skull The skull is divided into two parts: (1) the cranium; and (2) the face. The former consists of the posterior part, which encloses the brain.

Most of the bones of the skull are flat bones developed from a structure which is partly cartilage and partly fibrous membrane. Centres of ossification appear in these during early life, and soon after birth the greater part of each bone has assumed its eventual outline, but is separated from its neighbours by an intimately dovetailed joint. These joints, none of which is movable, allow growth until the animal is adult, when bony fusion usually occurs, and the joints become obliterated. Many of these joints – 'sutures', as they are called – can be felt in the skull of a newly born animal, particularly over the dome of the head in a foal or puppy, and for a time constitute especially vulnerable parts of the skull.

The bones of the cranium – those which enclose the brain and its membranes – are 10 in number: 4 single and 3 paired. They are occipital, sphenoid, ethmoid and interparietal (single), and parietals, frontals and temporals (paired). The occipital lies at the posterior lower aspect of the skull, and forms the hinder wall of the brain cavity. Through it passes the spinal cord, which emerges by the foramen magnum, and to a roughened prominence above this foramen is attached the very powerful 'ligamentum nuchae', which supports the head. On either side of the foramen are the occipital condyles which articulate with the atlas – the first of the cervical vertebrae. The lower part of the occipital – the basilar part – runs forward along the base of the brain to meet the body of the sphenoid bone. The inner surface is adapted to the cerebellum – the most posterior upper part of the brain, while above the basilar portion lies the medulla which is continued backwards into the spinal cord. It has the form of a body with two pairs of wings and one pair of projections. It is supposed to resemble a bird with two pairs of wings in flight trailing its legs behind it. The body is continuous with the basilar part of the occipital, and helps to form the base of the brain.

The dog's skull, and teeth of the upper jaw.

Skunks

Skunks belong to the Mustelidae, and the species usually housed in captivity is the common striped skunk (*Mephitis mephitis*). They are kept as pets in the USA and are increasing in the UK. They are OMNIVOROUS, eating prey, insects, fruit and vegetables. They are not very popular as they become less friendly with age and they can spray from their anal scent glands. The most common problems in pet skunks are metabolic bone disease, obesity, fatty liver, dental disease, gastro-intestinal parasites (including BAYLISASCARIOSIS, a zoonosis), ectoparasites, gastroenteritis, rectal prolapse, abscesses, cardiomyopathy, dermatitis, seizures (due to HYPOCALCAEMIA, HYPOGLYCAEMIA). Skunks and foxes are now the two most important wildlife hosts of the rabies virus in the USA.

Skye Terrier

A distinctive hardy ACHONDROPLASTIC breed of terrier with short legs (about 25 cm [1 ft]), proportionally a very long body (105 cm; 3½ ft is breed standard) and weighing about 121 kg (22 lb). It has a long straight-haired coat coloured grey, fawn-cream or black. The breed can suffer from premature growth plate closure of the distal RADIUS and it is advised not to over-exercise young dogs or allow them to jump, etc. Inherited LARYNGEAL HYPOPLASIA and INTERVERTEBRAL DISC PROTRUSION occur. Mammary neoplasia (see MAMMARY GLANDS, DISEASES OF - TUMOURS) appears to be common, as does HAEMOSARCOMA. The breed is becoming rare.

Slaframine

A mycotoxin produced by the fungus *Rhizoctonia leguminicola* which grows on clovers (especially red clover). It causes excessive exocrine secretion in animals ingesting infected clover. The most common sign is excessive salivation. Possible differential diagnoses include mouth trauma, BOTULISM, GRASS SICKNESS and BORNA DISEASE in horses. (See MOUTH, DISEASES OF; SWAINSONINE.)

Slag

(See BASIC SLAG.)

Slatted Floors

These were tried in England in the 19th century and described in the *RASE Journal* of 1860, and had been used for many years in Norway, before being reintroduced in Britain as a means of saving money on straw. The current practice is sometimes to sprinkle sawdust on the slats (of wood or concrete), but to use no straw. The use of slatted floors can hardly be regarded as anything but a retrograde step from the animal husbandry point of view, however attractive commercially. The animals obviously cannot rest as comfortably as on straw, and if strict precautions are not taken (as in Norway) they may be subjected to severe draughts with resultant ill-health and poor food conversion ratios. Teat and leg injuries, and injuries or abnormalities of the feet, may also develop in animals on slats. (See also EPIPHYSITIS.)

The space between the slats is critical, and there must be no sharp edges on the concrete. (See LAMENESS.)

A slatted dunging area and a bedded area are satisfactory. For pigs the dimensions and widths of gaps in slatted floors are controlled by legislation. (See also under SOW STALLS and SLURRY.)

Slaughter of Farm Animals

Animals have to be stunned before slaughter. It is an offence to permit avoidable suffering, excitement or pain when handling, stunning, or killing of animals. Slaughtermen must be competent and have a licence. A competent person must have authority to take action to safeguard welfare. Only permitted methods can be used to stun and kill animals. On 1st January 2013 the WELFARE OF ANIMALS AT THE TIME OF KILLING REGULATIONS 2012 which was EU-wide legislation and replaced the WELFARE OF ANIMALS (SLAUGHTER OR KILLING) REGULATIONS 1995, although differences were minor. (See under EUTHANASIA; RELIGIOUS SLAUGHTER; STUNNING, ELECTRIC, OF CATTLE; STUNNING, ELECTRIC, OF PIGS.)

Specified intervals between cessation of treatment of food animals with certain drugs are required before slaughter. (See IVERMECTIN.)

'Sleeper' Syndrome, Haemophilosis

A SEPTICAEMIA caused by *Histophilus somni* (formerly *Haemophilus somnus*). It occurs in cattle in feedlots in the USA. The syndrome is associated with an encephalomyelitis; as well as brain and spinal cord, many other tissues may be involved. It has also been seen in the UK. It is also called THROMBOEMBOLIC MENINGOENCEPHALITIS (TEME).

Sleep (Horses)

The rest obtained by horses sleeping in an erect position is, actually, not sufficient for their needs.

VetBooks.ir

They require complete relaxation of their muscles, and this can only be furnished in the recumbent position. When from fear, ankylosis of vertebrae, or other cause a horse does not lie down, it should be placed in slings, or given some form of support, such as a rope between the heel posts upon which the hindquarters may bear, so that it may obtain the requisite rest.

On board ship, and for surgical or other reasons, horses may be kept standing without harm for considerable periods, but they should be exercised for a short while two or three times daily, in order that the muscles may be prevented from becoming stiff. Horses are liable to fall while standing asleep, and may, in rare cases, actually come to the ground through the relaxation of their extensor muscles; what happens more frequently is that they knuckle over on to their fetlocks, recovering themselves almost at once, but not before a slight injury has been inflicted to the skin over the joint. The fall always occurs in front, not behind, probably because of the extra weight carried by the fore-legs.

Sleeping Sickness

Human trypanosomiasis transmitted by tsetse flies and caused by *Trypanosoma gambiense* and *T. rhodesiensis*. (See TRYPANOSOMES; TROPICS, LIVESTOCK PRODUCTION IN THE; FLIES.) Sleeping sickness caused by *T. rhodesiensis* can also be transmitted from person to person.

Sleep (Non-Human)

In animals, sleep is probably not the same as in humans. It is a reversible loss of consciousness, a loss of response to external stimuli and results in normally accepted sleeping positions. The duration of sleep varies with the species and in some there is a period of reduced reactivity. Usually sleep is of longer duration in predators (cats 12½ hours, dogs 10 hours) than larger prey species (cattle 4 hours, horses 3 hours). Some animals that nest or burrow have higher levels (mice 12½ hours, rabbits 8½ hours).

'Sleepy Foal Disease'

Infection with one of the Gram-negative bacteria (see under FOALS, DISEASES OF).

Slentrol

(See DIRLOTAPIDE.)

Slings

A device whereby a large animal may be kept in the standing position for long periods without becoming completely exhausted. The apparatus consists essentially of a broad strong sheet which passes under the animal's chest and abdomen, supported by a block-and-tackle or other means to a beam overhead. Connected with this there are two strong straps, one passing round the front of the chest, and the other passing round the buttocks. These latter serve to hold the sling in position, and prevent the animals from struggling free. The whole is adjustable so that it may fit animals of different sizes. The sling is often made with a metal or wooden bar along each end of the sheet; these bars serve to distribute the weight of the animal along the whole width of the sheet, and afford a rigid means of attachment to the cross-beam of the slings, to which the chain or rope of the block-and-tackle is attached.

In addition to the above use, slings are one of the means of lifting a horse that has either fallen or lain down in a stable and is unable to rise. The horse is placed so that the slings may be pulled under it, or is rolled on to them, and after the chest and breeching straps are arranged, the horse is lifted by the block-and-tackle high enough to be able to use its feet. It sometimes happens that if the horse has lain for a considerable time it refuses to support its weight on its feet, but hangs 'like a herring' in the slings. In such cases it may be necessary to startle the horse, when it will generally make a lunge and 'find its feet'.

Slings are employed in a variety of conditions, e.g. fractures.

When slings are applied to an animal, they should not be fixed up so tightly that the animal is unable to walk a step or so in each direction. They are only required as a means of support for the animal when it so desires, and not as a suspensory apparatus which is always in use. The animal soon learns to lean on the slings and rest its feet. The hand should be able to be passed under the sling webbing when the animal is standing immediately under the centre of the block-and-tackle, and neither the chest strap nor the breeching should be buckled up tightly. It is generally necessary to secure the head of the animal by a halter to restrict its movements, and to supply a suitable manger or other receptacle from which it may feed easily.

(See also 'DOWNER COW' SYNDROME for a means of lifting a cow.)

Slink Calves

Immature or unborn calves improperly used for human food. The flesh of slink calves is often called slink veal.

'Slipped'

A colloquial expression meaning aborted; also dislocated (see below).

'Slipped Shoulder'

(See DISLOCATION and SUPRASCAPULAR PARALYSIS.)

VetBooks.ir

Slipped Stifle
Slipped stifle is the popular term for dislocation of the patella. It may be partial, when the patella slides in and out of the trochlear depression on the femur with each step; or it may be complete, when the patella becomes fixed above the outer lip of the pulley-like trochlear surface, causing all the joints of the affected leg to become straightened, and the limb to be held pointing behind. PATELLAR LUXATION is a common condition in the dog.

'Slipped Tendon'
A condition seen in chickens, turkey poults, and ducklings, in which there is displacement of tendons and an inability of the leg to support the bird's weight. It is due to a manganese deficiency, and may arise from feeding lime to excess. The incidence is higher in bronze and black turkeys and in dark-coloured chicken breeds, as extra manganese is necessary to synthesise the pigment MELANIN.

Slope Culture
A method of growing micro-organisms on solid media (e.g. agar) in tubes which are usually arranged in racks at the correct angle for the agar to solidify on cooling.

Slough
Slough means a dead part separated by natural processes from the rest of the living body. The slough may be only a small part, such as a piece of skin that has been burnt by heat or chemicals, or it may be a whole foot. (See GANGRENE.)

The term slough is also applied to normal shedding of skin in reptiles. (See ECDYSIS.)

Sloughi Dogs
North African dogs somewhat like a greyhound. They are short-haired medium-sized dogs, straight-backed, light sand, dark sand or brown coloured with or without brindle and a black mantle, face, mask and ears. They are prone to PROGRESSIVE RETINAL ATROPHY (DNA test available).

Slowly Degradable Protein (SDP)
In ruminants, protein that can be digested in the reticulorumen may be divided into quickly degradable protein and slowly degradable protein which is relatively slowly (over hours) broken down into amino acids. The aim should be that the release of this SDP is matched by the breakdown of slowly fermentable fibre.

Slow-Milking Cows
(See under MILKING MACHINES.)

Slow Reacting Substances (SRS)
Also called leukotrienes, they are substances released in an anaphylactic reaction which induce prolonged smooth-muscle contraction. The effect is seen in asthma.

Slugs
The common field slug *Agriolimax meticulatus* is of veterinary interest as intermediate host of the sheep lungworm *Cystocaulus ocreatus*. (For the danger of slug poisons, see METALDEHYDE POISONING)

Slurry
Slurry is the liquid mixture of urine and faeces, together very often with washing-down water and rainwater, which has to be disposed of from pig, beef and dairy units. Deaths of pigs have been reported following agitation of slurry during the emptying of tanks or pits under the piggery slats. It is recommended that slurry should never be allowed to come within 45 cm (18 in) of the slats, and that especially in hot weather emptying should be carried out at least every three or four weeks. Methane, hydrogen sulphide, ammonia, and carbon dioxide may all be given off as the result of bacterial action on slurry, giving rise to a mixture both lethal and explosive.

Cows, too, have been overcome by slurry gases (ammonia, carbon dioxide, hydrogen sulphide, methane).

For methods of slurry disposal, see DAIRY HERD MANAGEMENT. (See also under SALMONELLOSIS; PASTURE, CONTAMINATION OF; 'MILK-SPOT LIVER'; SILAGE.)

SM
(See SYRINGOMYELIA.)

Small Blister
(See VESICLE.)

Small Intestine
The part of the alimentary tract that is between the stomach and large intestine. It consists of three parts, the duodenum, jejunum and ileum. (See also DIGESTION, ABSORPTION AND ASSIMILATION.)

Smear Preparations
A film of blood, pus, etc., smeared on to a slide, fixed – and if necessary stained – for microscopical examination.

Smedi (SMEDI)
An acronym for stillbirth, mummification, embryonic death, infertility in pigs – a syndrome caused by infection with subgroups of enteroviruses A, B, or C.

Smegma
Sebum with a distinctive odour found in the region of the clitoris and penis. For a test using smegma, see EQUINE CONTAGIOUS METRITIS.

VetBooks.ir

Smell

Smell is detected by the dissolving of minute particles of oderiferous substances, gaseous or solid, in the mucus lining the nose. This triggers a response in the hair-like processes attached to the nerve cells which is transmitted to the brain by the olfactory nerve. The sense of smell is much more highly developed in dogs and cats than in humans. They have a formation at the roof of the nasal passage (the subethmoidal shelf) that extends the range and accuracy of smell detection. The act of 'sniffing', familiar in the case of the dog especially, simply ensures that the particles are rapidly and forcibly drawn upwards into the nose. Smells may be air-borne or ground smells, those left on solid objects by an animal, person or object. The response to a smell can differ in different animals: thus the smell of fish, blood, and offal has a remarkably stimulating effect upon the carnivorous animals, while grass, grain, and vegetable substances stimulate the sense organs of herbivorous creatures particularly. The odour of flesh, blood, etc., is repulsive to the herbivora, and may cause great nervousness and fright. Most of the wild grass-eating animals have remarkably well-developed powers of smell, and are able to locate their enemies at great distances – over 1 kilometre – but they also detect ground smells which are important in marking out territory. It is through the sense of smell that the male is attracted to the female during the season or oestrus of the latter; the odour at this period is most persistent, and can be appreciated at great distances. Females recognise their offspring by their sense of smell and dams whose young have died can often be deceived and persuaded into accepting other young animals by clothing these in the skins of the dead ones. This fact is made use of in the case of ewes which have lost their lambs. (See JACOBSON'S ORGAN; PHEROMONE.)

Smells as Evidence of Disease

In certain cases the presence of a smell connected with an animal is almost a diagnostic feature of disease. Thus in decay of the teeth or decomposition of bone there is a characteristic smell which, when once it is appreciated, can never be forgotten, although it is difficult to describe. The breath, urine and the milk of a cow suffering from ACETONAEMIA have a characteristic sweetish sickly smell. Poisoning by certain drugs, e.g. carbolic acid, can be diagnosed to some extent by the smell of the drug that is left in the mouth or on the skin. The urine of the horse has the smell of violets after the administration of turpentine in large quantities.

It has been suggested that dogs might be trained to recognise certain smells associated with human diseases, and so aid diagnosis at an early stage.

Smog

A word produced by combining smoke and fog. It is the popular name for fog containing a dangerously high proportion of sulphur dioxide, other harmful gases and soot particles derived from coal fires and factory chimneys, usually in the colder months of the year. It is often yellow in colour. Smog can cause respiratory problems for animals. In London cattle at the Royal Smithfield Show in 1952 were severely affected resulting in some being slaughtered; some 12,000 people died in the same period of smog – the Great Smog. Introduction of Smoke Free Zones in cities greatly improved the situation but it still can occur in other countries. (See also OZONE for a further description of smog.)

Smoke Inhalation

It often occurs following fires and is of varying degree. It can damage the upper respiratory tract including the trachea and occasionally the mouth. It may result in destruction of the respiratory tract lining leading to eventual death or it may be less severe but result in reduction of the defence mechanisms present within the tract allowing infections and foreign bodies more easy access to the whole respiratory system and body. Such problems may not be immediately obvious and following a fire veterinary attention should always be summoned.

Smooth Collie

This breed, originally a shepherding dog, can inherit, like other collies, COLLIE EYE ANOMALY. CENTRAL PROGRESSIVE RETINAL ATROPHY is a dominant trait. They also show CANINE CYCLIC NEUTROPENIA and canine multidrug sensitivity. CANINE MULTIDRUG SENSITIVITY (DNA test available) is found in the breed.

Smooth-Haired Fox Terriers

Originally thought to be related to the wire-haired fox terrier, this is probably not the case. The breed is less popular than in the past. They suffer CEREBELLAR ATAXIA, DEAFNESS, LENS LUXATION and PULMONARY STENOSIS. (See FOX TERRIERS.)

Snails

One or two species are of veterinary interest in connection with LIVER-FLUKES and tapeworms.

The giant African snail (*Achatina fulica*) is commonly kept in UK schools to show to biology class pupils; however, it is a potential human health risk. Third-stage larvae of *Angiostrongylus cantonensis*, passed out in rats' faeces, are infective for mammals, and in the Far East have caused meningitis in people; though the majority of cases have occurred through eating uncooked snails.

Snails are farmed for food in Britain, as well as in France and elsewhere.

Snake Bites

Many are poisonous. In Britain the only poisonous snake is the ADDER, although in other parts of the world large numbers are venomous.

Signs Two kinds of signs are produced, depending upon the kind of venomous snake involved. In those of the cobra type there is a period of excitement immediately after the bite, lasting only for a few minutes and followed by a period of normality. Then nervous excitement appears, convulsive seizures follow, and death takes place from asphyxia. If death does not occur at once, dullness and depression are seen and death or recovery takes place some hours later. There is usually little pain at the site of injury, and practically no local reaction in rapidly fatal cases.

The signs of bite by the ADDER (*Vipera berus*) – the only poisonous snake found in Britain – are similar, except that there is local pain and considerable swelling. The skin becomes a livid colour, tumefied, and if in a limb there may be severe lameness. The dog often appears to be frightened. Treatment is ideally with ANTIVENOM.

With most snakes, the venom is introduced by their fangs, which have either a groove on the surface, as in cobras, or a canal down its centre, as in adders. The African Ring-hals, however, squirts its venom with uncanny accuracy for a distance of about 2 m (6 ft) into the eyes of its victim; the snake rising and opening its mouth wide, its head thrown back.

The rattlesnake venom contains compounds possessing zinc, plus an enzyme which causes destruction of muscle tissue.

In Australia, snake-bite was diagnosed at the University of Melbourne in cats over a six-year period – the tiger snake having caused several cases. Signs included weakness, dilated pupils and absence of normal reaction to light by the pupils, with vomiting and laboured breathing in some instances. Paralysis and a subnormal temperature suggest a fatal outcome. A high rate of recovery may follow the use of 3,000 units of tiger snake ANTIVENIN.

Animals susceptible Dogs are the animals most frequently affected by snake-bites, with sporting dogs suffering more than others. Sheep, cattle and horses come next in frequency, whilst cats and pigs are only rarely affected. The reasons for this appear to be that hunting dogs most often disturb snakes, and that grazing herbivorous animals, moving only slowly over a tract of country, disturb snakes less; while the cat is not often attacked because of its greater caution when hunting, and because of its superior agility. Pigs apparently are least often killed because of the protection of a hard tough skin, with a padding of fat immediately below it.

Snakes are kept as pets, by collectors (herpetologists) and in laboratories for research into their venom and the production of ANTIVENIN. Their husbandry and environment need special attention, especially regarding the PREFERRED OPTIMUM TEMPERATURE ZONE of the species. Environmental security also must be considered. Cleanliness is vital. Feeding should resemble that found in their natural habitat as closely as possible, although the provision of live prey may not comply with every country's welfare laws. Snakes must be handled with care. Rough handling can cause a fatal MYOSITIS. All species are capable of biting and can be very quick to strike. Non-venomous snakes are usually quite content to coil themselves around the handler's fingers, hands or arms and one must be aware of the dangers of allowing the constrictors to do this. Venomous snakes are best handed with tools such as snake hooks, one type of which can be used to restrain the animal's head against a soft substrate before the snake is grasped behind the head.

Snakes

Limbless reptiles, widely distributed and differing greatly in size. Many are poisonous. Broadly speaking, those which have two rows of small, solid, equal-sized teeth on either side of the upper jaw are non-venomous; while those with one row of small teeth on either side of the upper jaw, and two or more large, curved, hollow or grooved fangs on the outside of the smaller teeth, should be considered venomous.

Snake Venom Antiserum

(See ANTIVENOM.)

Sneezing

Sneezing is a sudden forced expulsion of air through the nostrils, designed to expel irritating materials from the upper air passages; the vocal cords being kept shut till the pressure in the lungs is high, and then suddenly released, so that the contained air is driven through the throat into the nose. Entrance to the mouth is prevented by the soft palate closing the exit from the mouth.

Sneezing is induced by the presence in the nose of particles of irritating substances, such as pungent odours, smoke, dust, foreign bodies, spores of certain species of fungi, pollen from some grasses, etc. It is also the forerunner of chills, colds, influenza, etc., when it is usually accompanied by a running at the nostrils, and it is a sign of the presence of certain parasites, such as *Oestrus* larvae in sheep and horses, and rarely *Linguatula* in dogs.

VetBooks.ir

In pigs, sneezing is an important sign of ATROPHIC RHINITIS and AUJESZKY'S DISEASE.

S-N-F
(See SOLIDS-NOT-FAT.)

Snood
The long fleshy appendage extending from the front of a turkey's head over its upper beak. It is often removed even in the hatchery as it is a target for injury during fighting, and can then result in infection especially with *Erysipelothrix rhusiopathiae*.

'Snow Blindness' in Sheep
(See under EYE, DISEASES AND INJURIES OF - KERATITIS.)

Soapwort Poisoning
Soapwort poisoning may occur when the soapwort plant (*Saponaria officinalis*) grows abundantly in pasture. The plant contains the glycoside saponin, which causes frothiness when stirred in water. When saponin is introduced into the body it causes dissolution of the red blood cells, stupefaction, paralysis, vomiting, and purging with the passage of large amounts of frothy faeces, which are mixed with blood.

Soay Sheep
A breed of small chocolate brown or black sheep, named after the isle of Soay in the St Kilda Archipelago, Outer Hebrides, where they have existed since before the Roman occupation of Britain. The rams are horned, ewes are horned, have SCURS or are POLLED. Their fleeces, which weigh 1 kg or 2 kg each (2.2 lb to 4.5 lb), are much favoured by hand spinners. The ewes produce only single lambs but mother them very well. The breed has found favour in Cornwall, where they do not graze clover in a grass/clover mixture, so that the hillsides are never overgrazed. When herded by dogs, the Soays scatter rather than flocking together.

Social Behaviour
(See BUNT ORDER.)

Sodium (Na)
A metal, the salts of which are white, crystalline and very soluble in water. Common salt, or sodium chloride, is contained in the fluids of the body under natural circumstances, and therefore the salts of sodium, when used as drugs, act not through their metallic base but according to the acid radicle with which the sodium is combined. Generally speaking, the salts of sodium act in a manner very like corresponding salts of POTASSIUM but are better tolerated. Sodium deficiencies can occur.

Sodium carbonate (washing soda) is an irritant internally, and is therefore never given by the mouth except, in an emergency, as an emetic for the dog. A solution of sodium chloride 0.9 per cent is called 'normal saline', as it is isotonic with body fluids.

Sodium Arsanilate
Sodium arsanilate is an organic preparation of arsenic used for the treatment of COCCIDIOSIS in poultry. It has been used by intramuscular and intravenous injection for treatment of certain diseases caused by the presence of trypanosomes in the blood.

Sodium Bicarbonate
This has the formula $NaHCO_3$ and is also baking powder. It is a mild alkalising agent, an antacid and is produced naturally in the saliva, particularly of ruminants, to act as a buffer against acid production in the rumen. It is also added to ruminant feeds when there are high cereal concentrations. It can be given intravenously to counteract ACIDOSIS and occasionally locally to remove mucus, other exudates and scabs.

Sodium Calcium Edetate
A compound licensed for use in cattle and dogs to treat lead poisoning. It is diluted with isotonic sodium chloride or glucose solution and injected slowly intravenously. Milk from cows so treated cannot be used for human consumption until the lead level has fallen below 0.02 ppm and meat from treated animals cannot be used for human consumption until three months after the removal of the source of poisoning. (See LEAD POISONING.)

Sodium Carbonate
(See WASHING SODA.)

Sodium Chloride
(See SALT.)

Sodium Deficiency
This may occur in dairy cattle in the UK in July. (See also SALT - SALT LICKS; METABOLIC PROFILE TESTS, 'LICKING SYNDROME'.)

Sodium Metabolism
Sodium is important in maintaining osmotic pressure in the body fluid outside cells, and so controlling body fluid volume. (See also KIDNEYS - FUNCTION, and ALDOSTERONE.)

Sodium Monofluoroacetate
A rodenticide also known as '1080'. If ingested by dogs, signs of poisoning include yelping, sometimes vomiting, and convulsions. This compound was sometimes used in wildlife rabies control operations against foxes, etc.

Sodium Nitrite
(See under NITRITE POISONING.)

Sodium Propionate
(See under PROPIONATE, SODIUM.)

Soft Coated Wheaten Terrier
A medium-sized dog of 15 kg to 20 kg (35 lb to 45 lb) originating from Ireland. It has a soft, wavy, wheaten or rust-coloured coat. It is prone to RENAL DYSPLASIA (DNA test available).

Soft Palate
For a condition of this causing distressed breathing in the racehorse, see under PALATE; likewise for prolonged soft palate in the dog.

Soft Tissue
Tissues other than BONE which support, surround and connect other body tissues and organs.

Soft Tissue Sarcoma (STS)
A MALIGNANT tumour of the CONNECTIVE TISSUES other than the SKIN.

Soil-Contaminated Herbage
Experiments in Australia and New Zealand with intensively grazed sheep were undertaken to investigate tooth wear in ewes and wethers at various stocking densities. It was found that 'tooth wear was low when soil content of faeces was low and they rose to a peak simultaneously'. Moreover, in the majority of cases, soil content of the faeces was highest where stocking rates were high; when stocked at nine adult sheep to 4,000 sq m (1 acre), the daily intake of soil per head could be as much as 370 g (13 oz) in the rainy season.

In Britain, it has been suggested, July thunderstorms over first-year leys may – by a combination of splashing by rain and poaching by feet – produce a herbage that is seriously contaminated with soil. This could well irritate the sensitive lining of the gut in young lambs, with consequent scouring; this is often seen among lambs believed to be reasonably free from parasitic worms. (See also SAND, COLIC.)

Solanum malacoxylon
A South American plant rich in the precursor of vitamin D. It has caused poisoning (hypervitaminosis D) when eaten by livestock.

Sole
The bottom or base of the foot or hoof.

Solids-not-Fat (S-N-F)
This refers to milk constituents including the protein casein, milk-sugar, and minerals.

Deficiencies of solids-not-fat lead to difficulties in processing the milk, and render it unsuitable for manufacture into high-class products. Milk produced by a cow affected with mastitis, or by one approaching the end of a lactation, is particularly undesirable.

Maintaining the S-N-F percentage at a satisfactory level is a more difficult problem for the milk producer than rectifying variations in the butterfat percentage. The causes of S-N-F deficiency are not always apparent, and attempts at remedying them may have no rapid effect.

Factors involved include breed of cow, her inherited capacity, age, stage of lactation, the season of the year, feeding, management and attacks of mastitis.

The diet should contain adequate fibre as well as protein. There is some evidence suggesting that an all-silage diet may lower S-N-F, unless the silage is of the highest quality. Hay, as well, is desirable. (See RATIONS FOR LIVESTOCK – Winter rationing.)

The percentage of solids-not-fat is relatively high in October and November, after which time it begins to decline and falls to a minimum in February and March. It then starts an upward trend, reaches a high level in May, and may drop again in July and August.

Milk from cows of the JERSEY and GUERNSEY breeds is relatively high in solids-not-fat. British Friesians, as a rule, give milk low in S-N-F. Inherited capacity is important.

The percentage of solids-not-fat in milk varies according to the stage in the lactation. It is high at the beginning, but falls rapidly to a low level within six to eight weeks after calving. Thereafter, it rises gradually if the cow is pregnant, while it tends to decline further if she is not again in calf. Towards the end of the lactation, when the cow is drying off, it may fall very low.

Soma
The body as opposed to the mind, or as opposed to the germ cells. It refers also to the cell body.

Somali Cats
A breed of cat similar to the Abyssinian. It is prone to HIP DYSPLASIA and to MYASTHENIA GRAVIS. There are DNA tests for PROGRESSIVE RETINAL ATROPHY and erythrocyte PYRUVATE KINASE DEFICIENCY.

Somatic
Somatic means all the cells belonging to the body except the germ cells in the gonads.

Somatic Cell Count (SCC, scc)
A term often used for the cells, mainly white cells, present in milk. The cell count can be used on a quarter or the combined milk from four quarters or from a herd. High levels in individual cow's

VetBooks.ir

milk or that of other mammals, or in bulk herd milk indicate MASTITIS. In a herd where milk is sold commercially it can indicate the quality of the milk and the number of animals with subclinical infection. It is usually shown as a rolling mean and so it is helpful in mastitis monitoring. Cell count levels are naturally higher in goats' milk. (See MASTITIS IN COWS.)

Somatic Nerves

Sensory or motor nerves of the somatic division of the central nervous system; they deal with awareness of sensation and with voluntary control of muscles. (See CENTRAL NERVOUS SYSTEM.)

Somatostatin

A peptide hormone, produced by the hypothalamus at the base of the brain, which acts as a brake on growth by regulating release of growth hormone directly responsible for tissue growth. Animals immunised against somatostatin are not subject to this 'braking' effect, and it has been suggested that this technique might be more effective than conventional growth promoters used in meat production.

Somatotropin, Somatotrophin, Somatotrophic Hormone (STH)

A growth hormone, produced by the pituitary gland, which stimulates growth of all body tissues, and influences mammary-gland development. Like insulin, somatotropin helps to maintain correct glucose levels in the blood.

In the 1930s the National Institute for Research in Dairying found that the hormone could increase the milk of dairy cows. In 1983 research was being directed towards production of growth hormone by genetic engineering techniques, with the aim of producing a commercial product which could increase milk yields. This research was successful and trials showed that in cows, fodder was metabolised more efficiently, producing higher milk yields for a given quantity of feed. However, the argument that this increased efficiency was beneficial did not prevail against UK and EU welfare concerns about its use. Although used in the USA and elsewhere, there is a moratorium on the use of somatotropin in the EU. (See SOMATOSTATIN; PITUITARY GLAND.)

Sorbitol

A sugar alcohol found in fruits and berries, it is one of the intermediate products in the conversion of glucose to fructose. In severe diabetes mellitus, it is deposited in the lens of the eye.

Sorbitol Dehydrogenase (SDA)

A liver enzyme; raised levels indicate liver damage, particularly in horses. Also called L-iditoldehydrogenase.

'Sore Hocks' in Rabbits

(See PODODERMATITIS IN RABBITS.)

Sores

(See ULCERS.)

Sore Throat

Sore throat is a popular term for laryngitis or pharyngitis, which is often present during catarrh, strangles, influenza, etc. (See THROAT diseases.) A person with a streptococcal-infected throat may pass the infection to the udders of cows being milked, setting up mastitis.

Sorghum

Widely-grown fodder and grain plant. Poisoninghas been recorded in horses grazing pasture containing *Sorghum* species. Hindquarter weakness and paralysis of the bladder may result. Expansion of feed pellets containing sorghum improved pellet quality but it had a deleterious effect on broilers fed the pellets.

Sorrel Poisoning

(See DOCKS, POISONING BY; SOURSOB.)

'Sound'

A blunt metal rod, either curved or straight, which is used for passing along a natural channel or duct of the body. They are generally used to discover whether there are any hard or solid foreign bodies present.

Soundness Examination

(See PRE-PURCHASE EXAMINATION.)

Sounds

Sounds are made both normally and abnormally by some of the organs of the body. For example, during the normal heartbeat there can be distinguished two definite sounds. The first of these, known as the 'first heart sound', is a long booming noise, similar to the syllable *lūb*, which is heard when the ventricles are contracting and the atrio-ventricular valves are closing, and which is produced by these processes. The 'second heart sound' is a short, sharp, sudden sound, similar to the syllable *dûp*, and is heard at the end of the contracting period of the ventricles, when the semilunar valves at the bases of the pulmonary artery and the aorta are closing.

Respiratory sounds are also present normally. The sound made by the air entering the alveoli is generally called the respiratory, or vesicular, murmur. It is a soft, low, quiet blowing sound, which can be imitated by the gentle blowing of air from a pair of bellows. In addition to the friction of the air in the alveoli there is also a sound produced by the air in its course down the trachea and along the greater bronchi.

VetBooks.ir

During disease there are unusual sounds produced, especially by the organs in the chest: for these see RALES; HEART DISEASES; LUNGS, DISEASES OF; etc.

Soursob

The Australian name for *Oxalis cernua*, a member of the sorrel family, found in Australia, South Africa, the continent of Europe, and now the West of England. It has caused fatal poisoning in sheep.

South American Camelids

(See CAMELIDAE.)

South Devon Cattle

Large cattle often known as 'gentle giants'. They are covered in orange-yellow hair, with white or yellow horns usually curved downwards and a slightly yellow fat. Bulls weigh 1,200 kg to 1,600 kg. (2,640 lb to 3,520 lb) They are believed to be descendants of the large red auk of Normandy and came over to Britain with the Normandy invasion (1066). The herd book started in 1891. Originally they were dual purpose (milk, meat) and draught.

South Devon Sheep

A longwool breed found in South West England and used for meat and wool. It is similar to, but larger than, the DEVON LONGWOOL SHEEP. Both sexes are polled, with a white face and black nostrils and a woolly forelock.

Southdown Sheep

A small dual-purpose (meat, wool) breed; it is becoming a rare breed. The rams weigh 85 kg to 105 kg (185 lb to 230 lb), the ewes weigh 60 kg to 80 kg (130 lb to 175 lb) with 2.25 kg to 3.6 kg (5 lb to 8 lb) wool. The rams were used to create the DORSET DOWN SHEEP.

Sow

A female pig that has had one or more litters.

Sows' Milk

The production of colostrum lasts for about five days, during which time the milk composition changes rapidly to 'normal'. In fact there is no such thing as 'normal' milk because its composition changes continually throughout lactation. The protein and mineral contents rise steadily, while lactose and fat contents fall.

Sows' milk is very rich in fat, reaching a peak at about the third week of lactation; levels may reach as much as 17 per cent. This high fat level may be significant in the frequent occurrence of piglet scours at about three weeks of age.

Although inadequate in iron, sows' milk appears otherwise to be an ideal feed for young pigs, allowing an efficiency of feed conversion on a dry matter basis of some 300 g (0.8 lb) feed per 450 g (1 lb) of gain. However, the sow is unable to produce sufficient milk to allow the piglet weight-gain expected. Thus, an average yield is about 45 kg (100 lb) milk per piglet suckled, or 9 kg (20 lb) dry matter in 8 weeks which, at an efficiency of conversion of 0.8, is sufficient to allow a weight gain of 11.3 kg (25 lb). With an average birth-weight of 1.4 kg (3 lb) this would allow the production of 13 kg (28 lb) weaners at 8 weeks. So to produce an 18 kg (40 lb) pig at this age it must have consumed some 11 kg (24 lb) creep-feed at an efficiency of feed conversion of about 2:1.

The major requirement of a creep-feed is energy as the sow's milk should provide adequate protein. An early-weaning diet, on the other hand, requires to have a high protein content, which will vary with the age of pig to which it is given.

Sows' Milk, Absence of

The absence of milk following farrowing may be due to prior feeding with excessive quantities of fodder beet, or to inflammation of the uterus (metritis). Another cause is an endocrine failure. Post-parturient fever is an important cause. Wet, cold floors and cold, draughty premises appear to predispose sows to MASTITIS and AGALACTIA.

In herds where agalactia is common, administration of PROSTAGLANDIN (PG) $F_2\alpha$ to induce parturition reduces the number of cases of lactation failure.

In parts of Africa, heavy losses of piglets have resulted from this failure of the sows' milk supply, and the cause was traced to the fungus ERGOT, parasitic on bulrush millet ('MUNGA'). (See PREDNISOLONE; POST-PARTURIENT FEVER OF SOWS; ERGOT OF MUNGA.)

Sow Stalls

S

Sow stalls, also called gestation stalls, have been widely used for dry and pregnant sows, and ensure that each animal obtains her fair share of food. However, in partly slatted stalls, high culling rates have sometimes resulted from defective slats causing foot and leg injuries, leading in some instances to partial or complete paralysis of the hind-quarters. Also the sow is cramped, and cannot move out of draughts; so the use of these stalls can lead to stress. They became illegal in the UK on 1 January 1999 by a unilateral decision of the British government. Leading retailers agreed to obtain pig meat only from sources where stalls are not used. Denmark and the Netherlands then also introduced a ban. From 1 January 2013, a ban on sow stalls and tethers was introduced throughout the EU. (See THIN SOW SYNDROME.)

VetBooks.ir

Soya
The name often used for SOYA BEANS produced from a leguminous plant. The main producers are USA, Brazil, Argentina, China and India. It is a rich source of DIGESTIBLE UNDEGRADED PROTEIN (43 per cent to 55 per cent) particularly for ruminants and other farm animals.

Soya Beans, Soybeans (US)
Soya beans are rich in protein and fat. Soya flour contains about 40 per cent protein and 20 per cent fat, and is a good source of thiamine, riboflavin, vitamin A, and lysine. In the raw state they are poorly digested, as they contain an anti-trypsin factor, but this is destroyed by micronisation (exposure to infra-red radiation). There are also some indigestible carbohydrates present. Some types have been genetically modified and are permitted to be used in the feed of European farm animals. Humans and occasionally dogs and cats can develop HYPERSENSITIVITY to it. (See SOYA.)

Soy Protein
This is found in the soya bean of SOYA. It is a meal produced after dehulling and defatting the soya beans. It is rich source of DIGESTIBLE UNDEGRADED PROTEIN, particularly for ruminants.

sp.
Abbreviation for species.

Spaniel Dogs
(See AMERICAN COCKER SPANIELS; CAVALIER KING CHARLES SPANIELS; CLUMBER SPANIELS; COCKER SPANIELS; ENGLISH SPRINGER SPANIELS; IRISH WATER SPANIELS; KING CHARLES SPANIELS; PAPILLON DOGS; SPROCKER SPANIELS; TOY DOGS [Cavalier King Charles Spaniels, King Charles Spaniels], WELSH SPRINGER SPANIELS.)

Spanish Fly
(See CANTHARIDES.)

Spanish Water Dogs
An all-purpose dog used developed in Spain for herding animals, as a gundog and for fishing. It is a medium-sized (15 kg to 20 kg; 30 lb to 45 lb) active dog with a curly woolly coat which is black, beige, brown, white or bicoloured. The breed suffers from PROGRESSIVE RETINAL ATROPHY (DNA test available).

Sparganosis
Infestation with *Spirometra* larvae of muscles and subcutaneous tissue. The adult worms infest dogs, cats, and wild carnivores in Australia, the Far East, and North and South America.

Sparganosis is a ZOONOSIS, as people can become infested through eating pork or drinking water containing the larvae at one stage in their development.

Spasm
An involuntary and, in severe cases, a painful contraction of a muscle, or of a hollow organ with a muscular wall. Further information is given under ASTHMA; COLIC; CHOREA; CONVULSIONS; CRAMP; EPILEPSY; MUSCLES, DISEASES OF; SPINE AND SPINAL CORD, DISEASES AND INJURIES OF; STRYCHNINE; TETANUS; TETANY; RABIES; HYPOMAGNESAEMIA.

Spastic
Spastic is a term applied to any condition showing a tendency to spasm, such as 'spastic gait'.

In British Friesian cattle, an inherited spastic form of lameness may appear when the calf is six or eight weeks old, but sometimes not until it is six months old. Before long, the toe may not touch the ground as the calf walks, and the affected hind-leg is held backwards. Later, the leg becomes shortened and useless. If, however, the case is treated early enough, a simple operation will correct the deformity and prevent these unfortunate sequels. But of course, that calf, grown to maturity, can transmit the deformity to a proportion of its offspring. The condition has also been seen in SHORTHORNS and ABERDEEN ANGUS crosses. (See TENOTOMY.)

Spavin
General name for diseases of the hock-joint (see BONE SPAVIN; BOG SPAVIN).

Spaying
Surgical removal of the ovaries, and usually of the uterus also, carried out mainly in cats and bitches. (See OVARIO-HYSTERECTOMY for reasons for the operation.)

Also, mares to be used in cavalry regiments, or polo pony mares, as well as certain thoroughbred racing mares, where the occurrence of oestrus and its associated phenomena would interfere with the proper performance of work, and mares which are suffering from some definitely hereditary disease, are subjected to the operation.

In 'nymphomania', ovariotomy, when performed before the signs have been in existence for long, usually results in a complete cessation of the kicking, squealing and fractiousness which generally render the mare unfit for work.

In the past it was common practice to spay both cows and sows – the former giving a continuous milk supply for 18 months or even much longer.

Cats are spayed to prevent the birth of unwanted kittens, adding to the problems of stray and feral

VetBooks.ir

cats. The operation is almost invariably satisfactory, and involves few, if any, disadvantages.

Bitches are spayed to a lesser extent than cats. The operation may be requested by the owner on account of domestic difficulties or convenience, or it may be advised as a means of preventing pyometra. Bitch puppies can be spayed from about 16 weeks of age but often are left until after their first heat; kittens also, though probably most are spayed between four and six months of age.

Ovario-hysterectomy is performed usually through a flank incision.

Special Import Certificate

Required by the VMD when importing registered medicines for specific animals or groups of animals from other EU Member States.

Species-Specific

This often refers to infections which look similar in different species but are caused by different organisms such as COCCIDIOSIS, POX viruses and WARTS.

Specific Chemical Injection (SCI)

This involves DARTING and can include the use of pole syringes. It is used for purposes of sedation, anaesthesia and therapy. (See also PROJECTILE INJECTION.)

Specificity

This indicates the number of affected animals which produce a false negative to a test, and so shows the proportion that are truly negative. Ideally specificity should be 100 per cent. (See SENSITIVITY.)

Specific Medicine, Specific Treatment

This is treatment that is specifically designed to treat the disease or condition present in the animal.

Specific Pathogen Free Animals

(See SPF.)

Specified Risk Material

(See SRM.)

Spectacles

Spectacles, so-called, of plastic material were sometimes used to prevent poultry from resorting to CANNIBALISM, etc. Their use is now illegal under the Animal Welfare Acts.

'Spectacles' for horses used in mines are really eye-shields. (See also LENSES, CONTACT; RETAINED SPECTACLES.)

Spectinomycin

An aminocyclitol antibiotic similar to streptomycin with a high activity against *Mycoplasma* spp. and some Gram-positive and Gram-negative micro-organisms. It is even more effective when given as a combined treatment with lincomycin in the ratio of spectinomycin:lincomycin = 2:1.

Speculum

Speculum is an instrument designed to aid the examination of the various openings of the body surface. Many are provided with small electric lamps which illuminate the cavity under examination.

Speeds of Animals

RACING CAMEL In Australia the record is quarter of a mile in 27 seconds.
CHEETAHS 100 km/h (62 mph).
GREYHOUNDS The record is 66 km/h (41 mph).
OSTRICHES can achieve a speed of 72 km/h (45 mph) over short distances.
PIGEONS can fly at 74 km/h (46 mph).
PORPOISES can swim at 64 km/h (40 mph).
PRONGHORN ANTELOPE 56 km/h (35 mph) for 6 km (4 miles); 88.5 km/h (55 mph) for 0.8 km.
RACEHORSES have reached 69 km/h (43 mph).
KILLER WHALE 30 knots.
(with acknowledgements to *Guinness World Records*)

Speedy-Cut

Speedy-cut is the name given to the injury that results from a horse striking the inside of the carpus or metacarpus with some part of the inside of the shoe of the opposite foot. (See BRUSHING AND CUTTING.)

Spermatic

Adjective used to describe blood vessels, nerves, and other structures that are associated with the testicle.

Spermatic Cord

(See INGUINAL CANAL and the illustration under PENIS.)

Spermatic Cord, Torsion of

This has been reported, as a rare condition, in the dog. In a review of 13 cases, the testicle involved was intra-abdominal in 11 dogs, and inguinal and scrotal in others. In most cases the torsion appeared to result from enlargement of the testis due to tumours. Two of the dogs died – one of uraemia due to retention of urine, the other from shock – and a third after surgery. However, 10 dogs recovered completely after castration.

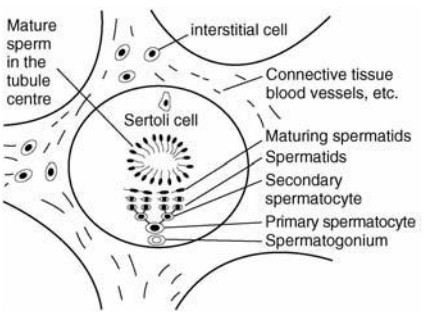
Spermatid

A developing stage of the maturing spermatozoa.

Spermatozoa, Sperms

Spermatozoa (sperms) are the motile male sex cells which, having matured in the epididymis, are

VetBooks.ir



ejaculated at orgasm and are normally capable of fertilising the ovum or egg. The sperms are derived from non-motile cells in the seminiferous tubules of the testicle. The first-stage cells, Spermatogonia, divide to form the primary spermatocytes. When these latter in turn divide, the chromosomes become paired, one from each pair being found in the resulting secondary spermatocytes, which accordingly have half the number of chromosomes found in all the somatic cells. The spermatid is a further stage of development which includes acquisition of the flagellum or tail which provides the sperm with its motility. For their journey to the Fallopian tubes, it appears that the sperms are not wholly dependent upon their own motive powers; the muscles of the female genital organs apparently assist onward movements of the semen.

Each spermatozoon has three main parts: the head, containing the cell's nucleus; a middle portion; and the tail. (See also SEMEN; REPRODUCTION; and ARTIFICIAL INSEMINATION.)

In the bull, it takes about 50 days from the time a sperm begins to be formed in the testicle to the time it appears in semen.

All normal semen contains some genetically deleterious diploid spermatozoa, distinguishable by their large size.

Fever may result in increased numbers of abnormal spermatozoa. For example, in Australia many abnormalities have been found in the middle portions of sperms from bulls suffering from bovine ephemeral fever.

Sperm formation in the testis. (From D. F. Horrobin, *Medical Physiology and Biochemistry*, courtesy of the author and Edward Arnold.)

Spermiophages

Spermiophages are macrophages which engulf sperms, thereby causing infertility. They have been found in both human and canine semen.

SPF

Specific pathogen-free. In Britain as in the USA, SPF pigs are available for repopulating farms where disease has become a problem. SPF piglets are removed from the uterus by surgery in a sterile manner, reared in elaborate isolation premises, and immunised and prepared for a normal farm environment. (See also 'DISEASE-FREE' ANIMALS (IN RESEARCH).)

Sphenoid

Sphenoid is a bone lying along the base of the skull in front of the occipital bone, and immediately above and slightly behind the throat.

Sphincter

A circular muscle which surrounds the opening from an organ, and by maintaining constantly a state of moderate contraction prevents the escape of the contents of the organ. The muscle fibres forming the sphincter relax when the contents of the organ are due to be discharged to the outside past the sphincter. Sphincters close the outlet from the stomach, bladder, and rectum, and regulate the escape of the contents from these organs. Under certain conditions the nervous mechanism which keeps these sphincters shut is liable to become upset, so that faeces and urine, for instance, can escape freely. This incontinence is one of the important signs seen in fracture of the spinal column, and in some forms of paralysis.

Sphincter ani

A very muscular valve separating the rectum from the exterior. Its weakness can result in faecal INCONTINENCE.

Sphinx Cats

(See SPHYNX CATS.)

Sphygmograph

Sphygmograph is an instrument used for recording the pulse.

Sphynx Cats

(Sphinx Cats)

A relatively new breed of cat; also known as 'Canadian hairless cats'. In Britain, the DEVON REX CAT has helped in the production of the breed. They are not really 'hairless' but lack guard hairs to keep them warm, but they do have a stubble that feels like chamois leather. This provides insufficient insulation and the breed needs a warm environment and protection from sunburn. They have wedge-shaped heads and a sturdy heavy body. Their characteristics include a high level of energy and intelligence. The breed has a high pain threshold and should not be given the opportunity to engage in fights. The lack of hair can result in increased respiratory problems, especially in kittens. They are recorded as having HYPERTROPHIC CARDIOMYOPATHY; they are susceptible to SUNBURN.

Spica Bandage

(See BANDAGES AND BANDAGING.)

VetBooks.ir

Spiders

In the USA and South America, dogs are often bitten by the black widow spider (*Latrodectus mactans*), which tends to lurk among piles of logs or in dark outhouses. The bite is extremely painful, and may be followed by vomiting, laboured breathing, weakness and paralysis. Death follows within hours or days, unless the ANTIVENIN is administered.

In the USA bites by the spiders of the suborder Labido are fairly common in horses and dogs, the bites being mostly on the head. Cats are mostly bitten on the face or forepaws. Two puncture marks provide a clue aiding diagnosis. Within minutes or hours, signs of neurotoxicity appear and may last for several days. Myalgia, abdominal rigidity, vomiting, panting, disturbance of vision and shock occur.

Another spider, the brown recluse (*Loxoceles reclusa*), causes an erythematous lesion, from which a central blister emerges; the skin there turns purple or black. Convulsions followed by death are not uncommon – the preliminary signs being those caused by the Labido spider.

Several of the larger 'bird-eating' spiders have setae, which they brush off their abdomens with their hind-legs. These setae (described under CATERPILLARS) can give rise to dermatitis, pharyngitis and eye inflammation.

Such spiders are becoming popular as pets, and veterinary advice is increasingly sought on their care.

The Sydney funnel-web spider (*Atrax robustus*) is poisonous to a degree which varies with its sex. The male is much more poisonous than the female. Seventy-five per cent of mice, and 95 per cent of guinea pigs, died after being bitten by male spiders, but only 20 per cent or so after bites by females.

'Spider Syndrome'

A name given by Minnesota sheep breeders to a crippling congenital disease seen mostly in black-faced lambs. The forelimbs may be bent, spines 'twisted', rump angled steeply from *tuber sacrale* to *T. ischii*.

Spina Bifida

A congenital abnormality of the vertebral column, involving a defect in closure of the arch formed by the dorsal laminae of one or more vertebrae. In most, there is hernial protrusion of the spinal cord membranes through the opening. Usually it involves the lower vertebral column. The worst lesions prove lethal. Signs of less serious lesions include paresis or paralysis and incontinence. The condition has been found in dogs and can be inherited. Breeds that are susceptible include BEAGLES. It is also thought to be associated with a deficiency of FOLIC ACID.

Spinal Anaesthesia

(See under EPIDURAL ANAESTHESIA.)

Spinal Column

The spinal column, the chain of bones reaching from the base of the skull along the neck and back to the tip of the tail, is composed of the vertebrae, and forms the central axis of the skeleton. Through the spinal canal, formed by the arches of adjacent vertebrae, runs the spinal cord, which gives off the spinal nerves running to various parts of the body. (See BONES; NERVES; SPINAL CORD.)

Spinal Cord

The spinal cord is the posterior part of the central nervous system and is situated within the spinal canal of the SPINAL COLUMN. It forms the direct continuation of the medulla of the brain, being usually arbitrarily held to commence at the foramen magnum, the large opening in the occipital bone at the back of the skull. Posteriorly, it ends about the middle of the sacrum, although in this region the cord has lost its original form, and consists of a bundle of nerves, the actual termination being at about the level of the joint between fifth and sixth lumbar vertebrae, the continuation of bundles behind this being known as the cauda equina, owing to its supposed likeness to a horse's tail. The spinal cord is thus considerably shorter than the spinal column which houses it. During its course in the horse it gives off 42 pairs of spinal nerves, each of which takes origin by means of a dorsal and ventral root, which join each other, before emerging from the spinal canal. These spinal nerves, according to their position, are known as cervical (eight), thoracic (18), lumbar (six), sacral (five), and coccygeal (five). The cord itself is divided into cervical, thoracic, lumbar and sacral parts. Like the brain, the cord is surrounded by three membranes, the dura mater, arachnoid and pia mater, from without inwards. In the spaces of the arachnoid is a quantity of cerebro-spinal fluid, and between the outside of the dura and the inside of the bony canal is a padding of fat and blood vessels, which together prevent injury to the spinal cord itself during the movements of the spinal column.

On cross-section the spinal cord is found to be composed partly of grey, but mainly of white, matter. It differs from the arrangement in the brain in that while in the brain the grey matter is on the outside of the white mass, in the cord the white matter is superficial. The arrangement of grey matter, as seen in section transversely across the cord, resembles the capital letter H 'horn', and the masses at each side are joined by a wide bridge of grey matter known as the 'grey commissure'. In the middle of this commissure lies the 'central canal' of

the cord, which communicates with the ventricles of the brain.

Microscopic structure The grey matter consists mainly of 'neuroglia' cells, the supporting scaffolding fibrous-tissue cells of nerve regions, and in the meshes formed by these cells lie the large multipolar motor nerve cells, and the fibres which spring from them and unite one cell to another, or pass out of the cord to form the fibres of the nerve trunks. The white matter is composed almost entirely of bundles of nerve fibres, most of which possess a myelinated sheath, the white colour being due to the appearance of these sheaths in the mass. (See NERVES.) There is also in the white matter a certain amount of supporting tissue. Blood vessels are found in both white and grey matter.

Functions The spinal cord conveys nerve impulses to and from the brain, but it also deals with spinal reflex actions. For example, sensation of pain in a dog's paw will cause the animal to snatch the paw away from the source of pain, e.g. a hot cinder. Such protective action is a spinal reflex, involving sensory and motor nerves, taken without reference to the brain. (See also CENTRAL NERVOUS SYSTEM and BRAIN.)

Spinal Dysraphism

Partial or incomplete closure of the neural tube. It is an inherited condition in WEIMARANER DOGS. The condition is seen as 'bunny hopping', often in young puppies. They tend to simultaneously and symmetrically use both back legs. The degree of this abnormality varies; it can overextend the hind-legs before moving them forward. More severely affected puppies develop musculoskeletal defects and may die in the perinatal period.

Spinal Meningocele

A congenital hernia in which the meninges of the spinal cord pass through an opening in the spinal column.

Spinal Muscular Atrophy

A rare inherited neurological condition resulting in atrophy of the spinal muscles. The disease is progressive and there is no treatment. It is seen in dogs such as the POINTER, GERMAN SHEPHERD DOG, ROTTWEILER and CAIRN TERRIER, and cats including the MAINE COON breed.

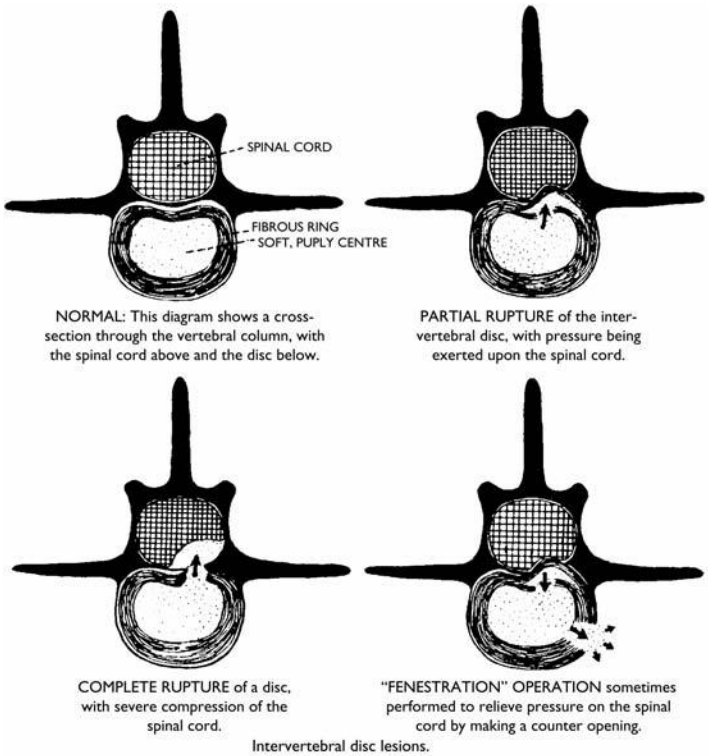
Spine and Spinal Cord, Diseases and Injuries of

These will be considered together, because the chief danger of injury to or disease in the spine is that the spinal cord and its nerves may be simultaneously injured or diseased.

Fracture of the spinal column is probably the commonest severe injury that affects this part. It may be encountered in any animal, but is probably commonest in the horse and dog. It usually occurs as a result of external violence, such as falls, falling timber, running into stationary objects and other run-away accidents in the larger animals; in the smaller animals it is often occasioned by road traffic accidents, kicks or blows from large animals, falls from great heights, etc. It may occur from powerful muscular contractions when a horse is cast, or falls in a loose-box, and cannot easily regain its feet; while suddenly pulling up during a gallop in a hilly field occasionally causes it in saddle-horses. Paralysis of the hindquarters, with loss of sensation, and often local sweating behind the injury, are signs of fracture, in addition to severe shock, occasioned by the laceration of the cord. (See also FRACTURES; PARAPLEGIA; PARALYSIS.)

Concussion of the cord, occasioned by factors similar to but milder than those which cause fracture, is also common. Generally speaking, if the onset of the signs of paralysis occurs a day or two after the accident, instead of at the time, concussion, with or without haemorrhage, should be suspected, and recovery can usually be hoped for. (See also HORSES, BACK TROUBLES IN.)

Intervertebral disc protrusion Each intervertebral disc, which has a soft, pulpy centre and a fibrous or gristly outer ring, acts as a shock-absorber between the vertebrae, and supports the spinal cord between them. The nature of the usual disc injury is one of partial or complete rupture, with compression of the spinal cord to a lesser or greater extent. The injury is most common in BEAGLES, DACHSHUNDS, PEKINGESE, SCOTTISH TERRIERS, SEALYHAMS, SHIH TZUS and spaniels. It also occurs in cats.



The cause would appear to be a gradual wear of the disc with age, and perhaps the extra strain on the spine which may be imposed upon the short-legged breeds. In some cases there is no history of violence; in others, a sudden muscular effort, e.g. in jumping to catch a ball, is the cause.

Signs consist of pain and weakness or paralysis of the hindquarters, and may appear shortly after the dog has been observed to jump, slip, or fall; or they may appear in cases where the owner has not observed any violent movement whatsoever: for example, a dog apparently normal at night may be found paralysed in the morning.

The muscles which control the passage of urine and faeces may become paralysed.

In uncomplicated cases, natural recovery may take place within a fortnight. Where paralysis persists, the outlook becomes progressively less

VetBooks.ir

Intervertebral disc lesions.

hopeful, though a complete recovery after 12 months is not unknown. It is essential that veterinary attention is given as soon as possible. In very early cases an intravenous injection of methylprednisolone can be effective in reducing the body's reaction to spinal compression and speed recovery.

Paralysis due to a ruptured intervertebral disc.

A 'fenestration' operation is occasionally performed to reduce pain by relieving pressure upon the spinal cord, but it is not of much use for paralysis. Other measures are for the treatment of paralysis generally. (See also INTERVERTEBRAL DISC PROTRUSION.)

Cervical spondylopathy (or 'WOBBLER' SYNDROME) is most commonly seen in the GREAT DANE but occurs in other breeds, especially the DOBERMANN and OLD ENGLISH SHEEPDOGS. The problem is also called CERVICAL SPONDYLOLISTHESIS. It is usually first seen between eight and 12 months, and the clinical signs include hind-limb incoordination, abduction of the limbs, a prancing gait, and dragging of the feet causing wearing of the toe nails. Diagnosis of cervical spondylopathy is confirmed by radiography. Lesions include stenosis of the vertebral canal, exostosis of the articular facets, and subluxation.

Hemivertebra 'Wedge-shaped' vertebra; in many cases this condition in dogs gives rise to no obvious signs, but in others the condition is characterised clinically by progressive hind-leg weakness, spinal pain, abnormalities of the nervous system and evidence of muscle atrophy or other abnormalities of conformation. Confirmation of the clinical diagnosis is by radiography. Breed

incidences are reported. The occurrence of the disorder in certain families of dogs suggests also that it may be hereditary.

Ankylosis of the vertebrae is not rare in horses. It originates from diffuse inflammation of the spinal column, frequently due to rheumatic causes, and one after another of the vertebrae becomes fused to its neighbour in front or behind. In severe cases practically the whole of the thoracic and lumbar regions of the horse may fuse into a rigid bar. Such horses usually can perform straightforward work for some time, but are unable to carry any weight, to back heavy loads, or to lie down or rise with ease. They may develop into 'shiverers', but so long as the spinal cord is not compressed, they may live for years.

Pachymeningitis, or inflammation of the membranes of the cord (perimeningitis), sometimes occurs in old dogs. It is called 'ossifying pachymeningitis' in these animals, because of the tendency for bone to be deposited in the dura mater.

Abscess in the cord, or in one of the vertebrae, may be discovered only at a knackery or at autopsy; or it may lead to signs of paresis/paralysis. (See also ABSCESS; SPINA BIFIDA, SYRINGOMYELIA.)

Spinone Dogs
(See ITALIAN SPINONE DOGS.)

Spinosad
A compound produced by a fungus and is highly active topically and by ingestion against several arthropods including FLEAS.

Spirillum
A bacterium with a wavy shape. (See RAT-BITE FEVER.)

S

Spirit
(See ALCOHOL POISONING; and SURGICAL SPIRIT.)

Spirocerca
Worms which are found in nodules on the oesophagus. In the dog they may sometimes give rise to cancer (sarcoma) of the oesophagus; and also to fatal haemorrhage. (See ROUNDWORMS.)

Spirochaetal Colitis in Pigs
A condition caused by *Brachyspira pilosicoli*. The signs are transient to persistent diarrhoea, resulting in decreased performance and a lack of uniformity in commercial pigs. The organism is seen in a variety of hosts including humans, dogs, domestic and wild birds. It is often found as a mixed infection with *Lawsonia intracellularis*. (See also PORCINE ULCERATIVE SPIROCHAETOSIS and SWINE DYSENTERY.)

Spirochaetal Enteritis of Poultry
This can be caused by *Brachyspira pilosicoli* or *B. alvinipulli*, both of which result in mild inflammation of the caeca. *B. intermedia* gives rise to moderate inflammation and more erosion of the epithelial surface.

Clinical signs can be an increase in soft droppings and frothy droppings with soiling of eggs, a drop in egg production (up to 12 per cent), egg weight and body weight. There may be an increase in mortality due to complications. Tiamulin alone, or in combination with chlortetracycline are the most effective treatments. The earlier the problem is spotted, the less the damage done. Cleaning and disinfection of the environment is essential in control; it is very difficult to treat and control in free-range flocks.

Spirochaete, Spirochete (US) (adjective, Spirochaetal)
Spirochaete is one of the names applied to bacteria possessing a more or less spiral or wavy outline. Another term applied to this group is 'spirillum'. There are three genera which are important causal agents of disease: *Borrelia, Treponema*, and *Leptospira*. The first has large wavy spirals and is flexible, the second has regular rigid spirals, while the last has small spirals and one hook-like end.

Many spirochaetes produce disease in man and animals, the best known among which is *T. pallida*, the cause of syphilis in man. *T. cuniculi* in rabbits causes 'rabbit syphilis', in Britain, on the continent of Europe and in America. *B. galinarum* is responsible for a form of spirochaetosis affecting fowls in the tropics and subtropics, and is transmitted by the fowl tick. *L. canicola* causes nephritis in dogs and canicola fever in man; *L. icterohaemorrhagiae* causes Weil's disease in man and jaundice in dogs. Leptospirosis also occurs in cattle and pigs, and there are many serotypes. (See LEPTOSPIROSIS and, for infection with *Treponema* in pigs, SWINE DYSENTERY.)

Spirochaetosis of Fowls
Spirochaetosis of fowls is met with in Africa, Asia, the West Indies, South America, Australia, and Europe. It occurs in fowls, ducks, geese, and turkeys. Canaries and other birds are susceptible to artificial infection.

Transmission The disease is transmitted from diseased to healthy fowls by the fowl tick *Argas persicus*, one of the most important parasites of poultry. The ticks are very active at night, and may travel long distances to reach a host. They remain hidden during the day in crevices and underneath

VetBooks.ir

the bark of trees. Myriads of these ticks may attack fowls on the roost, a large quantity of blood being sucked – the affected birds becoming weak and unthrifty and having ragged plumage.

If, however, the ticks have fed on a bird affected with spirochaetosis, they become carriers of this disease and may transmit the infection through the egg to the next generation of ticks.

Signs Affected fowls show diarrhoea, loss of appetite, loss of power of the head, and may die in convulsions. A more chronic course is also described, birds becoming paralysed and emaciated, and dying in about a fortnight.

Treatment Antibiotics are effective.

Preventive Treatment This consists of ridding the premises of ticks.

Spirochaetosis of Pigs

(See under PORCINE ULCERATIVE SPIROCHAETOSIS and SWINE DYSENTERY.)

Spiroindoles

A fifth class (purple class) of ANTHELMINTICS containing DERQUANTEL which is currently used in combination with ABAMECTIN to treat and control roundworms and lungworms in sheep by inhibiting protein synthesis. Some are antimalarial drugs.

Spirometra

A tapeworm which infects cats, dogs, and occasionally people.

Spironolactone

A licensed medicine for the treatment of congestive heart failure caused by valvular regurgitation in dogs. It may be used in conjunction with a diuretic. Spironolactone and its metabolites act by inhibiting aldosterone by binding to the mineralocorticoid receptors in the heart, kidneys and blood vessels. It delays the excretion of digoxin; its use in patients receiving both medicines has to be carefully monitored. If used with potassium-sparing drugs it can result in hyperkalaemia.

Splanchnic

Splanchnic means relating to the viscera (internal organs) of the body – as distinguished from its framework.

Splayleg, Congenital

Congenital splayleg of piglets may involve either the fore-legs or all four legs. Recovery from this defect can be expected if the piglet can manage to keep out of the sow's way. (See VITAMINS - VITAMIN E.)

In birds, splayleg can be found in newly-hatched chicks/poults that have been given too much room in the hatcher compartment of the incubator.

Splayleg, Inherited

This occurs in the rabbit. There is no adequate treatment.

Spleen

A lymphoid organ found in the abdomen and is attached to the stomach. It contains white pulp which is like a large lymph node detecting new antigens and producing B and T lymphocytes to counteract them. The red pulp is a reservoir of MACROPHAGES, MEGAKARYOCYTES (produce blood platelets) and white blood cells. It conditions ERYTHROCYTES, and stores up to 20 per cent of the body's red blood cells and up to 30 per cent of the body's BLOOD platelets as well as undertaking extramedullary blood cell formation.

Structure Beneath the outermost covering of peritoneum lies the dense fibrous-tissue coat, from the inner surface of which numerous strands or 'trabeculae' run into the organ. The fibrous coat and the trabeculae possess elastic fibres and plain muscular fibres. The trabeculae branch and rebranch throughout the substance of the organ, and in the meshes so-formed lies the spleen-pulp. This consists of delicate connective-tissue fibres passing between the trabeculae, and numbers of leukocytes and red blood corpuscles. Blood vessels run through the trabeculae and end in sinusoids containing Malpighian bodies.

Functions The spleen destroys old red blood cells, acts as a blood store, and appears to play some part in the formation of lymphocytes.

An animal is able to survive after removal of the spleen. There is a compensatory increase in the lymph nodes all over the body, and, after a period of adjustment, life continues normally.

The spleen is apparently concerned also with bodily defence, and resistance to liver-fluke infestation is reduced after removal of a sheep's spleen. (See RETICULO-ENDOTHELIAL SYSTEM.)

Spleen, Diseases of

It is often only at post-mortem examination that spleen diseases are revealed in the large animals. In ANTHRAX it becomes greatly enlarged, and also in BABESIOSIS. In the dog, splenectomy is occasionally performed in cases of tumour formation or injury. Rupture of the spleen, with resultant internal haemorrhage, occurs in small animals which have fallen from a height or have been involved in a road accident.

Splenectomy
Surgical removal of the spleen.

Splinting Materials
For the immobilisation of limbs to achieve external fixation of fractured bone, or to provide additional support for internal fixation, plaster of Paris and resin-impregnated materials are used.

For large-animal use, plaster of Paris has several disadvantages: it does not achieve its maximum strength for up to 24 hours after application, and is liable to break. The cast is often heavy and cumbersome, and will soften in contact with moisture.

A number of proprietary splinting materials are available, which offer advantages of strength, lightness and transparency to X-rays. They include: Baycast (Bayer), a polyester cotton bandage impregnated with a water-activated prepolymer resin; Scotchcast, which consists of polyurethane resin on a fibreglass bandage; Hexcelite, a thermoplastic material, stated to be easily applied and very strong.

Splints in Horses
The splint-bones are the rudimentary third and fourth metacarpals; 'splints' is the common name given to exostoses (bony outgrowths) on the splint-bones produced by inflammation. The inflammation itself may be caused by a knock or a minute fracture. They are more common in young horses and slight or severe lameness may be seen. Splint formation usually starts in the periosteum or ligament. The amount of new bone formed depends on the extent and duration of the inflammation.

The lameness disappears as the inflammation subsides. The causes include an inherited defect.

Signs Usually, lameness appears before any bony enlargement can be seen or felt, although pressure over the region of splints causes pain. This lameness usually increases with exercise. The horse may walk sound, but trots lame to a surprising extent, considering the apparently 'sound' walk. Later on, a soft putty-like swelling can be felt, and this becomes harder with time, until it can be finally recognised as bone. In knee-splint the leg is carried to the outside, and appears stiff. As a rule splints are not serious, since with rest and treatment the bony fusion becomes complete, and the horse goes sound. When they are placed high up, however, there is a danger that the new bone formation may involve the knee-joint, and when they are situated far back, so as to interfere with the tendons, they may produce permanent lameness and injury to the tendon. In a horse under six years old they should be looked upon as liable to cause future trouble, but in a horse over six years old they can be disregarded unless lameness is present.

Treatment Most mild cases require nothing further in the way of treatment than a rest from work, and later a run at grass for a fortnight or so. Topical applications of anti-inflammatory preparations or hot fomentations may help to relieve pain during the acute stage.

'Split Lip'
A common name for HARE-LIP.

Spoligotype
The DNA variation found in various types of MYCOBACTERIA within a species and is particularly used for *M. bovis* and *M. tuberculosis*. The different patterns assist in tracing from where an animal has contracted infection. (See TUBERCULOSIS.)

Spoligotyping
A method of genetic sequencing to differentiate various strains within a MYCOBACTERIUM species such as *M. bovis*. (See TUBERCULOSIS.)

Spondylitis
Inflammation (osteomyelitis) of a vertebra, due to trauma or an infection.

Spondylopathy
Disease of the vertebrae such as may cause compression of the spinal cord, disc degeneration, and narrowing of the intervertebral space.

Spondylosis
A degenerative condition or changes of the spine which can lead to ANKYLOSIS. It is diagnosed by radiography. Studies in cats showed about 39 per cent had spondylosis, increasing with age. Lesions in the lumbosacral region altered feline behaviour.

Spondylosis Deformans
A chronic condition of the vertebrae, most commonly seen in the lumbar region. It is most frequently present in old bulls, especially at artificial insemination centres, and also in older dogs. There is a degenerative arthropathy of the articular surfaces with the development of osteophytes along the ventral edge of the vertebrae. In many instances there are no clinical signs unless the new bone is damaged. If this occurs the animal may be in considerable pain and may be reluctant to rise, move their backs or serve. In dogs it is seen more in some breeds including AIREDALE TERRIERS, AMERICAN COCKER SPANIELS, BOXERS, DACHSHUNDS and GERMAN SHEPHERD DOGS.

Sponges
In modern stables it is recognised that if a contagious disease breaks out, the sponge used for a number of horses is an important factor in the spread of the disease: sponges used repeatedly can

VetBooks.ir

carry bacteria. Consequently, a piece of flannel or other material which can be boiled, or disposable cloths are generally used instead for 'quartering' (see GROOMING). A sponge used at the end of a hosepipe for udder-washing of cattle led to an outbreak of mastitis due to *Pseudomonas aeruginosa*.

Spongiform Encephalopathy

A brain condition that can be found in a variety of animals besides classical SCRAPIE in sheep, BOVINE SPONGIFORM ENCEPHALOPATHY (BSE) in cattle and human CREUTZFELDT-JAKOB DISEASE (see SPONGIFORM ENCEPHALOPATHY (HUMAN)). Other animals affected with these conditions include the cat (FELINE SPONGIFORM ENCEPHALOPATHY), North American mink and ferrets. In the Egyptian Mau cat breed it is thought to occur as an inherited condition or as the result of exposure to certain toxins. Clinical signs appear from a few weeks to a few months of age and consist of pelvic limb ataxia, seizures, HYPERMETRIA followed by depression.

Spongiform Encephalopathy (Human)

The human spongiform encephalopathies – Creutzfeldt-Jakob disease (CJD), Gerstmann-Straussler-Scheinker syndrome (GSS) and kuru – are pathologically very similar to scrapie in sheep and to bovine spongiform encephalopathy (BSE). Like them, they are transmissible, although there is very little evidence of person to person transmission, except in a very few iatrogenic cases, such as the grafting of corneal or dura mater tissues from donors subsequently shown to have had CJD, and the use of human growth hormone prepared from the pituitary glands of patients dying with CJD. Kuru was transmitted by cannibalism in Papua New Guinea.

(See also BOVINE SPONGIFORM ENCEPHALOPATHY; FELINE SPONGIFORM ENCEPHALOPATHY.)

'Spooky' Behaviour

This can occur in any mammalian species. It can follow an unpleasant experience, or result from a condition such as CORPORA NIGRA, which are found in the eyes of horses, cattle goats and alpacas.

Sporadic Disease

A sporadic disease is a disease occurring in single cases here and there, as distinct from disease occurring as an enzootic, throughout a district, or epizootic, through a country or large tract of land.

Spores

Reproductive cells of protozoa, bacteria, and fungi, etc., usually able to withstand an adverse environment.

Sporidesmin

A poisonous substance, isolated from the fungus *Pithomyces chartarum*, which causes facial eczema and liver damage in sheep and cattle in New Zealand and Australia.

Sporotrichosis

A fungal disease of horses, cattle, dogs, cats and man, caused by *Sporothrix schenckii*. This gives rise to nodules under the skin, and thickening of the lymphatics with ulceration. In the dog, liver, lungs and bone may show lesions. Of 19 people reported to have acquired this infection from cats, 14 had no history of traumatic injury at the site; 12 were veterinarians or assistants/nurses. All had a localised cutaneous lymph-node infection, lesions resolving in one to 10 months after potassium iodide treatment. One patient had a deep ulcer on a finger. Although rare, infection through inhalation has been recorded in people.

Sporozoa

This is a group of Protozoa which are all parasitic and produce spores at some stage of their life-cycle. It is divided into a number of orders, of which only two are important. These are the Haemosporidia which are parasites of the red blood cells, and the Coccidia which are parasites of epithelia.

'Spot-On' Preparations

These are commonly used as a method of controlling ECTOPARASITES in sheep, dogs and cats. They need to be applied at the site directed, and must be used as indicated by the manufacturers. They tend to be in oily bases and so can cause marks on fabrics and furniture for about 24 hours after application.

Spotted Fever

(See ROCKY MOUNTAIN FEVER.)

Spotted Horse

(See under APPALOOSA.)

spp.

Abbreviation for species, usually more than one species.

Sprained Tendons

Sprained tendons is an extremely common condition in both the heavy and the light draught horse. The flexors, superficial and deep, are mostly affected.

Causes The superficial flexor tendon is sprained during maximum weight-bearing by the limb, and the deep flexor becomes sprained at the period of thrust.

Signs There are the usual signs of inflammation – heat, pain, swelling. A horse with a badly sprained deep flexor may walk almost sound, but goes pronouncedly lame when made to trot. A localised sprain of the check ligament and its insertion into the deep flexor tendon often produces acute lameness, but the condition is not as serious as a sprain of the tendons lower down. From an owner's point of view, however, differential diagnosis between the various forms and situations of sprain is not important.

Treatment A firm elastic support bandage, and adequate rest. A poultice, spread on cotton-wool and applied hot, before bandaging, is a traditional remedy.

Generally a horse with a badly sprained tendon is not fit for work for a month to six weeks, although it may be apparently sound before this time.

Chronic sprained tendons are often incurable, but good results have sometimes been obtained with DIATHERMY.

Sprains

Sprains involve the wrenching of a joint, often with the simultaneous tearing of a ligament. The term is also applied to an inflammation of a tendon, generally the result of an excessive stretching of its fibres. (See SPRAINED TENDONS; SYNOVITIS.)

Spray 'Drift'

By this is meant droplets of spray liquid carried by the wind to fields adjacent to that which is being intentionally sprayed with some farm chemical for purposes of weed control, pest control, haulm destruction. It is a potential cause of poisoning in grazing animals. The fine powder arising, for example, when fields are limed can also cause drift. Such drift onto a field grazed by cattle can result in burning of the mouth lining with signs similar to FOOT-AND-MOUTH DISEASE. (See SPRAYS USED ON CROPS.)

Spray Race

A race which can be used for spraying sheep or cattle. Nozzles are arranged at intervals and fed with suitable parasiticide liquid by means of a pump. The system has not been found as satisfactory as dipping for sheep scab.

Sprays used on Crops

Sprays used on crops include weedkillers such as DNOC, insecticides such as parathion, and potato-haulm destroyer such as arsenites. Such substances constitute a hazard to livestock which gain entry into fields. (See POISONING; INSECTICIDES; WEEDKILLERS.

'Spreading Factor'

(See HYALURONIDASE.)

Springer Spaniel Dogs

(See ENGLISH SPRINGER SPANIEL.)

Spring Viraemia of Carp

A serious viral disease to which farmed or ornamental fish are particularly susceptible. It is transmitted by lice which parasitise carp. Clinical signs vary, but affected fish swim erratically, may be swollen, and have small red spots on the skin. It is a NOTIFIABLE DISEASE.

Sprocker Spaniels

A common first cross (HYBRID) between the SPRINGER SPANIEL and COCKER SPANIEL; an example of a MONGEE.

Spur

This is seen in some birds including some poultry breeds, It is an outgrowth from the TARSOMETATARSUS BONE (the bird's lower shank), and is the remnants of the fifth toe which is covered in a sheath of horn. It can be used in fighting.

Spurges, Poisoning by

The various species of spurges (*Euphorbia* spp.) are, apparently, mostly poisonous, though not to the same extent. Animals are not likely to eat them because of the acrid milky sap. Species which have been blamed for causing poisoning are as follows: caper spurge, *E. lathyris*; Irish spurge, *E. hibernica*; petty spurge, *E. peplus*; and the sun spurge, *E. helioscopia*. Of these, the first seems to be the most dangerous.

Signs Inflammation and swelling of the mucous membranes of the mouth and tongue, pains in the abdomen, coldness of the extremities of the body, dizziness, fainting, leading to unconsciousness and death in two or three days. In one of the South African spurges, *E. genistoides*, the typical sign, in addition to these mentioned here, is an acute inflammation of the urethra, accompanied by frequent and painful attempts at urination. Signs of acute enteritis may also be seen.

Treatment Veterinary advice should be sought at once and, since the milk of affected cows may cause illness to people drinking it, it should not be used for either human or animal consumption.

SRM (Specified Risk Material) In the case of bovines, for animals aged 12 months or more this is the skull including brain, eyes, tonsils and spinal cord. For bovines over 6 months, the spleen, thymus and intestines are also included. SRM must be stained to prevent its consumption and destroyed by incineration or rendering. For sheep and goats older than 12 months, SRM includes

the skull, including brain, eyes, tonsils and spinal cord; the spleen of any age of sheep or goat is included. The tongue is exempt, provided it is removed immediately after slaughter.

VetBooks.ir

Spur Veins
The veins liable to damage by the horseman's spurs.

SQP (Suitably Qualified Person)
Under the Veterinary Medicines Regulations, Suitably Qualified Persons (SQP) were authorised to supply medicines in the category NFA-VPS (Non Food Animal – Veterinarian, Pharmacist, Suitably Qualified Person) and POM-VPS (a medicine for food-producing animals (including horses) to be supplied only on veterinary prescription, which must be prescribed by a veterinarian, pharmacist or SQP (either orally or in writing) and which must be supplied by one of these three groups of people in accordance with the prescription).

Squames
Scales or scale-like masses.

Squamous
Scaly or plate-like.

'Squint'
(See STRABISMUS.)

Squirrels
The native red squirrel (*Sciurus vulgaris*) of Great Britain and Ireland has been partly reduced in numbers by the introduction of the North American eastern grey squirrel (*Sciurus carolinensis*). The grey squirrel carries the squirrelpox virus – also called squirrel fibroma - without apparent illness, but it causes high mortality in red squirrels with multiple tumour formation. Adenoviruses can cause sporadic or group mortality mainly in wild and captive red squirrel populations, and are often also present with other infections. The intestines are inflamed.

SRM (Specified Risk Material)
In the case of bovines, for all ages, tonsils, intestines from duodenum to rectum and the mesentery. For animals aged 12 months or more this is the skull including brain, eyes, tonsils and spinal cord. For bovines over six months, the spleen, thymus and intestines are also included. For bovines over 30 months the vertebral column including dorsal root ganglia except the tail SRM must be stained to prevent its consumption and destroyed by incineration or rendering. For sheep and goats older than 12 months, SRM includes the skull, including brain, eyes, tonsils and spinal cord; the spleen and ileum of any age of sheep or goat is included. The tongue is exempt, provided it is removed immediately after slaughter.

SRUC
(See SCOTLAND'S RURAL COLLEGE.)

SSPCA
(See SCOTTISH SOCIETY FOR THE PREVENTION OF CRUELTY TO ANIMALS.)

'Stable Cough'
(See EQUINE INFLUENZA.)

Stable Fly
Stable fly is a serious pest to horses and other animals, and transmits diseases such as surra and anthrax in the tropics. (See FLIES - FLY CONTROL MEASURES; SUMMER SORES.)

Stables for Racehorses
A survey of 96 racehorse stables in the southwest of England showed that a 'typical' racehorse is kept in a loose-box with a floor area of 12 m^2 and is bedded on straw; it shares its airspace of 39 m^3 with seven other horses. In calm conditions, with the top door of the stable open, natural convection would provide 6.6 air changes/hour, but with the door closed, only 2.2 changes. The top door should rarely, if ever, be closed. It has been suggested that present-day stables are based on designs which are worse than the best available in the 19th century. (See also BEDDING AND BEDDING MATERIALS.)

Stable Vices And Tricks
(See 'VICES' AND VICIOUSNESS.)

Staffordshire Bull Terrier
A medium-sized muscular breed with a smooth coat, often mainly white. CATARACT (DNA test available) may be inherited and the breed is prone to CLEFT PALATE. DEMODECTIC MANGE is quite common in the breed. L-2-HYDROXYGLUTARIC ACIDURIA (DNA test available) also occurs. The AMERICAN PIT BULL TERRIER was derived from the Staffordshire, which it resembles; it is advisable to keep a pedigree record to avoid confusion and impounding under the Dangerous Dogs Act.

Stag
In deer, it is a male of some species; the female of those species is always called a hind and the young, calves. It is also the British term for a male turkey.

Staggers
Erratic gait caused by incoordination of the limbs, as in 'rye-grass staggers'. It may be seen in hypomagnesaemia.

'Staggers Weed'
A poisonous South African plant. (See 'PUSHING DISEASE'.)

VetBooks.ir

Staining
For differentiation of bacteria, see ACID-FAST ORGANISMS; GRAM-NEGATIVE.

Stallion
An adult male horse, uncastrated, over 4 years old.

Standard
In animals that are pedigree, 'standard' can refer to the definition of a particular breed. It can also in dogs and some other species mean the original size of the breed. Some may then develop larger (giant) or smaller (miniature, toy) sizes.

Standard Agglutination Test
(See SERUM AGGLUTINATION TEST.)

Standardbred Horses
These were first bred in America in the 18th century to trot at fast speeds. They had to be able to trot one mile in two and a half minutes, which was the 'Standard'. Now, many animals can trot a mile in under two minutes. They are more muscled and longer than a thoroughbred. They are normally bay and very quiet, good-tempered animals.

Standard International Units
(See SI UNITS.)

Staphylococcosis
The disease caused by *Staphylococcus* spp. In many cases the lesions are superficial, with DERMATITIS in dogs and MASTITIS in cattle and other animals. The condition can become SYSTEMIC and as such is often seen as the first presentation to the clinician in small animals (e.g. RABBITS) and in cage-birds.

Staphylococcus
(plural, Staphylococci; adjective, Staphylococcal)
(See BACTERIA.)

S

Staphylococcus aureus
The organism is found particularly on the surface of animals. It can cause skin infections, septicaemias and MASTITIS. (See MRSA.)

Staphylococcus intermedius
This form of staphylococcus was thought to be common on the skins of companion animals, but new classification methods show it to be uncommon. It is closely related to S. *pseudointermedius* which is considered to be a common skin inhabitant.

Staphylococcus pseudointermedius
This is often found on the skin and is usually non-pathogenic. It has been found in the cat (lungs), dog, horse and parrot. (See MRSP.)

Staphyloschisis
A cleft palate; a fissure of the UVULA.

Staples for Wound Closure
These have long been used in human surgery in place of stitches and are also used as wound closures in some types of surgery for animals.

The advantages of the use of staples in veterinary surgery is the speed of their application and removal. Removal requires a special instrument. Some species such as sub-human primates, rabbits and parrots are adept at their removal. In these species, subcuticular SUTURES are preferred.

Starch
A group of carbohydrates that may vary depending on the source in the feed. Depending on the type of starch in the diet, the site of digestion in the intestine will vary. It used to be considered that all starch was completely digested, but this may not be so, especially in young animals. Starch digested in the upper part of the small intestine results in a shorter insulin response, whereas digestion in the lower half of the small intestine results in better performance by the animal. The slow digestion of starch has a protein-sparing effect in the animal. Steam-pelleted starches give higher rates of digestion. Rapidly-digested starches fed to chickens increased the number of clostridial organisms in the caeca.

(See CARBOHYDRATE; DIET AND DIETETICS; DIGESTION, ABSORPTION AND ASSIMILATION.)

Starch Equivalent
This term is no longer used, and the starch equivalent in the UK was replaced in 1975 by units of METABOLISABLE ENERGY as part of the introduction of metric and SI UNITS.

Starch Gel Electrophoresis
This is one of the commonest techniques for studying the genetic variation in serum proteins. (See ELECTROPHORESIS.)

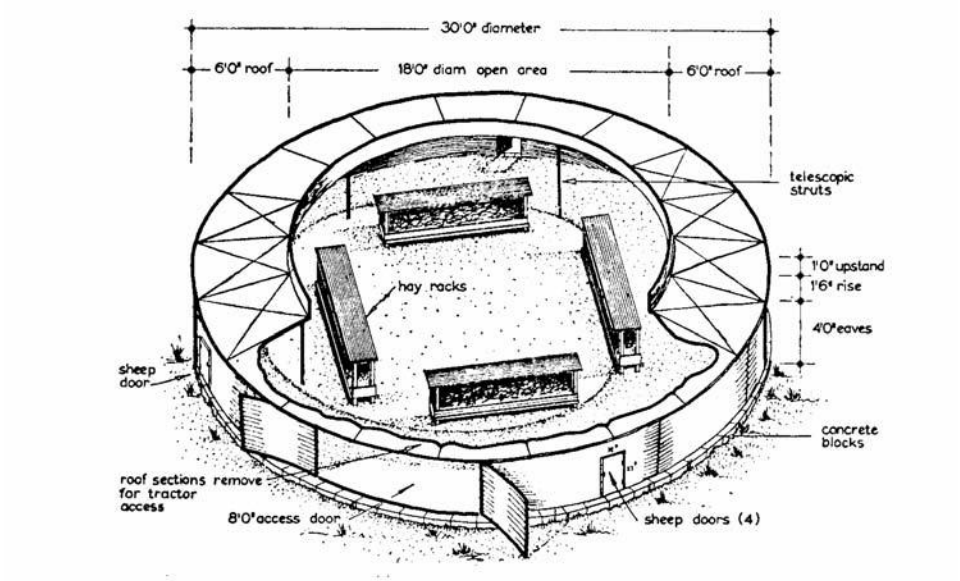
Stargazer
The term applied to a newly hatched chick or poult where the head is permanently held back with the beak pointing directly upwards. Affected birds may twist their heads continuously. The cause is a deficiency of thiamine.

Staring Coat
Dry, dull, scurvy hair or fur. A common sign of poor condition of whatever cause. In the dog, one cause is lack of suitable fat in the diet. As a first-aid measure, offer bread and butter or dripping (but not margarine) for a few days as an 'extra'. It is seen in, e.g., cattle, often as the result of parasitic gastroenteritis. (See also under WORMS.)

Starvation
The lack of sufficient quantities of feed to maintain an animal. It results in signs of hunger, loss of weight, reduction in milk yield, loss of fat and then of muscle, often rapid. The faeces reduce and drinking stops. The animal becomes weak; the skin becomes tight without dehydration. The animal shows signs of emaciation and may eventually die. Often the blood biochemical parameters are within the normal range.

Stasis
Stasis is a term applied to stoppage of the flow of blood in the vessels or of the food materials in the intestinal canal.

Statutory Instruments
These are secondary or subsidiary legislation taken out to support Acts of Parliament. They are passed by the British Parliament for England and the devolved authorities. They are Orders, Regulations, or Legislative and Reform Orders.



'Steaming up'
A term used by dairy farmers to describe the practice of feeding a concentrates ration 4 to 5 weeks before calving in order to provide for growth of the fetus and provide reserves against the onset of lactation. Nowadays, it is generally considered that 'steaming up' is not to be encouraged as it tends to lead to poor dry matter intakes after calving, and fatty liver and acetonaemia. Usually, the aim is to provide small quantities (3 kg to 5 kg; 6½ lb to 11 lb dry matter) of the production ration in a complete diet for about 2 weeks prior to calving. Concentrate should not usually be fed at more than 2 kg to 3 kg (4½ lb to 6½ lb) daily in two feeds for a similar period. For detailed advice on 'steaming up', see under ACETONAEMIA Prevention.

Excessive 'steaming up' is regarded as one cause of LAMINITIS and lameness.

Steatitis
A yellow discoloration of fat occurring in cats, mink and pigs fed mainly on fish scraps or tinned fish. Listlessness, tenderness over the back and abdomen and a reluctance to move are observed. In cats, steatitis may follow prolonged and continuous feeding not only with red tuna or pilchards, but also with white fish such as coley. The signs include stiffness and pain. Steatitis in horses has also been reported. Pathological changes in the fat taken from the abdominal wall was found in 44 of 173 horses and ponies examined post-mortem at the Institute of Veterinary Pathology, Utrecht, over a two-year period. Steatitis was found in fetuses from normal mares, and in adult horses. Subclinical steatitis was the most common type, but a few deaths were attributed to this cause. Lesions varied from the presence of macrophages in the fat, to some fibrosis in addition, and to necrosis.

Treatment includes a change of diet and a vitamin E supplement.

Steatorrhea
Fatty faeces.

Of metal construction, on a base of concrete blocks, this modified stell at the Rowett Research Institute, Aberdeenshire, was designed by Dr E. Cresswell. Sheep doors and a doorway for tractor access are shown.

VetBooks.ir

VetBooks.ir

Stell
A circular stone or corrugated metal shelter for sheep or cattle, built on moorland or hill, and affording good protection against snow drifts. Stells were in use in the early 19th century, if not earlier. (See illustration on previous page.)

Stenosis
Stenosis is any unnatural narrowing of a passage or orifice of the body. It is often applied to the heart valves (mitral stenosis), and to the opening through the larynx – the glottis – but is applied to any of the large arteries (aortic stenosis), as well as to the parotid ducts and the stomach's pyloric sphincter (pyloric stenosis). (See HEART DISEASES; LARYNX; PAROTID GLAND; PYLORIC STENOSIS.)

Stenotic
An unnatural narrowing of a passage or orifice.

Stenson's Duct
Stenson's duct is the duct which carries saliva from the parotid gland into the mouth. (See PAROTID GLAND.)

Stent
A device used to support or to keep in place a skin graft or other surgical suture. Stents woven in the form of a tubular mesh from surgical-grade stainless steel, and self-expanding when released from a small-diameter delivery catheter, were developed for endovascular use, but are also used to relieve urethral stricture in human patients.

Stephanofilariasis
A chronic skin disease occurring in cattle in parts of the USA, and caused by the nematode worm *Stephanofilaria stilesi*. The intermediate host is the horn fly.

Stephanurus dentatus
(See KIDNEY WORM.)

Sterculia
A bulk-promoting agent which absorbs up to 60 times its own mass of water. When given by mouth, it promotes peristalsis and relieves constipation in small animals. It is otherwise inert. It is used in management of anal sac infection in dogs.

Sterilisation
(See CASTRATION; also SPAYING for sterilisation in the sexual sense.)

With reference to sterilisation in its other sense, see DISINFECTION; ANTISEPTICS; ASEPSIS; WOUNDS. For most general purposes the best sterilising agent is boiling water. Boiling should be continuous and should last for 30 minutes in order to kill vegetative bacteria, viruses, and most other types of micro-organisms. Surgical instruments and dressings are usually sterilised in an autoclave which reaches temperatures in excess of 100° C (212° F).

Sternum
The breastbone. This forms the floor of the chest (in quadrupeds), provides attachment for the pectoral muscles, and for the costal cartilages of the sternal (true) ribs. (The asternal (false) ribs are not directly connected to the sternum.) The sternum comprises sternebrae – segments which fuse together with advancing age. The horse and dog each have eight of these; the cow seven; pig and sheep, six.

Steroids
Chemical substances closely related to the sterols, e.g. the sex hormones, hormones of the adrenal cortex, bile acids. (See also CORTICOSTEROIDS; DIABETES MELLITUS.)

Prescribing steroid hormone products (where allowed) Steroid hormone growth promoters are substances with an androgenic, oestrogenic or gestagenic action. In general they must not be administered to farm animals. 'Farm animals' includes cattle, sheep, pigs, goats, horses, poultry, the wild animals of these species and any ruminants raised on a holding.

The prohibition does not apply to:

(a) the administration for therapeutic treatment by a veterinarian in the form of an injection of oestradiol-17-beta, progesterone or testosterone or derivatives of these substances which readily yield the parent compound on hydrolysis after absorption at the site of application;
(b) the administration of a steroid hormone product for the termination of unwanted gestation or the improvement of fertility;
(c) the administration of a steroid hormone product by, or under the direct responsibility of, a veterinarian for the synchronisation of oestrus or the preparation of donors or recipients for the implantation of embryos.

For the purposes of the controlling regulation, the term 'injection' does not include implantation and the term 'therapeutic treatment' has a very restricted meaning – i.e. the treatment of a fertility problem diagnosed by a veterinarian in an animal not intended for fattening.

A small range of products is licensed in the UK for the purposes listed above. **The regulations are subject to change; the current status of hormonal products should be checked.**

VetBooks.ir

Sterols
Solid alcohols, waxy substances derived from animal (and plant) tissues, e.g. cholesterol, ergosterol.

Stertor
Noisy breathing resembling snoring.

Stethoscope
An instrument invented in 1816 used to listen to sounds within the body such as heart, lung and alimentary tract. It is also used in humans when taking blood pressure. In human medicine it is being superseded by ultrasound monitors.

STH
(See SOMATOTROPIN.)

Sticking
The name used for cutting the throat of an animal in the slaughterhouse once stunned.

Stick Insects
Slow-moving green or brown insects that resemble twigs, often kept as 'pets'. They are vegetarian and must have fresh food that is not allowed to wilt. Hygiene is important in their care.

'Sticky Ends'
A term used to describe DNA sections. Usually a part of a strand of DNA has three 'sticky ends' at one extremity and two 'sticky ends' at the other. This ensures that any added DNA is correctly aligned.

Stiff Lamb Disease
This is a mild disease occurring in East Anglia due to infection with *Erysipelothrix rhusiopathiae*, the cause of swine erysipelas. The same name is also applied to muscular dystrophy, a condition similar to that occurring in cattle as a result of vitamin E deficiency.

'Stiff-Limbed Lambs'
This is a hereditary condition affecting newly born lambs, to which the name *Myodystrophia fetalis deformans* has been given. It is commoner among Welsh Mountain sheep than among other breeds. The condition is an arrest of the development of muscular tissue during fetal life, and a replacement by fibrous tissue. This contracts and pulls the limb into an unnatural, stiff attitude, and gives rise to difficulty in parturition.

The condition is a Mendelian recessive lethal. It has been reported from Britain and America as affecting cattle, but it is not at all common in them.

Stiff Sickness
(See STYFZIEKTE.)

Stifle
The joint corresponding to the human knee (see BONES and JOINTS). In horses, stifle lameness is often the result of OSTEOCHONDRITIS DISSECANS or of subchondral bone cysts.

In 42 cases of stifle lameness in cattle, the diagnoses included subchondral bone cysts (18 cases), joint instability (15), degenerative joint disease (12), cranial cruciate ligament injury (9), sepsis (9), collateral ligament injury (3), femorotibial luxation (2) and intra-articular fracture (2). The prognosis for animals with bone cysts was good, irrespective of treatment (75 per cent recovered), while it was much poorer for animals with sepsis (22 per cent) or joint instability (27 per cent).

In the dog, indications for surgery of the stifle are congenital medial luxation and rupture of the anterior cruciate ligament.

Stilbenes
Substances consisting wholly or partly of stilboestrol, hexoestrol, dienoestrol, or benzestrol. (See HORMONES IN MEAT PRODUCTION.)

In accordance with an EU directive, the sale of veterinary medicines, veterinary products or animal feeds containing these stilbenes was banned in 1982 in the UK for use in food animals.

An exemption allows the limited use of stilbenes in companion animals for treating enlarged prostate glands and anal adenoma in dogs, MISALLIANCE in the bitch, and urinary incontinence in spayed bitches.

Stilboestrol
A synthetic oestrogen formerly used both therapeutically and as a growth promoter in food animals. Such use is now illegal. (See HORMONES; HORMONE THERAPY; HORMONES IN MEAT PRODUCTION; STILBENES.)

Stillborn Pigs
Breeding stock should, of course, have access to pasture, but if for any reason this golden rule is going to be broken, then rations should be supplemented in summer as well as in winter, with vitamin A. In a group of 20 gilts which were suddenly switched from succulent feeding to dry, fibrous grazing late in pregnancy, severe constipation resulted, and there were dead piglets in 19 of the litters.

A survey carried out by the Veterinary Investigation Service in England and Wales showed a 4.8 per cent incidence of stillbirths out of a total of 4,394 piglets born in 371 litters. The incidence varied widely from herd to herd, as would be expected – ranging from 0.4 per cent to 12.9 per cent. Constipation appears to be a cause of stillbirths and SENNA may be used.

VetBooks.ir

There are several infections which give rise to abortion and stillbirths. (See AUJESZKY'S DISEASE; ABORTION; MUMMIFICATION OF FETUS; INFERTILITY; CARBON MONOXIDE.)

Stimulants

Heart 'stimulants' include caffeine, digitalis, etc. (See also RESPIRATORY STIMULANTS.)

Stings

(See BITES, STINGS AND POISONED WOUNDS.)

Stirk

A young female bovine of six to 12 months old, sometimes a male of the same age, in Scotland.

Stitching

(See SUTURE; WOUNDS.)

Stockard's Disease

An inheritable flaccid posterior paralysis found in individuals of certain breeds of dog, including the ST BERNARDS.

Stocking Rates

The stocking rate is the number of animals within a given area, usually per acre or per hectare (although it can be for a field or farm). During the peak of grass growth from early April to mid-June, 8 to 10 ewes and their lambs can be carried per acre (4,000 m^2). But this is a maximum figure for this period only. For cattle, continuous grazing, the figure is perhaps 1 to 3 acres (12,100 m^2).

In Britain, 'most grass is greatly understocked during the grazing season, chiefly due to the lack of capacity to carry more stock over winter.

'Good farmers, using intensive grass-farming methods, require 1½ acres (6000 m^2) or more per cow, even when winter feeding is supplemented considerably with concentrates.

'Estimates in New Zealand have suggested that dairy cows at 1.2 per acre may consume as little as 30 per cent of the available herbage.' (Director, Grassland Research Institute, Hurley.)

Many farmers can achieve 0.8 to 1.0 acres (0.3 to 0.44 hectares) per cow without using or purchasing more than 10 to 15 per cent of their winter feed requirements other than production concentrates.

Stockmen, Stockwomen

For health hazards, see under COWHERDS; SHEPHERDS; MEAT-HANDLERS' OCCUPATIONAL HAZARDS; ZOONOSES.

Stomach

Functions of the stomach (See RUMEN; RUMINAL DIGESTION; RETICULUM; OMASUM; ABOMASUM.) Broadly speaking, the function of the stomach is to store, warm, soften, and prepare food materials, and then to pass them on in regulated amounts into the intestine, where the more important digestive processes and absorption occur.

Stomach, Diseases of

In all animals bacterial diseases, such as SALMONELLOSIS, may be involved in diseases of the stomach; likewise parasitic worms.

Horse In view of the comparatively simple arrangement of the stomach, and the natural fastidiousness of the horse in the matter of food, stomach disease is not so common as in some other animals.

Gastritis (irritation of the stomach) is usually brought about by the ingestion of irritant, poisonous, or otherwise harmful substances, or by the presence of bots, or spread of disease from other parts of the body. (See also SALMONELLOSIS; ROUNDWORMS.)

Signs In horses, attacks of violent abdominal pain, occurring shortly after feeding or even before feeding is completed, indicate that the stomach is affected. Dullness and depression are noticed; patchy sweating may break out; food is refused; the temperature rises slightly in mild cases, and to as high as 41° C (106° F) in severe instances. Usually within two to three hours after taking food the acute pain ceases, but the horse remains dull, and gives the impression that it is affected with a dull ache rather than with acute pain. Vomiting does not usually occur unless the stomach is ruptured or the oesophagus is dilated.

Impaction of the stomach is a condition in which engorgement of the stomach with food takes place. It may be due to lack of vitality (atony) in the muscular walls, to impaired gastric secretion.

Signs Signs of impaction may occur, suddenly or gradually. There is depression, uneasiness, and perhaps colic, in those cases where a horse over-eats. (See COLIC.)

Sometimes a horse obtains relief by vomiting through the nostrils a quantity of the impacted material, which reduces the amount in the stomach so that the remainder can be dealt with in the usual way.

Prevention It is easier to prevent impaction of the stomach than it is to cure it.

Whole beans, peas, wheat or barley should not be used for horses. Horses should always be allowed as much water as they desire to drink, and

VetBooks.ir

should be watered before feeding in all cases. Diseased or rough and irregular teeth should be treated.

Tympany of the stomach When vegetable food ferments from any cause, gas is produced. Certain foods, especially when unsound, undergo fermentation in the stomach instead of digestion, and the gas so formed is liable to collect in that organ, often under pressure, producing great distension. Foods which ferment easily are succulent green crops, clovers, lucerne and potatoes eaten in quantity.

Signs There is no remission of pain, such as is usually seen when the intestines are tympanitic. Horses may roll, plunge, and paw the ground during the earlier part of the attack. Respirations increase in rate and become laboured. The abdomen becomes tense and often swollen, and in many instances horses assume a crouching attitude with their hindquarters, not unlike the way in which a dog sits. When the tympany is severe, unless relief is afforded by the passage of the STOMACH-TUBE, rupture of the stomach may occur, and death follow. (See COLIC.)

Rupture of the stomach may also occur when a horse falls violently to the ground soon after a big feed, i.e. when the stomach is full.

Signs The distress characteristics of engorgement and tympany suddenly cease when the stomach ruptures, and for a short time the horse appears so much better that the owner imagines recovery will result. After a short time, however, the more serious signs of peritonitis and shock occur. Profuse perspiration usually breaks out; the pulse changes to what is called a 'running down pulse', i.e. there are a few strong beats which gradually become weaker until they are almost imperceptible, and then a succession of strong beats return; this is repeated rhythmically. Ears and feet become cold and clammy to the touch; respiration is blowing; and the expression on the face of the horse is one of anxiety. Vomiting is said to characterise rupture of the stomach, but it is probable that in most cases the vomiting occurs before the rupture takes place; the food material escapes into the abdominal cavity after rupture has occurred rather than up into the pharynx and nostrils. (See also COLIC.)

Treatment is usually regarded as useless; euthanasia is advisable.

Ulceration Gastric ulcers are common but usually with no signs. In foals and adult horses, they may be seen to affect performance. They can be treated with OMEPRAZOLE.

Cattle Acute indigestion with acidosis, and sometimes impaction of the rumen, may follow overeating of grain or green foods. (See ACIDOSIS.)

Tympany of the rumen (bloat) consists of a collection of gas in the rumen. (See under BLOAT for signs, prevention and treatment.)

Inflammation of the rumen (see also RUMEN, ULCERATION OF) may be due to ingestion of irritant poisons, of either chemical or vegetable origin, to penetrating foreign bodies, or to the spread of inflammatory conditions from other parts in specific diseases.

Foreign bodies in the reticulum are of great importance in both young and adult cattle, because of the close proximity of this organ to the pericardium and heart. In the reticulum two things may happen: they may fall to the lowermost part of the sac and remain there for an indefinite period, or they may slowly penetrate its wall and wander forwards through the diaphragm. Their subsequent course is described under HEART DISEASES Traumatic pericarditis of cattle. (See also HAIR-BALL.)

Inflammation of the abomasum, abomastitis, or gastritis, is caused by a lack of long-fibre roughage and the too-rapid introduction of concentrate diets after calving; it may also be caused by parasitic roundworms. (For the causes, signs, and treatment of parasitic gastritis in cattle and sheep, see PARASITIC GASTROENTERITIS.)

Displacement of the abomasum may be associated with stenosis of the sigmoid curve of the duodenum in cattle. The abomasum is then found to be distended with fluid and gas, and displayed to the right.

Signs include a distended abdomen, loss of appetite, loss of weight, and depression of milk yield, and may sometimes be successfully treated by casting the cow and, with her lying on her back, rotating or rocking her through an angle of 45° from the vertical each way. Surgical treatment may be necessary. (See TYMPANITIC RESONANCE IN CATTLE.)

Ulceration is a condition by no means rare in cattle. It is sometimes associated with displacement of the abomasum, and may give rise to signs a few days after calving. Death follows perforation. Signs are similar to those given above. Ulceration is not uncommon in calves after weaning, giving rise to capricious appetite and sometimes evidence of abdominal pain. *Fusiformis necrophorus*, *Arcanobacterium (Actinomyces) pyogenes*, and

Pasteurelle organisms in other parts of the body may be associated.

Sheep The diseases of the stomachs of the sheep resemble in general those of the same organs in cattle.

Braxy is characterised by a patch of acute inflammation in the wall of the abomasum, usually about the size of the palm of the hand, where the mucous membrane is to a large extent destroyed.

Another form of gastritis is due to parasitic worms in the young lambs. (See WORMS.)

Pigs

Gastritis Irritating or poisonous substances, specific disease, or parasites are among the causes. Salt poisoning is a cause of gastritis, as are also poisonings by arsenic, copper, saltpetre, sheep dips, etc. During the course of swine fever, swine erysipelas, foot-and-mouth disease, and even tuberculosis, the wall of the stomach may become involved, and inflammation may result. (See under GASTRIC ULCERS.) Parasites may also cause this condition. (See WORMS, FARM TREATMENT AGAINST; MUCORMYCOSIS.)

Signs Vomiting is the first and most important sign of stomach disturbance. Thirst, depression, and sometimes skin discoloration are other signs. Convulsions and twitching of the limbs may be seen in young pigs.

Treatment All solid foods must be withheld, and soft light foods given instead. Whole milk is one of the best. Where the condition is believed to be due to poisonous substances, the appropriate antidotes must be given. (See ANTIDOTES.)

Dogs Gastritis may be bacterial in origin, caused by parasitic worms, irritating substances which include poisons, or be associated with foreign bodies. It is probably less common than enteritis or nephritis, both of which may give rise to vomiting.

Gastritis

Causes Gastritis/gastroenteritis may be a complication of DISTEMPER, CANINE VIRAL HEPATITIS, or may arise during SALMONELLOSIS and other bacterial disease; or follow the eating of infected or decomposing food.

Ulceration of the stomach in dog and cat may be associated with gastritis – sometimes with tuberculosis, malignant growths and actinobacillosis. Ulcers similar to peptic ulcers in human beings, and leading to perforation, occur occasionally.

Signs As a rule, a severe attack of vomiting immediately after a feed and refusal to touch food subsequently. Thirst is nearly always excessive and, if gratified, vomiting usually follows.

If capillary haemorrhage occurs into the stomach, perhaps as the result of retching, the blood which slowly oozes from its walls collects in the cavity of the stomach, undergoes partial digestion, and becomes changed into a brownish granular material, strongly resembling moist coffee grounds. This always has a most foul and objectionable odour. The dog itself becomes extremely miserable, dragging itself slowly from place to place, and showing preference for cold places where it may lie stretched out with its hind-legs straight behind it, so that the lower wall of the abdomen is in close contact with the cold surface, e.g. a stone step, or linoleum in a passage. Constipation usually occurs unless the intestines become involved, when diarrhoea is noticed. Pressure on the abdomen causes pain, and sometimes a dog lifted by the hand under the abdomen cries out. The temperature is raised at first.

Treatment Hot packs applied to the abdomen soothe pain. Dogs affected with gastritis should be under the charge of a veterinary surgeon, who will vary the treatment according to the circumstances.

At first food is better withheld. (See PYLORIC STENOSIS; GLUCOSE; NORMAL SALINE; PROTEIN, HYDROLISED.)

Foreign bodies in the stomach may include pieces of carpet or other fabric, the rubber from a golf ball, the covers of tennis balls, bones, pieces of wood, etc. A depraved appetite may be due to hunger, a mineral or vitamin deficiency, rabies, or to bad habits – such as picking up and swallowing pebbles (often misguidedly thrown by the owner).

Signs Ineffectual attempts to vomit, accompanied by painful retching, an arched back, salivation from the mouth, and signs of discomfort. Sharp-pointed bodies may cause perforation of the stomach walls, peritonitis and death. (See PERITONITIS.)

In small toy dogs it is quite usual for signs of acute nervous excitement to be shown.

With chronic gastritis due to swallowed pebbles, signs are those of occasional vomiting, discomfort, and even a rattling sound as the dog walks.

First-aid An emetic, e.g. a crystal of sodium carbonate and water.

Treatment Apomorphine given by hypodermic injection will rid the stomach of the greater part of fibrous or soft ingesta, but where sharp-pointed foreign bodies have been swallowed, obviously it is

VetBooks.ir

unsafe to give emetics. To remove these and large rounded objects which cannot be easily vomited, surgery will be necessary.

Torsion of the stomach Except in the giant breeds of dogs, torsion or twisting of the stomach is rare. The abdomen becomes painful to the touch, swelling may be apparent, and vomiting likely to occur. The dog is soon in a very distressed condition, and needs emergency treatment or death will result.

Pyloric stenosis and pylorospasm (See under these headings for disease affecting the pylorus of the stomach.)

Rabbit

Dilation of the stomach Obstruction of the small intestine, often the jejunum, with hair or fur, is the usual cause. As the rabbit constantly salivates, swallowing the saliva, and the stomach has a well-developed cardiac sphincter, it cannot return to the oesophagus, The fluid also cannot pass or penetrate the obstruction and so accumulates within the stomach, which dilates. Treatment involves the use of OPIATES and NSAIDs and monitoring the passage of the obstruction into the caecum and colon. In rare cases ENTEROTOMY will be required, which is a difficult procedure in rabbits. (See CAECAL RESONANCE IN RABBITS.)

Stomach-Tube
A flexible, often rubber, tube used for introducing into the stomach (either through the mouth or more often through the inferior meatus of the nostril on one side), with a view to relieving tympany, or introducing medicines in the treatment of disease. It is about 3 m long for horses and cattle, and about 10 to 15 mm in diameter (proportionately smaller for other species).

A tube which possesses 2 channels is sometimes used to attempt to remove from the stomach portions of poisonous plants which may have been eaten. Water is pumped down through one channel, and when the stomach is full it runs from the other carrying with it small pieces of the harmful material. It is not possible to empty completely the stomach by the double stomach-tube, but considerable amounts of the harmful material may be removed.

The stomach-tube is extremely useful in those cases of colic which depend upon disturbances in the stomach, and if warm water is introduced by it in impaction of the large colon, peristalsis can often be stimulated. (But see DEHYDRATION.)

Its use demands care and a knowledge of the structure of the nasal passage, pharynx, gullet and stomach.

Stomatitis
Inflammation, often painful, of the mouth and gums (gingivitis), tongue (glossitis) or lips (cheilitis). (See BOVINE PAPULAR STOMATITIS; FOOT-AND-MOUTH DISEASE; VESICULAR STOMATITIS; SWINE VESICULAR DISEASE; MOUTH, DISEASES OF; FELINE STOMATITIS.)

-stomy
A suffix signifying formation of an opening in an organ by operation, e.g. gastrostomy and colostomy.

Stones
(See CALCULI and FOREIGN BODY.)

Stool
(plural, Stools)
The name used for FAECES in dogs, cats, some other animals and man.

Storing Feeds
(for safe storage periods see under DIET AND DIETETICS).

Storms
(See THUNDERSTORMS.)

Stot
A steer.

Strabismus
A condition in which each eye appears to be looking in a different direction. Also called a 'squint'.

Straights
Single feeding-stuffs of animal or vegetable origin, which may or may not have undergone some form of processing before purchase, e.g. flaked maize, soya bean meal, fish meal, barley.

Strain
The over-stretching of muscle fibres. Often a few of these are ruptured. A painful condition requiring rest. The same is true of overstressed tendons. (Compare a SPRAIN which involves ligaments of a joint.)

Stramonium
Stramonium is *Datura stramonium*, which is popularly known as the thorn apple or the Jamestown or jimson weed. The leaves contain the alkaloid daturine, which is almost identical in its actions with atropine.

The plant has caused fatal poisoning in pigs in Britain. However, the fatalities which have been reported appear to be the result of ingestion of large quantities of the plant in the absence of other food. See illustration on the next page.

VetBooks.ir

Thorn apple (*Datura stramonium*), which is also known as the Jamestown or jimson weed. The flower may be white or purple. On the left is a fruit capsule. Well-developed plants may be 1.6 m (5 ft) high.

Strangles

Strangles is an acute contagious fever of horses, donkeys and mules. Morbidity can be 100 per cent and mortality is usually 2 per cent (up to 10 per cent).

Cause *Streptococcus equi*. Strain 151 produces a more severe disease. Strangles is commonest and most serious in horses under six years of age. Mature horses living in a stable where an outbreak has occurred are frequently unaffected. Carriers occur, the organism survives a week in soil.

Signs Typical attacks begin with dullness, lack of appetite, rise in temperature to between 39.5° C and 40.5° C (103° F and 105° F) and congestion of the visible mucous membranes, especially of the nose and eyes. Nasal discharge is at first thin and watery, but soon becomes thicker, and profuse. There is often a cough. One or both of the submaxillary nodes, or perhaps one of the pharyngeal nodes, becomes enlarged, hot, tense and painful to the touch; until a soft spot, usually over a most prominent part of the swelling can be detected. This indicates the 'pointing' of the abscess. Following its resolution the horse improves greatly; temperature falls, appetite returns, and the animal becomes much brighter.

Complication: occasionally a suppurative pneumonia occurs. There may also be abscess formation in the liver or other abdominal organs.

Treatment A veterinary surgeon should be called. Immediate isolation of the affected horse is necessary. (The box or stall where it stood must be disinfected as carefully and thoroughly as possible, and should be left vacant for three to four weeks afterwards.) The sick horse should be clothed and made comfortable. Soft foods, such as mashes, are indicated, as swallowing may be painful. (See NURSING OF SICK ANIMALS.) Antibiotics and/or sulfa drugs are used.

Prevention An efficient vaccine can be produced only if encapsulated *S. equi* is used (i.e. from very young cultures) and the capsule not destroyed by formalin and excessive heat. In older cultures, the capsule is lost and the organism no longer invasive.

Human Infection by *S. equi* has been recorded.

Strangulated Hernia

The term is applied to a loop of intestine becoming trapped in a hernia, so that the blood supply to that section of it is cut off. (See HERNIA; 'GUTTIE'; VOLVULUS; INTESTINES, DISEASES OF.)

Strangury

Difficulty and pain in passing urine. It is a sign of an inflammatory condition of one or more of the kidneys, bladder, or urethra.

Stratum Corneum

The outer layer of the epidermis. (See SKIN - THE EPIDERMIS.)

Stratum Germinativum

The inner layer of the epidermis. (See SKIN - THE EPIDERMIS.)

Straw

(See under BEDDING AND BEDDING MATERIALS; DAIRY HERD MANAGEMENT; DEEP LITTER FOR CATTLE; DEEP LITTER FOR POULTRY.)

Straw feeding of cattle Straw is commonly included in diets, particularly when treated with sodium or ammonium hydroxide. It has been used in a strict maintenance diet of 2 kg (4 lb) each of barley and a low protein-mineral-vitamin concentrate with some 4.5 kg to 5.5 kg (10 lb to 12 lb) barley straw.

Experimentally, up to 30 per cent of ground straw has been incorporated into beef rations, along with 10 to 20 per cent molasses, 45 per cent cereals and 5 per cent total minerals, vitamins and urea to provide a complete ration. Fed *ad lib*, this is claimed to have consistently given daily

liveweight gains in excess of 1.3 kg (2.8 lb) with Friesian steers in commercial trials.

The main snag with feeding ground straw is its tendency to produce frothy bloat (with loss of appetite and loss of weight in subclinical cases). This has been overcome, it is claimed, by inclusion in feeds of an anti-bloat preparation (Poloxalene).

(See also NITRITE POISONING.)

Straw is a very useful bedding material for livestock.

'Strawberry Foot-Rot'

The colloquial name applied to a condition caused by the fungus *Dermatophilus pedis* or *D. congolensis*. (See DERMATOPHILUS.)

Stray Dogs and Cats, Strays

Local authorities have powers to deal with this problem under the Clean Neighbourhoods and Environment Act 2005. (See UNOWNED PETS.)

'Stray Voltage'

(See under ELECTRIC SHOCK, 'STRAY VOLTAGE' AND ELECTROCUTION.)

Streams

As a source of drinking water for cattle these should always be suspect, since they often carry infection from one farm to another, e.g. COCCIDIOSIS; JOHNE'S DISEASE; SALMONELLOSIS.

'Street' Virus

This term refers to the naturally occurring rabies virus, such as may be isolated from a rabid dog.

Streptococcal Meningitis

(See under PORCINE STREPTOCOCCAL MENINGITIS.)

Streptococcus

(plural, Streptococci; adjective, Streptococcal)

A micro-organism which under the microscope has much the appearance of string beads. It is responsible for strangles, mastitis, acute abscess formation, etc. (See BACTERIA.)

Streptococcus suis

Streptococcus suis infection is a common cause of meningitis and lymphadenitis in pigs. (See under PORCINE STREPTOCOCCAL MENINGITIS.)

Streptodornase, Streptokinase

Enzymes used to dissolve pus, fibrin and blood clot in infected wounds. They have also been used in the treatment of mastitis.

Streptomyces salmonidae

This causes a generalised disease in sock-eye salmon in Western America.

Streptomycin

An aminoglycoside antibiotic obtained from *Streptomyces graces*. Active almost entirely against Gram-negative organisms, streptomycin has given good results against infection with *Arcanobacterium* (previously *Corynebacterium or Actinomyces) pyogenes, Staphylococcus pyogenes, C. renale, E. coli*, and *Pasteurella septica*.

It has been used in cases of calf pneumonia and calf scours, some types of bovine mastitis, and complications of viral diseases in the dog, and in septic conditions in the cat. (In medical practice, streptomycin is regarded as one of the most toxic of the antibiotics in common use. It may cause deafness and vestibular disturbance in dogs and cats and paralysis in hamsters.) Resistance to this antibiotic develops readily and is usually multiple. For these reasons, other antibiotics are to be preferred when suitable.

In common with other AMINOGLYCOSIDES, streptomycin is used in a SYNERGISTIC manner with PENICILLIN, allowing the use of a lower, less toxic dose.

Streptothricosis

Infection with streptothrix organisms. In Britain, the name is applied to the disease in cattle equivalent to lumpy wool or wool rot, caused by *Dermatophilus dermatonomus*. A scurfy, scaly condition of the skin is produced, and scabs come away with a bunch of hairs attached if plucked. Anything which lowers the resistance of a hitherto healthy animal facilitates infection; and prolonged wetting, insect bites, thistle pricks, and other tiny breaks in the skin may all predispose to infection.

In the tropics, the name is applied to infection with *D. congolensis*.

The onset of the rains brings an increase in the incidence and severity of the disease, which is of great economic importance in Central and West Africa. Flies, ticks, and thorn bushes appear to play some part in the production and spread of the disease. Zebu cattle, as exotic cattle, appear highly susceptible; while N'dama and Muturu humpless cattle are resistant. It seems that infection does not give rise to later immunity.

Treatment with antibiotics or sulfonamides offers most chance of success, but is impracticable in many areas. (See DERMATOPHILUS.)

Streptothrix

Dermatophilus congolensis (See STREPTOTHRICOSIS and SENKOBO.)

VetBooks.ir

Stress

In human medicine it is now recognised that mental stress, anxiety and frustration can exert a profound effect for the worse upon bodily health. Similar effects may be found in animals. Stress can adversely affect production in food animals and behaviour in companion animals.

On a farm in New Zealand where theoretical considerations were all against high milk yields, the yields were, in fact, extremely high. After a detailed investigation it was concluded that the reason could only be sympathetic handling at milking time by the farmers – father, son and daughter – who were strikingly 'in harmony' with their cattle.

By contrast, on another New Zealand farm where everything – staff, milking machines, and herd management – remained the same, the strangeness of a new milking shed was apparently the sole cause of a 15 per cent reduction in milk yield. (See also CALF HOUSING.)

Stress is recognised as a predisposing cause of diseases in pigs, following the mixing of litters, castration, etc.; and in all species following parturition.

Subjection of animals to noise in intensive livestock production, or in the course of transport, can be a source of stress. Poultry subjected to 64 dB showed decreased adrenal activity resulting in poor feed uptake and a slower passage of digesta through the intestinal tract. Reduction of noise could have considerable economic benefits.

Many animals can hear sound that humans cannot and animals may, therefore, be stressed in an apparently silent environment.

(See TRANSPORT STRESS.)

Sheep Problems can arise in paddock grazing. The grassland breeds need a greater space, if stress is to be avoided. They are the hedge-breakers and fence-testers. They 'work away' at weak places with a will to escape.

Where a very large number of sheep are dealt with in one unit, it has been shown that it is especially desirable to reduce the flock to units of 80 ewes during the intensive management period at grass. Stress can result in a subclinical infection turning into overt illness. (See also BUNT ORDER; INTENSIVE LIVESTOCK PRODUCTION; INFECTION.)

Dogs Stress may result from being left tied up for long periods, or alone in an otherwise empty house; sometimes from ill-treatment by one member of a family. Dog fights are another cause, or merely the presence of a large dog in the vicinity, known to be a fighter. Being lost or abandoned, placed in boarding kennels, change of ownership, etc., can all cause stress. Diarrhoea, sometimes vomiting, and 'compulsive' polydipsia may result.

Cats The presence of a particularly aggressive tom (perhaps newly arrived in the district); the addition of another cat or dog to the household, or a mother paying less attention to the cat after the birth of a baby; or too many cats in the same house or confinement in a boarding cattery – these are all potential causes of stress.

During times of stress, a cat may develop a transient hyperglycaemia. This could lead to a mistaken diagnosis of DIABETES MELLITUS. (See also INTERSTITIAL CYSTITIS.)

Stricture

An abnormal narrowing of one of the natural passages of the body, such as the oesophagus, bowel, or urethra.

Strike

Blowfly myiasis, the condition resulting from infestation of the living skin of sheep by the larvae of blowflies which, in certain circumstances, lay their eggs in the wool. Animals affected are often said to have been 'struck'. It can also occur in dogs, cats and rabbits, especially where they have long coats, if there is faecal soiling. The flies are, apparently, attracted by putrefactive odours, and strike accordingly most often occurs in the region of the hindquarters in sheep which have been scouring. Some cases of strike begin, however, in the clean wool covering the shoulders and loins; and other parts may be affected.

Where there is sufficient moisture the eggs hatch in about 12 hours and the resulting larvae attack the skin with their mouths and secretions, causing raw areas. The consequent moisture favours the larvae, and their excreta attracts further blowflies which give rise to further generations of larvae.

Signs A characteristic twitching of the tail is seen when the hindquarters are affected. Tufts of white wool, discoloured wool, and the odour are indications of strike in other parts of the body. Death may occur within a week, and the mortality may be high among hill sheep especially, as the trouble may in them go undetected.

Treatment consists in the use of a dressing which will kill the larvae and facilitate healing of the wounds.

Prevention (See DIPS AND DIPPING; INSECTICIDES.)

String as a Foreign Body

It might reasonably be thought that string would be the least dangerous of foreign bodies, but such is not the case. Gravy-soaked string may inadvertently be included in a dog's or cat's meal of chicken scraps or leftovers from a joint of beef.

Occasionally string will form a loop around the base of the tongue, but more often it will pass into the stomach, causing local inflammation and sometimes obstruction. In the intestine, swallowed string is apt to lead to an accordion-pleated appearance of the bowel wall, which may perforate. One dachshund had no fewer than 15 such perforations, each of which had to be sutured during the course of a life-saving operation.

Stringhalt

Stringhalt is the sudden snatching up of one or both hind-legs of the horse when walking or, less often, when trotting.

All classes and ages of horses may be affected, although it is perhaps commonest in older horses. It often appears about the time when maturity is reached, i.e. five to six years or a little sooner.

Causes The cause of stringhalt is unknown. An Australian form of stringhalt is seasonal in incidence, and possibly associated with plant poisoning. Several horses in a locality may be affected. Recovery occurs after weeks or months, but not in all cases.

Neither pain nor lameness is associated with stringhalt, but the condition constitutes an unsoundness, and is incurable.

Strip-Cup

(See MASTITIS.)

Strip-Grazing

Strip-Grazing of cattle behind an electric fence tends to give greater production per acre, but it carries with it a risk of worm infestation under lush condition unless a back-fence is brought up at 5-day periods, and 'resting pastures' avoided. The use of an electric fence for strip-grazing on 'early-bite' is valuable. It induces the cattle to eat the whole plant instead of nibbling off the most succulent leaf-tips which predisposes to bloat.

Stroke

A problem resulting from a rapid loss in blood supply to an area of the brain, usually either ISCHAEMIA due to a THROMBUS or brain HAEMORRHAGE. It is not common as in people, and is mainly seen in dogs, particularly KING CHARLES SPANIELS, GREYHOUNDS and LABRADOR RETRIEVERS and cats (domestic shorthairs). There is a sudden onset of one-sided neural signs often with balance problems. Treatment is symptomatic.

Stroma

Tissue which forms the structure of an organ but does not play a part in its function. For example, the stroma of a secretory gland does not itself secrete.

Strongyles

Roundworms (red worms) of the family Strongylidae. They are parasitic in many farm animals and can cause anaemia, unthriftiness, debility, intermittent colic. (See FOALS, DISEASES OF; and under ROUNDWORMS.)

Strontium

Strontium 90 radioactive isotope is used in β-plesiotherapy (a form of radiotherapy) as an

Controlled grazing, showing use of an electric fence. (*Farmers Weekly*.)

VetBooks.ir

VetBooks.ir

adjunct to other therapy in treating squamous cell carcinoma, melanoma, haemangiosarcome, mast cell tumours and angiosarcoma. Animals under therapy are a source of radiation and have to be handled with specialist care.

(See under RADIOACTIVE STRONTIUM.)

Strontium Ranelate

This is used where stimulation of new bone growth is required.

Struthio Camelus

(See OSTRICH.)

Struvite

A magnesium-aluminium-phosphate compound found in urinary calculi. (See FELINE LOWER URINARY TRACT DISEASE.)

Strychnine

Strychnine is one of the two chief alkaloids of the seed of *Strychnos nux-vomica*, an East Indian tree – the other being brucine, which is less powerful and not used medicinally, although its actions are similar to those of strychnine. Strychnine itself is a white crystalline substance, possessing an intensely bitter taste. Strychnine (or nux vomica) was at one time much used as a tonic, especially during convalescence from debilitating illnesses, in pneumonia, and in atony of the bowels.

It is now used only for the killing of moles, under strict control.

Strychnine Poisoning

Signs In the larger animals the signs consist of convulsive seizures, characterised by a pronounced spasmodic contraction of the muscles of the limbs and trunk, and by a drawing back of the head and hollowing of the back (opisthotonus). In the horse, the eyeballs roll and the eyelids are seen quivering and often becoming drawn back, exposing the white of the eye. In the smaller animals the same signs are seen, but the seizures are of a more violent nature, and the periods of relaxation are shorter.

First-aid If a large dose has been taken, an emetic should be given to the smaller animals at once, preferably apomorphine given hypodermically; the larger animals should have their stomachs emptied as far as possible by the use of the stomach-tube. Strong tea is indicated for immediate first-aid.

Treatment Expert advice should be sought immediately. The patient should be anaesthetised.

STS

(See SOFT TISSUE SARCOMA.)

Stud Tail

An overproduction of sebum by the modified sebaceous glands (SUPRACAUDAL GLANDS) on the dorsal aspect of a cat's tail. The fur tends to become matted, and bare patches may occur. The precise cause is unknown, but it has been suggested that close confinement, and a consequent failure of the cat to groom itself, leads to 'stud tail'. Prolonged treatment may be necessary, including clearance of the secretion with mild, refined detergents and/or alcohols.

Stunning

This is used for farm animals to render them unconscious before slaughtering them, so that they do not feel pain when dying. Captive bolt stunning is used in cattle sheep and some pigs. Electrical stunning is used in sheep, calves and pigs, and for poultry it is undertaken using an electrically-charged water bath. Gas stunning is used to kill pigs and poultry. Stunning is not always used in RELIGIOUS SLAUGHTER.

Stunning, Electric, of Cattle

This is practised in Sweden and the Netherlands by means of the Elther apparatus (prior to Jewish ritualistic slaughter or otherwise). It is used also for calves, sheep, and goats.

Stunning, Electric, of Pigs

This has been practised extensively since the 1930s, and involves the use of brine-soaked electrodes, applied on each side of the pig's face, by means of which the electric current is passed. A voltage of not less than 75 is recommended and a current of not less than 250 milliamperes, assuming 50 cycles-per-second alternating current. An electroplectic fit is caused, with anaesthesia lasting for about 60 seconds, when conditions are satisfactory. After 60 seconds, there may be a half-minute period of paralysis during which sensation is present. Therefore, the pigs must be killed during the first 60 seconds. If care is not taken or the apparatus is faulty or unsuitable, paralysis only, and not anaesthesia, may result; the pig being conscious when killed.

High-voltage stunning The trend towards the use of 180 to 600 volts has been impeded by the commonly held belief that it might adversely affect 'bleed out'. However, the ARC's Meat Research Institute has shown that this need not be so.

Stunted Chick Disease

This syndrome in chickens was first recognised by Kouwenhoven and others in 1978, and has since been found to occur worldwide. The cause is believed to be a virus, possibly exacerbated by *Campylobacter* spp. and spirochaetes.

VetBooks.ir

Sturdy
A neurological disease in sheep caused by *Coenurus cerebralis*, the intermediate stage of *Taenia multiceps*; it is also known as GID. (See COENURIOSIS; GID; TAPEWORMS - COENUROSIS (GID OR STURDY) IN SHEEP AND GOATS.)

Stye
(See EYE, DISEASES AND INJURIES OF; HORDEOLUM.)

Styfziekte
Styfziekte is a name meaning 'stiff sickness', which is used to describe either the signs associated with chronic aphosphorosis, which is the forerunner of lamziekte in South Africa, or those associated with a mineral deficiency in certain parts of northern Nigeria.

Subacute
A condition less rapid in onset than acute but not chronic. (See also ACUTE, CHRONIC, PERACUTE.)

Subacute Ruminal Acidosis (SARA)
A condition of ruminants, especially dairy cows, seen when the cow ingests large amounts of carbohydrates and is unable to process them adequately. It usually occurs in the post-calving period. The animal does not develop the full signs of ACIDOSIS, but performs suboptimally and may show poor ruminal function and contractions, sloppy faeces, and cud dropping. It is often undetected but possibly 30 per cent of dairy cows suffer intermittently. An intraruminal device can record ruminal pH and relay records by radiowaves to a computer for analysis.

Subclinical
A disease is said to be subclinical when the signs are so slight as to escape the notice of the animal-owner. Examples: subclinical MASTITIS, which by lowering the milk yield of a herd of cows may be of considerable economic importance and is best recognised by a high milk cell count in the affected quarter(s); similarly, a subclinical infestation with parasitic worms. (See also STRESS.)

Subcutaneous
Subcutaneous means anything pertaining to the loose connective tissue lying under the skin, such as a subcutaneous injection, where the injected fluid is introduced below the skin. (See under INJECTIONS.)

Subcuticular
This refers to anything pertaining to the tissues lying under the EPIDERMIS.

Subcutis
The lowest of the three layers of the skin. (See SKIN - SUBCUTIS.)

Sub-human Primates
(See MONKEYS.)

Subluxation
A partial dislocation. Atlantoaxial subluxation is a cause of neck pain and muscle dysfunction in some toy breeds of dogs.

Treatment In 13 cases the atlas and axis were stabilised with a wire suture; in 10 cases lag screws were used for fixation of the ventral articular facets. Nine of them recovered within 2 months.

Sucking, Intersucking
This habit or 'vice' occurs among dairy calves. If allowed to go unchecked, the practice may become habitual, involving a risk to the health of the calves, and, if persisting into adulthood, the welfare of the herd in general may be affected. In a herd of 50 Friesian cows the habit grew so pronounced that the herd became uneconomic and had to be dispersed. Cattle of all ages were involved and milk loss was considerable. Purchased calves acquired the same habits after a short while. Intersucking is a problem in only a small proportion of herds, usually those of above average size, where the calves are bucket fed, or where they are grouped at, or shortly after, birth.

The most effective remedy is to separate the calves after feeding, but if this is not practicable, mechanical devices or the provision of dry food are good alternatives. It seems that a useful preventive measure is to delay grouping calves until they are more than four weeks of age, although this may be considered contrary to welfare legislation in some countries.

Suckling
(See CALF-REARING.)

Sudden Acute Retinal Degeneration Syndrome (SARDS)
A sudden BLINDNESS due to the total destruction of the RETINA; in some cases sight appears to have deteriorated for five to 10 days. It is seen in dogs of all breeds and crossbreeds aged seven to 14 years and mainly female. The cause is not known but often there have been tests results suggestive of HYPERADRENOCORTICISM (CUSHING'S SYNDROME.)

Sudden Death
(See under DEATH, CAUSES OF SUDDEN.)

Sudden Death Syndrome
This occurs in broiler breeders often between 20 and 30 weeks old. The birds are well developed

and there are rarely any clinical signs before death. Part of the problem is that the modern broiler breeder has a high demand for potassium and phosphorus and it is suggested that diets contain at least 0.65 per cent potassium and 0.4 per cent digestible phosphorus.

Sudoriferous, Sudoriparous
Related to the production and secretion of SWEAT.

Sudorifics
Sudorifics are drugs and other agents which produce a copious flow of perspiration. (See DIAPHORETICS.)

Suffering
The dictionary definition is the undergoing of, endurance of, or subjecting to, pain or disease. It is often used in terms of the LAW and animal welfare, when it is usually described as 'UNNECESSARY SUFFERING'. (See ANIMAL WELFARE ACT 2006.)

Suffocation
(See ASPHYXIA and 'CHOKING'.)

Suffolk Punch Horses
These HEAVY HORSES have been bred for over 300 years in East Anglia to work on farms. The animals are very large, being normally 17 to 19 HANDS high. They are chestnut in colour with clean (non-feathered) limbs. They are not so quiet as Shires. At one point there were only 80 on the stud book but more are now being bred.

Suffolk Sheep
A popular breed which is used as a common sire (TERMINAL SIRE) for other breeds to produce a good quality fast-growing offspring. The animals have a distinct black head which is partly seen in their crossbreeds. Rams weigh 110 kg to 160 kg (240 lb to 350 lb) and ewes are 80 kg to 100 kg (175 lb to 220 lb) with fleece of 2.3 kg to 4 kg (5 lb to 9 lb).

Sugar
Sugar is a substance containing the elements carbon, hydrogen and oxygen, and belonging therefore to the chemical group of carbohydrates. This group includes three main subdivisions as follows:

1. Monosaccharides, or glucoses ($C_6H_{12}O_6$):
   e.g. Dextrose or grape-sugar, Levulose.

2. Disaccharides, or sucroses ($C_{12}H_{22}O_{11}$):
   e.g. Cane-sugar, Lactose or milk-sugar, Maltose or malt-sugar.

3. Polysaccharides, or amyloses $(C_6H_{10}O_5)n$:
   e.g. Starch, Glycogen (animal starch), Dextrin and other gums.

Glucose is the form of sugar present in the blood, and reserves are stored in the liver in the form of glycogen.

The appreciation of sugar varies with the species; cats appear unable to detect its sweetness. Poultry can only appreciate one sugar – xylose, which is toxic to birds.

Starch is mentioned under a separate heading, and its use as a food-stuff is described under DIET AND DIETETICS.

Suitably Qualified Person
(See SQP.)

Sulfa Drugs
The International Non-proprietary Name (sulfa-) has superseded the original UK form (sulpha-). However still at times both tend to be used in different contexts. (See SULFONAMIDES.)

Sulfaquinoxaline
Mixed in food or drinking water, for the control of coccidiosis in poultry. It is the SULFA DRUG of choice for turkeys who find sulfa drugs impalatable.

Sulfasalazine
A SULFONAMIDE derivative used to control COLITIS in dogs and cats. (See EYE, DISEASES AND INJURIES OF - 'DRY EYE'.)

Sulfonamides, Sulphonamides
A group of drugs which are, to susceptible organisms (e.g. streptococci), bacteriostatic (rather than bactericidal); that is to say, they prevent the multiplication of bacteria rather than killing them. Sulfonamide drugs are all synthetic and closely related to *p*-aminobenzoic acid, which is believed to be essential to bacteria, and which is absorbed by them; and it is believed that the sulfonamides are absorbed by the bacteria similarly, with the result mentioned above. Individual sulfonamide drugs do not have specific action against specific bacteria; their differences lie in the differing concentration or level which can safely be obtained in the animal's bloodstream, and their excretion route.

Uses Sulfonamides have been extensively employed in veterinary medicine for dressing wounds, for the prevention of post-operative sepsis, and in the treatment of pneumonia, metritis, enteritis, 'joint-ill', foul-in-the-foot of cattle and arthritis in young pigs, etc. They must be used in full dosage, or resistant strains of bacteria may develop.

VetBooks.ir

Residues Traces of sulfonamide are occasionally found in pig kidneys. Where sulfonamides are prescribed for farm use, management procedures should be examined to avoid risk of residues. Likely causes of residue problems include: sows having access to medicated creep in farrowing pens; barrows used to carry medicated feed being used for carrying feed for finishing pigs without being cleaned; failure to clean pens used for medicated pigs before restocking.

Toxicity Sulfonamides may have an adverse effect upon the host's cells as well as upon the invading organisms. For this reason (and to avoid giving rise to resistant strains), sulfonamides should be used only under veterinary advice and not indiscriminately. Fortunately, however, domestic mammals, with the exception of the goat, show few signs of intolerance. Sulfanilamide is, however, highly toxic to birds.

Names of individual compounds The list is being continually extended, but they include:

Sulfacetamide. It is used as an ointment to treat eye infections.
Sulfadiazine. Has been used in the treatment of calf pneumonia, etc. It is incorporated with silver in a cream for application to burns.
Sulfadimidine. Of value in foul-in-the-foot in cattle, pneumonia, enteritis. Is readily accepted in the food by all animals.
Sulfaguanidine. Used in the treatment of white scour of calves, necrotic enteritis in pigs, and enteritis in other animals. Readily taken in the food.
Sulfamerazine. Has been used in the treatment of calf pneumonia, etc.
Sulfamethoxipyridazine. Used to treat coccidiosis in sheep.
Sulfanilamide. Of value as a dry dusting powder for wounds, teat sores, etc. May be combined with 1 per cent neutral proflavine sulphate.
Sulfaquinoxaline. Used in the control and treatment of coccidiosis in chickens and turkeys.
Sulfathiazole. Has been used in the treatment of calf pneumonia.

Sulfosalicylic Acid, Sulphosalicylic Acid

A white or slightly pink powder soluble in water and used as a reagent to detect albumin in urine.

Sulfur

American and official international spelling of SULPHUR.

Sulpha Drugs

The International Non-proprietary Name (sulfa-) has superseded the original UK form (sulpha-). (See SULFONAMIDES.)

Sulphur (S)

Sulphur is a non-metallic element which is procurable in several different allotropic forms, e.g. 'flowers of sulphur'. As a parasiticide, sulphur has been largely replaced by more effective substances, although proprietary organic preparations of sulphur are still used in the treatment of mange. It is mainly used in ORGANIC FARMING.

Internally, sulphur was at one time a popular laxative and mild tonic, and no doubt still enjoys a vogue among some animal-owners.

Sulphur is an essential ingredient in the diet and is best given in an organic form such as dimethylsulphoxide, its metabolite methylsulphonylmethane, or glucosamine sulphate, all of which also have therapeutic effects. Organic sulphur is usually about 34 per cent available to the animal. These sulphur products are used in the synthesis of S-adenosylmethionine, glutathione, taurine and N-acetylcysteine. S-adenosylmethionine increases the hepatic glutathione concentration in normal cats and prevents glutathione depletion in dogs with steroid-induced hepatopathy.

Poisoning Overdosage must be avoided: 85 g (3 oz) of flowers of sulphur has killed cattle. Dosing by guesswork on the part of a shepherd killed 140 ewes in a single flock.

Accidental poisoning by sulphur occurred in 14 horses, 2 of which died.

Sulphur Dioxide

A poisonous gas which is a constituent of diesel engine exhaust fumes. The gas causes irritation to the upper respiratory system and can result in PNEUMONIA. (See SMOG.)

Summer Mastitis

Summer mastitis is caused by *Trueperella pyogenes* (previously *Arcanobacterium pyogenes*, then *Actinomyces pyogenes*) and *Peptococcus indolicus*. Both the headfly and *P. indolicus* are implicated in the aetiology of this disease. (See MASTITIS; FLIES.)

Summer Sores

Summer sores in horses are caused by infective *Habronema* larvae deposited in wounds by stable- or house-flies. They are very itchy. Eyelids may be affected. The infestation results in the formation of fibrous nodules which may later ulcerate. Summer sores are uncommon in Britain.

Sunburn

Ssee LIGHT SENSITISATION; EYE, DISEASES AND INJURIES OF; CANCER). This is a hazard for a number of animal species. White pigs must be protected from sunburn by providing shade. Small animals, particularly those with short coats, can be

affected: MEXICAN HAIRLESS DOG, SHAR-PEI, SPHYNX CAT, etc. A type of sunburn can occur in some fish in clear water where no shade is available.

Sunlight
(See under RICKETS; INFERTILITY; LIGHT SENSITISATION; TROPICS, LIVESTOCK PRODUCTION IN THE.)

Sunstroke
(See HEAT-STROKE.)

Superfetation
The presence in the uterus of fetuses of different ages, due to successive services.

For example, a cow is got in calf at one service, comes on heat again, and settles to a further service – in due course producing a calf as the result of the first mating, but more often than not having little or no milk. She later calves again, as the result of the second mating, and this time lactation begins. Calves born in this way are not, of course, twins. Although contemporaries within the dam, they are of different ages, and can have different sires.

Superficial Pyoderma
This was usually described as CANINE STAPHYLOCOCCAL DERMATITIS and may be seen in IRISH SETTERS, COLLIES and SHETLAND SHEEPDOGS (shelties).

The lesions appear on the fine skin with few hairs on the abdomen or between the thighs. The condition causes irritation and the dog will scratch or lick the affected part. The lesions consist of roughly circular areas of reddened skin, some with a ring of blackish or greyish crust, having papules or pustules at the edge. The appearance may suggest ringworm at first glance. The *Staphylococcus aureus* involved is resistant to penicillin, so other antibiotics must be used. An autogenous vaccine may be needed if antibiotics are not effective.

S

Superinvolution
Superinvolution is the contraction of the uterus after parturition when the shrinkage proceeds beyond the normal, and the organ is less in size than before conception. It may proceed to such an extent that the dam is subsequently unable to breed, or it may result in a reduction in size of the organ, which is not very important.

Superovulation
The production of extra (mammal's) eggs. It can be induced by means of hormones. (See TWINNING, ARTIFICIAL.)

Superpurgation
Superpurgation is excessive purgation which continues for some considerable time, and may end fatally. It is most serious in the horse, where it may follow the administration of aloes. It may also arise through the ingestion of food-stuffs which are unwholesome, such as sprouted potatoes and decomposed mouldy oats; and it may result from horses breaking out from a stable and getting into a field of clover or lucerne. (See PURGATIVES; LAXATIVES; COLIC.)

Supplementary Feeding
(See FLUSHING OF EWES; FEED BLOCKS; UREA; SUPPLEMENTS; CREEP-FEEDING.)

Supplementary Veterinary Register
Recognised veterinary practitioners (without a veterinary degree or MRCVS) were allowed to continue practising following the introduction of the Veterinary Surgeons Act; no names were added to the Supplementary Register after those allowed under the VETERINARY SURGEONS ACT 1966.

Supplements
Products for use at less than 5 per cent of the total ration in which they are included, and designed to supply planned proportions of vitamins, trace minerals, one or more non-nutrient additives and other special ingredients.

Supportive Medicine, Supportive Treatment
This is mainly used as a treatment of the animal to maintain its strength whilst it deals with a disease, illness or injury.

Suppository
A suppository is a small conical mass made of glycerine or a similar substance, and containing drugs intended for introduction into the rectum.

Suppuration
The formation or discharge of pus. (See under ABSCESS; CELLULITIS; FISTULA; INFLAMMATION; PHAGOCYTOSIS; WOUNDS.)

Supracaudal Glands
A collection of modified sebaceous glands situated in the skin of the dorsum (back) at the junction of the dorsal and middle thirds of the tail in dogs. In cats they are arranged along the dorsal aspect of the tail. These organs produce PHEROMONES. When they become blocked they give rise to the condition, STUD TAIL, with the glands becoming prominent and an associated loss of hair.

Suprarenal Glands
(See ADRENAL GLANDS.)

VetBooks.ir

Suprascapular Paralysis

Suprascapular paralysis occurs as a result of injury to the suprascapular nerve. The term 'slipped shoulder' is applied to the signs which are shown in a typical case. The supraspinous and infraspinous muscles act as ligaments of the shoulder-joint, and when they are paralysed the shoulder slips outward each time the foot is placed upon the ground and when weight is put upon it. After the paralysis has been in existence for some few days, two distinct hollows appear over the shoulder, due to atrophy of the muscles, and the spine of the scapula stands out prominently between these hollows. When viewed from in front the animal appears to have lost the symmetry of the two shoulder regions. In typical cases there is difficulty in bringing the limb forward, and often the leg appears to swing outwards with a circular movement. When a horse stands quietly, the affected limb is usually brought well under the body, and may even take up a position across the middle line of the body. The paralysis may disappear in 6 weeks; but in more severe cases, 18 months may elapse before the horse is fit for work.

First-aid Fomentations, or application of a liniment may be helpful until the acute signs subside; thereafter a run at grass generally results in improvement.

In the dog there may be permanent paralysis, sometimes requiring amputation of the leg or other surgery.

Suramin

A drug used against trypanosomes.

Surfactants

Substances that reduce the surface tension of a liquid; soap and detergents are examples. Surfactants are used in frothy bloat to allow the release of gas from the bubbles which are formed and in premature NEONATES to improve the action of the lungs.

Surgical Spirit

A preparation of alcohol used, for example, as a skin cleanser before giving an injection. It consists of industrial methylated spirit with the addition of castor oil (2.5 per cent), methyl salicylate (0.5 per cent) and diethyl phthalate (2 per cent).

Surra

Surra is a disease of most economic importance in camels and horses, but it can affect all the domestic animals. The disease occurs in Africa (north of the tsetse fly belt), Asia and Central and South America. In the latter, *Trypanosoma equinum* is responsible; elsewhere it is caused by *T. evansi*.

The infection is spread by blood-sucking flies, such as tabanids and stable flies. Vampire bats are believed to transmit the infection also. Animals which eat the meat from carcases infected with trypanosomes may themselves become infected in the case of surra.

In the Sudan, surra affects mainly camels, which die within weeks or a few months, after showing signs of fever, anaemia, progressive emaciation, oedema and paralysis. In Asia, surra in camels is often a chronic disease which may persist for years.

In horses, signs are similar, but the dropsical swellings (oedema) are especially noteworthy, affecting several parts of the body (as they do also in the dog). Mortality is high, and occurs in horses after a matter of weeks or months. Loss of power in the hind limbs and exaggerated heart sounds may precede death.

In Central America the names 'murrina' and 'derrengadera' have been used for vampire bat- and fly-transmitted infection with *T. equinum*.

Treatment involves use of drugs such as antrycide, diminazine and suramin which have specific action on trypanosomes. Fly control is also important in reducing the incidence of the disease.

Suspected Adverse Reaction Surveillance Scheme (SARSS)

In the UK, the Veterinary Medicines Directorate monitors reports of unusual unexpected adverse reactions to veterinary medicines and lack of efficacy. The manufacturers are kept informed of such reports so that they can take appropriate action.

Sussex Cattle

These medium-sized cattle are mainly found in the Weald of Sussex, Surrey and Kent. The breed was recorded in the 18th century and was used as a draught animal and for beef. They are red in colour and the hair is thin in summer with many sweat glands, but with a thick coat in winter. They have a placid temperament but are stubborn. They have white horns, although some are naturally polled, and with a white switch to the tail. They are useful to mate with heifers as they cause little DYSTOKIA.

Sussex Light Chickens

They can be used for meat or producing brown eggs. They originate from Roman times and there is a bantam form. There are eight colours: brown, buff, light, red, speckled, silver, white, coronation, and they are docile. They are often used pure-bred as a good egg producer or crossed with RHODE ISLAND RED and BROWN LEGHORN. Point of lay pullets can suffer from rupture of the Achilles tendon which is associated with high female hormone levels. Some may recover.

Sussex Spaniel
A small, compact spaniel, with a long back, not unlike the CLUMBER SPANIEL. The weigh is 16 kg to 20 kg (35 lb to 45 lb). The coat is a golden liver colour coat and it suffers from PYRUVATE DEHYDROGENASE PHOSPHATASE DEFICIENCY (DNA test available) and INTERVERTEBRAL DISC PROTRUSION.

Sustainable Control of Parasites in Sheep (SCOPS)
This is a series of principles to reduce and delay the development of anthelmintic resistance in sheep worms. It includes procedures to quarantine and treat for worming all new sheep entering the farm, followed by exposure to the indigenous worm population. All treatments are planned, ideally following demonstration of worming, identification of need by faecal worm egg counts, only using the correct dose, not treating a proportion of the flock that look healthy and checking the efficacy of treatment.

Suture
Suture is the name given either to the close union between two adjacent flat bones of the skull at their edges, or to a stitch or a series of stitches by which a wound is closed. The term is also used to describe the materials used for surgical stitching or SUTURING. (See INTENTION WOUNDS.)

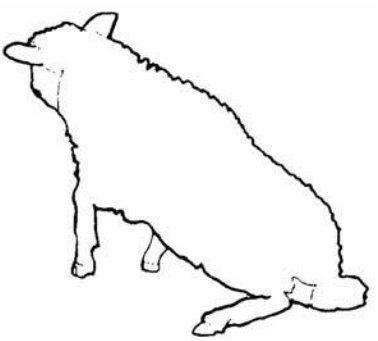
Suturing
The application of SUTURES.

Suxibuzone
A non-steroidal anti-inflammatory drug licensed for use in horses in cases of osteoarthritis, laminitis, bursitis and other painful conditions in the locomotor system. It may be antagonistic to other drugs used, such as warfarin and sulphonamides. Its use in competition horses is subject to strict observation of the recommended withdrawal period.

Swabs
Swabs are used for sampling mucus, etc., for diagnostic purposes; the material subsequently being cultured so that pathogenic organisms, if present, may be identified. For swabbing as a guide to infertility in the thoroughbred mare, see under EQUINE GENITAL INFECTIONS IN THE MARE.

Swainsonine
A mycotoxin produced by *Rhizoctonia leguminicola*; it has an additive effect with slaframine. Both are metabolised from pipecolic acid, which in turn is derived from L-lysine.

Swaledale Sheep
A breed originating from Yorkshire Vales. The sheep is small, with off-white wool and a white face with some black marks. The male has horns. The ewes are often mated with BLUE-FACED LEICESTER rams to produce North Country MULES.



Swallowing
As soon as food ready for swallowing enters the pharynx, it touches areas of mucous membrane supplied with nerves which automatically inhibit breathing, in order to prevent food going the wrong way; the larynx is closed by being pulled forwards and upwards, while the base of the tongue folds the epiglottis over the opening of the larynx. The pharynx is shortened and its muscles force the food into the oesophagus, where peristalsis takes the food to the stomach.

Swallowing is one-third voluntary and two-thirds reflex. The voluntary part is placing the food on the upper surface of the tongue which is raised, tip first, against the hard palate towards the rear. At the same time the soft palate is raised, closing the gateway to the nose. The base of the tongue forces food into the pharynx. The next two stages of swallowing are involuntary, reflex actions. (For difficulty in swallowing, see DYSPHAGIA)

Swamp Cancer
A condition affecting horses in Australia. The lesion is, in fact, a fungal granuloma caused by *Hyphomyces destruens*.

Swamp Fever
(See EQUINE INFECTIOUS ANAEMIA.)

Swayback
Swayback is a copper deficiency disease seen in the last third of pregnancy in the ewe and resulting in signs in newborn and young lambs and occasionally kids. It is characterised by progressive cerebral demyelination, which results in paralysis and often death. It occurs in many parts of the UK and in other countries.

Swayback – a characteristic posture.

VetBooks.ir

Signs A staggering gait or inability to walk, lambs often rocking back on their haunches, hence swayback. Severely affected cases cannot rise, and so cannot suck, and die. A delayed form can occur with less severe signs.

Treatment None, for the congenital form. In the delayed form, dosing with copper-containing preparations may assist.

Prevention In mid pregnancy, give the ewes copper capsules or injections of a suitable copper preparation. Blood test the ewes before treating.

Sweat, Perspiration

The excretion produced by the SUDORIFEROUS glands of the mammalian skin; it exerts a cooling effect by evaporation. In the horse, there are parts of the skin which sweat more readily than others such as the bases of the ears, under the fore-arm, and around the dock and, generally speaking, fore-parts of the trunk. Mules and donkeys do not sweat readily, and when they do it is generally confined to the bases of the ears. In cattle, sweating occurs chiefly at the neck and over the chest. In Brahman cattle the hump is an important sweating site. Panting (and loss of water vapour from the lungs) is the chief means of heat loss in sheep, but they do sweat. The dog, cat and pig are, for all practical purposes, non-sweating animals, though sweating may occur from the pads of the feet of dogs and cats; dogs rely mainly on panting. (See also ANHIDROSIS; HYPERTHERMIA; HYPOTHALAMUS; TROPICS, LIVESTOCK PRODUCTION IN THE.)

Sweat Glands

(Like all other tissue, the sweat glands can become the site of cancer. The head, neck, pinna of the ear and base of the tail can all be affected in cats usually aged more than six years. (See SKIN - GLANDS OF THE SKIN).

Sweating Sickness

This is a tick-borne disease of cattle in southern Africa, affecting mainly calves. (Sheep can also become naturally infected.)

Signs Fever, eczema. (See also TICKS.)

Swedish Lapphund Dogs

A spitz-type dog originally used to herd and guard reindeer. They have a thick black long coat and upturned tail, and weigh about 20 kg (44 lb); they suffer from PROGRESSIVE RETINAL ATROPHY (DNA test available).

Swedish Red and White Cattle, Swedish Red Cattle

This is the main breed of Sweden, now often called the Swedish Red. The herdbook dates from 1928, when the Swedish Ayrshire and the Swedish Red-White breeds – similar in origin and characteristics – were amalgamated. Each was the result of breeding from old Swedish stock to which had been introduced some DAIRY SHORTHORN and AYRSHIRE CATTLE blood.

It is a long-lived breed, with an overall milk yield average in excess of 8,730 kg (1900 gallons) at 4.1 per cent butter fat and 3.5 per cent protein. They are hardy animals, easy calving and can compete with Holsteins. Their milk is used in Parmesan cheese.

There is very little white in the coat-colour; and some animals are entirely red.

'Sweet Itch'

A seasonal inflammation of the skin of horses, caused by hypersensitivity to the bites of *Culicoides* midges. Lotions containing benzoyl benzoate or pyrethrins are used to control the midges; calamine, antihistamine and CORTICOSTEROID (unlicensed but often effective although can have side effects) creams can help relieve the signs.

Fly repellents are effective for such short periods as to be worthless for control, probably best achieved by stabling in the early evening; a Vapona (dichlorvos) strip being hung in the stable to kill any midges entering.

Treatments to modify the immune response using *Culicoides* extracts or *Actinomyces* bacterial extracts are often helpful, but should start before signs and may take up to a year to show efficacy.

Sweet Potato Poisoning

There are records of the sweet potato (*Ipomea* spp.) causing poisoning if used for cattle feed, especially if the potato is damaged. The signs are usually colic and loss of appetite; the head is held low. In mild cases recovery is quite quick, but in more severe cases a cautious prognosis should be expected.

Sweet Vernal Grass, *Anthoxanthum odoratum*

Hay containing this has caused poisoning owing to its DICOUMAROL content. The dicoumarol content of the grass varies, but may increase in hay which has become overheated or mouldy.

Swill

The feeding of swill has been illegal since 2001 in the UK. Inadequately processed, swill was a frequent source of SWINE FEVER, SWINE VESICULAR DISEASE and FOOT-AND-MOUTH DISEASE (cause of UK 2001 foot-and-mouth disease outbreak) infections. Scouring and deaths occurred among swill-fed pigs on premises where it was the practice to use daily only 2,275 litres (500 gallons) out of a total of 9,095 litres (2,000 gallons) of steam-

VetBooks.ir

sterilised swill, the remainder being stored. There was no further trouble after the tank was emptied and the swill fed as soon as possible after processing. Swill should always be treated correctly within any regulations applying and fed soon after processing.

Swimmers

The colloquial name for puppies showing the juvenile femoral rotation syndrome. They are unable to rise on to their hind-legs at the usual age, due to the head and neck of the femur being wrongly positioned on the shaft. Sometimes the name 'flat pup' syndrome is applied. (See 'FLAT PUP' SYNDROME.)

Swine Dysentery

An important disease, characterised by haemorrhagic enteritis, and dependent for its cause upon synergism between the spirochaete *Serpulina hyodysenteriae* and *Bacteroides vulgatus* and other bacteria.

About one in three pigs in a herd become ill, and the mortality rate is 10 to 60 per cent. Chronic scouring, without dysentery, may persist. The faeces are greyish.

Prevention and Treatment Antibacterials such as tiamulin or dimetridazole (no longer used in the UK) may be added to drinking water or the feed of susceptible animals, or tiamulin given by injection.

Swine dysentery and chickens Retarded growth rate and delayed onset of egg production in pullets have, as one of the causes, infection with *S. hyodysenteriae*. Pullets reared on deep litter with indirect contact with pigs have become infected.

Swine Enzootic Pneumonia (SEP)

(See ENZOOTIC PNEUMONIA OF PIGS.)

Swine Erysipelas

Swine erysipelas is an infectious disease of pigs and characterised by high fever, reddish or purplish spots on the skin, and haemorrhages on to the surfaces of certain of the internal organs in acute cases; and by general debility, lameness, and difficulty in breathing in chronic cases. In the latter there are usually found characteristic cauliflower-like masses on the valves of the heart.

The disease may occur in man; also in chickens, turkeys, ducks, pheasants and grouse. According to American research, dogs are susceptible to one strain of the organism, which gives rise to bacterial endocarditis.

Incidence In Europe it is usually prevalent both in the acute form and in the chronic, and at times it assumes the nature of an epizootic, sweeping throughout large territories, and leaving a high percentage of death in its wake. In the UK the chronic form is usually met with in small outbreaks in different parts of the country, but from time to time in certain areas, especially in East Anglia, and during hot dry summer weather, it breaks out in a more menacing form, and large numbers of pigs become affected with the acute form, and considerable numbers die.

Cause *Erysipelothrix rhusiopathiae*, which may also infect sheep at shearing or dipping time through small wounds or abrasions.

Signs There are three recognised forms of swine erysipelas: the subacute, the acute, and the chronic. Mild or subacute attacks come on suddenly; there is high fever, loss of appetite, dullness, a tendency to lie buried in the litter, and when moved, to do so reluctantly: the skin over the chest, neck, back and over the thighs becomes flushed at first, and soon changes to a red or purple colour. The outlines of the areas affected are often square, or they may be the shape of the playing-card diamond, from which the disease gets one of its names – 'diamond disease'. The areas are usually raised above the level of the surrounding skin, are painful to the touch at first, but not so later, and, appearing about the second or third day of the attack, last for four days, and then disappear. Recovery may be followed by the chronic form. In some cases, pigs may show painful swellings of the knees and hocks, but this is not invariable. Young pigs between three and five or six months old are most commonly attacked; it is rare before three months, but may occur in older animals.

Acute type, or septicaemic type, often results in sudden death.

Chronic type is the most insidious, and pigs affected with it are probably responsible for causing most of the outbreaks of the previous types, since, being bad thrivers, they are often disposed of through the open market and bought by owners of clean herds. They feed, but do not always finish their food; they have a normal temperature, but are easily distressed when made to take exercise. Breathing becomes shallow, and a cough generally develops. The pulse becomes thready, and if the heart is listened to, a continuous murmur can be heard over the left side of the chest. This is due to endocarditis, which is almost the characteristic feature of post-mortem examination of pigs dead from chronic swine erysipelas. The chronic form may last for several weeks, or even for two or three months, especially in strong robust young breeding gilts, but towards the end emaciation and prostration become very obvious.

Infertility involving abortion, stillbirths and mummified fetuses commonly results from erysipelas.

Treatment Antibiotics have been used.

Prevention Avoid any pigs in the open market which appear to be thin and not thriving, especially sows and boars, or older pigs. Any showing wrinkling of the skin of the ears, or patches or flushing on the skin, those which have swollen joints, or those which have diarrhoea, should not be bought. Pigs showing extreme breathlessness upon mild exertion should be likewise avoided.

Vaccinate piglets from non-immune sows at seven days old, repeated at four weeks; pregnant sows and gilts should be vaccinated at six and three weeks before farrowing and a booster given three weeks before subsequent farrowings.

Arthritis and heart disease may be a result of pigs becoming hypersensitised to the bacteria, and not the result of attack by the bacteria themselves. This must be borne in mind when prescribing the vaccine.

Public health Stockmen exposed to infection must be careful to wash their hands.

Swine Fever, Classical Swine Fever

Also called hog cholera or pig typhoid, this is a highly infectious and contagious disease of pigs. It is a NOTIFIABLE DISEASE in the EU.

Cause The cause of swine fever is a pestivirus (a member of the Togavirus family). Secondary bacterial invaders include *Salmonella suipestifer* and *Pasteurella suiseptica*. None of these secondary organisms is, however, necessary for the production of swine fever.

It inevitably happens that pigs harbouring the virus of swine fever, but not yet showing signs of the disease, are slaughtered for human food. Under such circumstances, the virus can survive in the skin and muscle for 17 days. In frozen pork the survival time has been quoted as over 4 years; in bacon, 27 days.

At public markets, the urine of infected pigs often drains into adjoining pens and alleyways. The urine may, too, get splashed on to clothing, boots, etc., and droplets of it find their way into lorries and on to farms. In one instance about 30 outbreaks, spread over 10 counties, arose from the sale of a single infected pen at a large market.

It seems probable that the virus may be carried by rats and mice for short distances at least. Horse-flies can carry the virus, which – according to an American report – can be harboured by larvae of the pig lungworm. These larvae are, in turn, harboured by earthworms.

The use of antibiotics contained in feeding-stuffs has had the effect of masking the classical signs of swine fever, and is sometimes said to have extended the incubation period.

Signs In young pigs the disease is often acute or peracute, while in older pigs it tends to assume a chronic form, although they also may be affected with the severe rapidly fatal form.

Acute type: After an incubation period of 5 to 10 days, signs of the disease include thirst, sometimes vomiting, shivering, loss of appetite. There is a tendency to lie with backs arched and tails uncurled. If forced to move, pigs are seen to be unsteady on their legs. If their temperature is taken, it is found to be high. Initial constipation is usually followed by diarrhoea, with a foul odour. There is often a discharge from the eyelids. The skin becomes reddened or purplish. Some pigs may cough or show laboured breathing. Convulsions may precede death. The mortality rate can be as high as 90 per cent.

Pneumonia is a common post-mortem finding and 'button ulcers' may be present in the intestines.

Chronic Type: The pigs are dull and unthrifty, lose weight, have a variable appetite; coughing and/or diarrhoea may be other signs. The temperature may be only slightly raised or as high as 41° C (106° F). A partial recovery may be followed by relapse and death.

Subclinical Swine fever may exist in a herd in a subclinical form; pregnant sows showing no obvious signs (though fever may be present), and the disease remaining unsuspected until the finding of a few dead piglets, or of others showing muscular tremors.

Death of the fetus may occur (see MUMMIFICATION OF FETUS) or weak or deformed piglets may be born. If infected late in pregnancy, piglets may die without signs of swine fever. Meanwhile, being viraemic, they may have infected others.

Infection of a pregnant sow can be followed by the presence of virus in her piglets, either stillborn or living. The sow is not a carrier in the usually accepted sense, since after the birth of her piglets the virus – having crossed the placental barrier – no longer remains within her body. A period of 56 days may elapse between the last deaths on a farm and a recrudescence of the disease.

Diagnosis The fluorescent antibody test.

Prevention Swill must be boiled for at least an hour, and it must be prepared only in registered premises for pieces of infected pig meat may otherwise give rise to an outbreak of the disease. NB: Swill feeding is illegal in the UK since the 2001 outbreaks of FOOT-AND-MOUTH DISEASE.

VetBooks.ir

Pigs introduced into a herd should be from premises shown to be free from the disease. Visits by pig-dealers should be discouraged.

Control A swine fever eradication programme, with compulsory slaughter, and compensation, was introduced in 1963. The disease was eradicated in 1966, but reappeared briefly in Yorkshire in 1971; and a single outbreak occurred in 1986. In 2000, a serious outbreak occurred in East Anglia, resulting in the imposition of movement restrictions on animals from affected areas and the slaughter of thousands of pigs. Sixteen areas were affected, the first case being confirmed on 8 August; the final restricted area was cleared on 30 December. The outbreak might have originated from a pork pie, made from imported pork, discarded where free-range pigs could have consumed it.

Swine Fever, African

This disease, formerly indigenous in the African continent, appeared in Spain and Portugal during 1960.

During 1978 there was an outbreak in Malta; eradication was effected by slaughter of the entire pig population and restocking in a quarantine station on the island of Comino. An outbreak in Sardinia, also in 1978, spread into the wild boar population, in which it remains endemic. The risk of introduction to other countries is a serious one; there were 5 outbreaks in Belgium in 1985. The disease may be carried by airline meals or by passengers. The disease has been seen in 2011 in Georgia and spread to Armenia and the Russian Federation, reaching the vicinity of St Petersburg and, therefore, close to EU borders.

The disease is also known as wart-hog disease, as these animals besides bush-pigs are affected. In some parts of Africa, pig-raising has had to be abandoned on account of the disease, which is highly contagious, nearly always fatal, and gives rise to carriers – those few that survive often transmitting the infection to other pigs for a year or more.

Cause A pestivirus, resistant to heat, drying, and putrefaction, and which can survive in smoked or partly cooked sausage and other pork products. The virus attacks blood-vessel cells and the disease is accordingly characterised by haemorrhages.

Signs After an incubation period of 5 to 15 days, there is fever, the pig running a temperature of 40.5° C (105° F) or so. This is followed by blotching of the skin, depression, anorexia, diarrhoea and weakness of the hindquarters with a disinclination to rise. Death may occur within a day or two. Clinically, the disease is indistinguishable from acute classical swine fever.

Control African swine fever is a NOTIFIABLE DISEASE in the UK and throughout the EU; control is by slaughter.

At the beginning of 1978 there were approximately 80,000 pigs on the islands of Malta and Gozo, supplying the inhabitants with all their requirements of fresh pork and bacon. By the end of January 1979 there were no pigs at all.

It was the first time that any country had slaughtered all the surviving members of a species in order to eliminate a disease – in this instance, African swine fever. The decision to slaughter all survivors was taken when the pig population had fallen to 13,975. Swill feeding and the movement of weaners to fattening premises helped to spread the disease.

Swine Influenza

A common problem which can rapidly spread through a pig unit; affected animals usually recover within a week, but other respiratory problems may be precipitated. An H1N1 virus was causing the disease in Europe in 1986, and was isolated from an outbreak involving a 400-sow unit in the UK. Morbidity was nearly 100 per cent, but all recovered. H3N2 virus is also present in the UK.

In many outbreaks, several deaths are to be expected. (See also INFLUENZA and ENZOOTIC PNEUMONIA OF PIGS.)

Cause An orthomyxovirus; important secondary invaders include *Haemophilus influenzae suis, Pasteurella suiseptica, Brucella bronchiseptica*, and streptococci.

Signs Coughing, fever, anorexia, laboured breathing. (See also INFLUENZA.)

Swine Plague

Swine plague is the term applied to what in Britain is considered to be the pneumonic form of swine fever, but what in America and the continent of Europe has been regarded as a separate disease. (See SWINE FEVER.)

Swine Pox

A virus disease identified by lesions on the abdomen, in adults, and on the face in piglets, in which the disease is more serious; they also have conjunctivitis and some may die. The cause is infection with swine poxvirus and/or vaccinia virus. (See POX.)

Swine Vesicular Disease (SVD)

A NOTIFIABLE DISEASE. An enterovirus disease whose signs resemble those of foot-and-mouth disease. It first appeared in the UK in 1972. In the Staffordshire outbreak of that year it was at first mistaken for foot-and-mouth disease, from which

VetBooks.ir

it cannot be differentiated on clinical grounds alone. However, it was shown at the Animal Virus Research Institute, Pirbright, that the virus was not that of foot-and-mouth disease but related to an enterovirus which had caused outbreaks in Italy and Hong Kong.

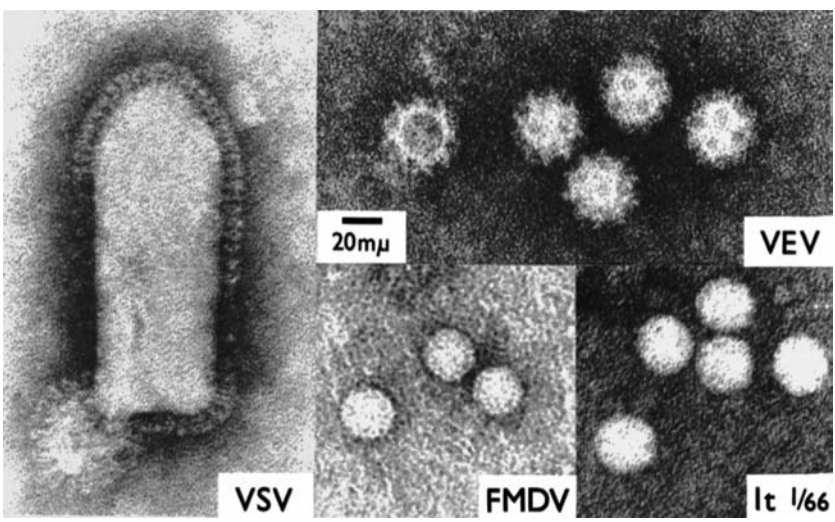
All cases in the UK were linked either to swill feeding of pigs or to the movement of pigs from infected to clean premises. The disease appears to be spread rapidly through contact, with an incubation period of perhaps four to eight days. Airborne infection appears less likely than with foot-and-mouth disease.

A similar disease has been reported in Austria among pigs imported from Poland, and also in France.

SVD virus is very closely related to Coxsackie B5 virus, which causes not only influenza-like symptoms in man but also sometimes heart disease and meningitis. It is thought possible that SVD arose as a result of pigs becoming infected by people ill because of Coxsackie B5 virus, which locally then became adapted to pigs or underwent mutation.

SVD has been transmitted to laboratory workers, so precautions must be taken.

Control Experience has shown that the incidence of the disease has been quickly reduced by the imposition of Controlled Area measures, and this fact led to the Movement and Sale of Pigs Order 1975, and subsequent legislation, designed to slow down the movement of pigs so that infection can show up and be dealt with before it spreads further.



Licences are required for all movement of pigs; entry of pigs on to a farm precludes movement of animals off that farm for 21 days, except for those going direct to slaughter. Swill-fed pigs could be moved only to a slaughterhouse. All pigs consigned to a slaughter market or to a slaughterhouse must be marked with a red cross of specified dimensions.

Sporadic outbreaks have occurred since the original outbreak. The infection can be subclinical. The British legislation currently in force is Pigs (Records, Identification and Movement) Order 2008 with separate orders for England, Scotland and Wales and the time restriction on movements has altered to 20 days.

Mode of Infection Although the SVD virus belongs to the enterovirus group, it has been difficult to obtain evidence for infection by mouth. Many experiments, in which precautions were taken to prevent entry of virus by other routes, have failed to produce the disease. In contrast, infection by rubbing or scarification of the skin regularly produces infection, and it seems that the most likely route of infection in the field is through damaged skin.

Swinge Coat

An abnormality in which the hair is short, sparse and curly.

The virus causing swine vesicular disease is shown bottom right, labelled It 1/66. Extreme left is the bullet-shaped virus of vesicular stomatitis (VSV), and top right is the virus of vesicular exanthema (VEV). Centre bottom picture shows foot-and-mouth disease virus. All these viruses affect pigs and have to be differentiated. (The scale shown 20mm = 0.00002 mm. Photographs by electron microscope, with acknowledgements to C. J. Smale and the Animal Virus Research Institute, Pirbright.)

Swollen Head Syndrome of Chickens (SHS)

Signs An oedematous swelling beginning round the eyes and progressing to the intermandibular tissue. There is coughing and a nasal discharge. Opisthotonus may be seen. If picked up the birds become uncoordinated, roll over, and have difficulty in regaining a normal posture; diarrhoea may be seen. The disease lasts about 2 weeks.

Cause A paramyxovirus.

Sycamore Poisoning

This has been reported in horses due to a toxin, hypoglycin A, in sycamore (*Acer pseudoplatanus*) seeds. The clinical signs include depression, muscle weakness and recumbency. Death can occur from MYOPATHY. Young horses and those grazing parched land are most at risk.

Symbiosis

Symbiosis means an obligatory association between two different species for their mutual benefit.

Symmelia

A congenital condition in which there is fusion of the limbs.

Symmelus

A fetus in which there is fusion of the limbs.

Sympathetic Nervous System

(See CENTRAL NERVOUS SYSTEM; AUTONOMIC NERVOUS SYSTEM.)

Sympathomimetic Agents

Also called ALPHA (A)-2 ADRENERGIC AGONISTS. They mimic the activity of drugs that affect the SYMPATHETIC NERVOUS SYSTEM such as ADRENALIN and CATECHOLAMINES.

Symphysis

A joint, in which bones are united by a flattened disc of fibro-cartilage.

Sympodia

A congenital condition in which the lower extremities are united.

Symptomatic Medicine, Symptomatic Treatment

Treatment designed to alleviate untoward signs and then allowing 'nature to take its course'.

Syn-

Syn- is a prefix signifying union.

Synapse

(See NERVES.)

Synchilia

A congenital adhesion of the lips or atresia of the mouth.

Synchronisation Of Oestrus

(See CONTROLLED BREEDING.)

Syncope, Fainting

Syncope (fainting) is generally due to cerebral anaemia occurring through weakened pulsation of the heart, sudden shock, or severe injury.

It is common in dogs and cats, especially when old; cases have however been seen in all animals.

Syncytial Viruses

(See RESPIRATORY SYNCYTIAL VIRUS.)

Syncytium

Tissue composed of a mass of nucleated protoplasm without cell boundaries, such as the outer layer of the trophoblast of a placenta; or a mass of cells united by protoplasmic bridges.

Syndactyly

A congenital fusion of two or more of the digits. It is also called ZYGODACTYLY.

Syndrome

A group of clinical signs in animals or group of symptoms in humans.

Synechia

Adhesions in the eye, e.g. involving the tissues of the iris to the cornea or lens (See EYE, DISEASES AND INJURIES OF - IRITIS).

Synergism

Synergism is the opposite of antagonism. Synergism between drugs, e.g. trimethoprim and sulfadiazine, may be of practical value, for with the two it may be possible to obtain the required effect with a dosage of one which, if used alone, would be insufficient, but which cannot be increased because larger amounts would cause side-effects. Another advantage of using two drugs is the possibility that this would tend to prevent the multiplication of strains resistant to one of the compounds.

The word 'synergism' is also used to describe an interaction between a virus and bacteria in their combined invasion of, for example, the lungs; implying that the result of the 'combined forces', as it were, is greater than the sum of the effects produced by the agents individually. Synergism occurs in calf pneumonia between *Mycoplasma bovis* and *Pasteurella haemolytica*. (For another example, see SWINE DYSENTERY.)

VetBooks.ir

VetBooks.ir

Synergistic
Description of two medicinal substances which when given together have an greater effect than would be expected from adding each one. It also occurs with some disease organisms such as PARAINFLUENZA 3 VIRUS with *Mannheimia haemolytica* in cattle.

Syngamiosis
Infestation of a bird with *Syngamus trachea*. (See GAPES.)

Synophthalmia
A congenital partial fusion of the eyes.

Synopsia
A congenital fusion of the eyes.

Synostosis
Synostosis is the term applied to a union by bony material of adjacent bones usually separate. It may occur in the spinal column in old animals. (See also HORSES, BACK TROUBLES IN.)

Synotia
The (virtual) absence of a head in a stillborn animal. It is a developmental abnormality often seen as a persistence of the ears below the mandible, usually associated with the absence of, or incomplete development of the lower jaw (MANDIBLE).

Synovial Membrane
Synovial membrane forms the lining covering the surfaces of the opposed articular cartilages, which enter into the formation of a joint. (See JOINTS.)

Synovitis
Inflammation of the membrane lining a joint. It is usually accompanied by effusion of fluid within the synovial sac of the joint. It is found in various injuries and inflammation of joints.

Synovitis, Infectious
This is a disease of chicks, of about 2 to 10 weeks old, and of turkeys; first diagnosed in Britain in 1959.

Cause *Mycoplasma synoviae*.

Signs Reluctance to move, lameness, swelling of joints, anorexia.

The confined conditions under which broilers are raised appear to render them particularly susceptible to this disease. Mortality is low, but a third of the survivors may be downgraded, so that severe financial loss may be caused. Control depends upon hygiene, and being careful about the breeding stock.

Treatment TETRACYCLINES have proved effective in high doses.

Syphilis (of Rabbits)
Caused by *Treponema cuniculi* and is a venereal disease. Kittens can be infected at birth and may remain in a carrier state for life. When clinical signs appear, they consist of crusting lesions around the genitalia, face and legs. There can be secondary bacterial infection and untreated lesions can progress to the formation of eosiniophilic granuloma. Treatment is by the use of penicillin, but must be undertaken with care as enterotoxaemia may result.

Syringe, Hypodermic
A pump-like device used to introduce solutions to, or withdraw them from, the body. (See INFECTIONS, DETERGENT RESIDUE; also PROJECTILE SYRINGE.)

Syringomyelia (SM)
A problem of the brain in which there is reduction in caudal fossa volume with descent or herniation of the cerebellum, and often the brainstem, into or through the foramen magnum. This can also be associated with CHIARI-LIKE MALFORMATION. It is particularly seen in the CAVALIER KING CHARLES SPANIEL, where up to 95 per cent are believed to be affected to some extent, and, where neural pain progressed, in about 75 per cent of those affected. Onset is usually between 6 months and 3 years. It is also common in the GRIFFON BRUXELLOIS. It is also suspected to be inherited in other small (toy) breeds including KING CHARLES SPANIELS, CHIHUAHUAS, POMERANIANS, AFFENPINSCHERS and MALTESE DOGS. It occurs in the WEIMARANER. It is diagnosed by MAGNETIC RESONANCE IMAGING. A BVA/Kennel Club Canine Health Scheme for this and SYRINGOMYELIA began in January 2012.

Syrinx
The organ of vocalisation in birds. It is situated at the end of the trachea and in front of the division into the two main bronchi. It contains two opposable membranes under tension and it is the modulations of these that are responsible for the great range of sounds that birds can produce.

System
The anatomical term for a group of organs all with one main function, e.g. the gastro-intestinal system (which has a digestive function), respiratory system, urinary system, reproductive system, central nervous system, endocrine system, etc.

Systematic
A term describing the activity of an infection which affects all the body's organs and systems.

Systemic
(adverb, Systemically)
The term applied to infections that can spread around the body from one organ to another such as ANTHRAX, PASTEURELLOSIS, STAPHYLOCOCCOSIS.

Systemic Lupus Erythematosis
This is an autoimmune condition in which multiple tissues undergo damage from the body's own immune system. The skin, kidneys, joints and components of the blood may be involved. Antibodies directed against proteins in the cell nucleus help support the diagnosis (antinuclear antibodies, ANA tests).

Systole
Systole means the contraction of the heart as opposed to the resting phase, which is called 'diastole', and which alternates with the former contracting period. In the cardiac cycle systole takes about one-third, and diastole about two-thirds, of the whole period of the heartbeat. (See HEART DISEASES.)

VetBooks.ir

VetBooks.ir

T

T2 Toxin
This fungal toxin may poison cattle, pigs or poultry eating stored corn containing the fungus *Fusarium tricinctum*. The poisons belong to a group of chemicals called trichothecenes. In cattle, the toxin may cause multiple haemorrhages and sometimes death; in poultry, there may be mouth lesions.

T3
(See TRIIODOTHYRONINE.)

T4
(See THYROXINE.)

Tachycardia
Tachycardia is a disturbance of the heart's action which produces great acceleration of the pulse.

Tachypnoea
An increase in the rate of breathing due to some pathological condition, or an environmental or stress factor. (See BREATHLESSNESS; PARAQUAT poisoning.)

Taenia
(See TAPEWORMS.)

Tail, Amputation of
Amputation of the tail (docking) is, or has been, undertaken for a variety of reasons. In the UK the Royal College of Veterinary Surgeons has ruled that docking a puppy's tail is an unethical procedure except when it is done for prophylactic or therapeutic reasons. Under the ANIMAL WELFARE ACT 2006 and 2011, it is a prohibited mutilation in dogs, unless they are of certain breeds, and in Wales these breeds are specified. Once the tail is amputated (docked) a dog cannot be a show dog. If a tail is amputated for other reasons, a veterinary certificate is then required for the dog. Docking by lay persons is illegal. A Scottish study showed working breed dogs were at significantly greater risk of tail injuries than other breeds of dogs.

In cattle, amputation of the tail is illegal except following injury and must, except in an emergency, be undertaken by a veterinary surgeon. Pigs' tails are often docked to prevent tail-biting but, legally, this should only be undertaken where other methods to control tail-biting have failed. Lambs' tails are docked legally to prevent faecal soiling and FLY STRIKE (see under DOCKING; LAW; WELFARE CODES FOR ANIMALS).

Tail-Biting
In pigs this 'vice' can be of great economic importance. There are various reasons why it occurs: boredom, absence of bedding, and overcrowding (floor space of less than 1.5 m^2 (5 sq ft) per pig), are regarded as conducive to tail-biting. High temperature and humidity are possible causes. Bitten tails require amputation or dressing if PYAEMIA is to be prevented. When tail-biting occurs it is best to remove from the group the one with lesions and those causing it.

Tail sores in pigs These may follow tail-biting by one or two pigs out of a large batch and, if untreated, can lead to pyaemia.

In six months, out of 135 pig carcases condemned in an Oslo abattoir, 56 (41.5 per cent) were affected with pyaemia – and of these, 43 (76.8 per cent) had tail sores.

Talfan Disease, Teschen Disease; Porcine Viral Encephalomyelitis
This disease of pigs was first recognised in the Czech Republic and occurs throughout Europe. In the UK, it was made a NOTIFIABLE DISEASE in 1974. Its cause is an enterovirus. Experimentally, the incubation period is stated to be 12 days. Piglets three weeks old and upwards are affected; adult pigs may be infected but show no clinical signs. By no means all piglets in a litter or on a farm become ill, and the mortality is usually low. The main sign is weakness or paralysis of the hindlegs. There is little or no fever or loss of appetite. Recovery occurs in a proportion of animals which are hand-fed. The disease is present in Britain to a small extent and apparently may be associated with abortion.

Talipes
A congenital condition in which there is abnormal flexure of the carpal and/or the tarsal joints (commonly called club foot). The problem may involve one or more limbs. There are two types: talipes VALGUS, where the animal walks on the inner side or part of the foot with the sole turned outwards and talipes VARUS, where the animal walks on the outer part or side of the foot and with the sole turned inwards.

Talus
(See ASTRAGALUS.)

Tampan
A soft tick of the family Argasidae. (See TICKS.)

Tamponade, Cardiac
A rapid accumulation of blood or other fluid in the pericardial sac, compressing the heart and sometimes suddenly arresting its function.

Tamworth Pigs

One of the oldest pig breeds. There are now only 300 registered breeding females. The skin and hair are pale red to dark red mahogany, the snout longish and ears erect. The boar weighs 250 kg to 370 kg (550 lb to 815 lb) and sows 200 kg to 300 kg (440 lb to 660 lb). The Tamworth strain probably helped to produce the PIÉTRAIN breed. The litter sizes are smaller than those of LARGE WHITE PIGS and LANDRACE PIGS.

Tannin, Tannic Acid

Tannin (tannic acid) is a non-crystallisable white or pale-yellowish powder, which is soluble in water and glycerine. It is prepared from oak-galls, and is found in strong tea or coffee. When brought into contact with a mucous surface, tannin causes constriction of the blood vessels. When brought into contact with many poisonous alkaloids it renders them temporarily inert by forming the insoluble tannate, and so is a valuable antidote.

Uses Tannic acid has been used in diarrhoea and dysentery in young animals, usually as CATECHU or kino – two vegetable drugs which contain a large amount of tannin. It is often administered, in the form of strong tea, as the first step in the antidotal treatment of poisoning by ALKALOIDS.

Tannic-acid jelly is a valuable burn dressing. It lessens the absorption of breakdown products from the burned area and hence diminishes the secondary effects of a serious burn. It is not suitable for extensive areas owing to the danger of liver damage if large quantities are absorbed.

Tapetum Lucidum

Latin for shining carpet, the tapetum is a modified part of the choroid coat of the eye reflecting light in certain mammals, especially those, like cats, active in times of reduced daylight. (See EYE - COATS OF THE EYEBALL - THE CHOROID.)

Tapeworms

An intestinal parasite commonly found in vertebrates. Their life-cycle requires two hosts, sometimes three. The presence of the adult worm may give rise to few if any signs or, on the other hand, to anaemia, indigestion, and nervous signs – or even to blockage of the intestine. The cystic stage of tapeworms may involve the brain. Tapeworms are of considerable public-health importance.

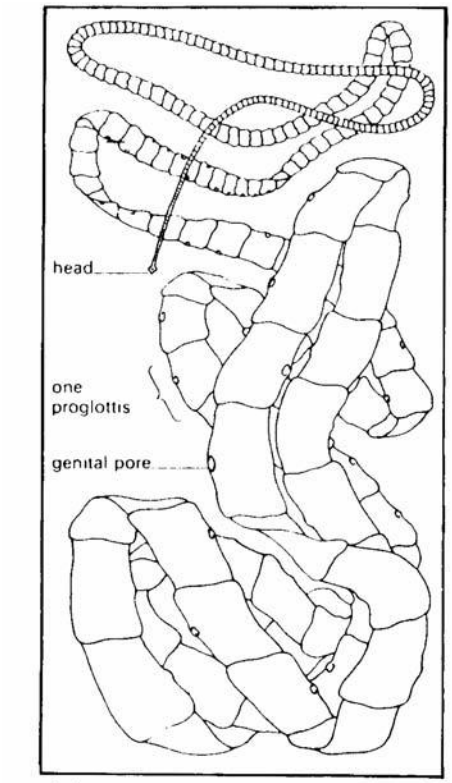
A typical tapeworm has a head or scolex, provided with suckers and, in some species, with hooks also.

Behind the scolex follows a neck, and behind that are the segments, each being called a proglottis. The segments nearest to the head are the smallest, and are immature. Next follow mature segments, and lastly the gravid segments containing eggs. These older segments fall off and are passed out of the host's body in the faeces.

Taenia. This is the common genus of worms found in dogs and cats, and includes:

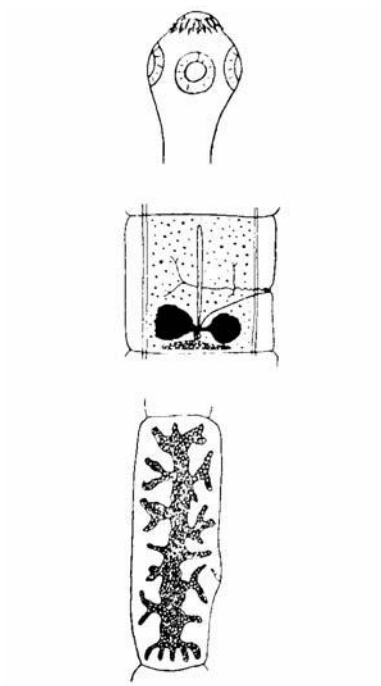
T. pisiformis (*T. serrata*) is one of the commonest. Its cystic stage, *Cysticercus pisiformis*, is found in rabbits and hares.

T. hydatigena (*T. marginata*) is the largest form, with mature segments wider than long. It may reach a length of over 5 m (16 ft). Its cystic stage, *C. tenuicollis*, occurs in the viscera of various animals, especially sheep, cattle and pigs. *T. ovis* is frequently mistaken for the last form, from which it can be distinguished only by microscopical examination. Its cysticercus, *C. ovis*, is found in the muscles and organs of sheep and goats. It is a small form, easily overlooked.



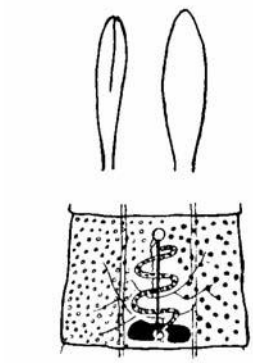
T. multiceps (*T. coenurus*) is a more delicate form than the others, semi-translucent. The intermediate stage is a coenurus, found in the nervous system of sheep and other ruminants and man.

T. serialis is a more robust form, its coenurus being found in rabbits and hares. Only one species is common in the cat, *T. taeniaeformis* (*T. crassicollis*). The cystic stage *C. fasciolaris* is found in the liver of rats and mice.



T. saginata is a tapeworm of man which produces cysticercosis infection in the muscles of cattle; this is *C. bovis*, known as measly beef. *T. solium* is another tapeworm of man, the intermediate stage of which (metacestode) is found in the skeletal and heart muscles of pigs, producing measly pork.

Diphyllobothrium. D. latum is the broad tapeworm of man, the dog and the cat. It is rare in Britain, but has a wide distribution. Several species are found, but this is the commonest. The life-history is interesting. The ciliated larva liberated from the egg is swallowed by a crustacean, *Cyclops strenuus* or *Diaptonius* spp., in which it becomes an elongated form with a terminal sphere containing three pairs of hooklets, called a 'procercoid larva'. The crustaceans are swallowed by a fish, when the larva, migrating to the muscles, becomes an elongated infective larva called a 'plerocercoid'. The fish is eaten by a suitable host, and the adults develop. In man, the tapeworm may attain a length of 18 m (60 ft), and it may cause a grave form of anaemia (bothriocephalus anaemia) associated with gastric and nervous symptoms.



D. mansoni is also widely distributed and has a similar life-history, but the infective stage is found in many hosts, including man, pig, and carnivores. It is common in frogs in Japan. The adult worm is found in carnivores.

A typical tapeworm. Each segment is called a proglottis. (From H. T. B. Hall, *Diseases and Parasites of Livestock in the Tropics*, Longman.)

Taenia. Head, mature and gravid segments.

Diphyllobothrium. Head and segment.

Treatment of dogs infested with tapeworms is very important, because some of the species in their intermediate stages are dangerous to food animals. Farm dogs should never be allowed to harbour tapeworms. Routine use of ANTHELMINTICS is essential: a wide range is available, many based on PRAZIQUANTEL or DICHLOROPHEN. All faecal material passed should be destroyed.

Dipylidium caninum infests cats also; and may be transmitted by swallowing a flea.

In pigs, cattle and sheep cysts of the tapeworm *Taenia hydatigena* (which infests the dog and may occasionally attain a length of 5 m (16 ft)) may be so numerous in the liver that the latter ruptures, causing death.

Tapeworms in horses Three species occur in horses, all belonging to the genus *Anoplocephala*. *A. perfoliata* and *A. mamillana* are not uncommon in Britain, while *A. magna* is also sometimes encountered.

A. perfoliata, a stoutish worm with large head and no hooks, is a cause not only of unthriftiness but occasionally also of ileal and caecal obstruction, and/or INTUSSUSCEPTION, where numerous *A. perfoliata* are present. The infection may therefore be more serious than is generally supposed. The intermediate host is a mite. Diagnosis in the horse is the presence of tapeworm segments in faeces, or an accurate blood test.

Tapeworms in ruminants All the tapeworms of ruminants have four suckers and no hooks. In *Moniezia* the intermediate host is a free-living mite.

The segments of *Moniezia* worms are much broader than they are long. The worms may attain a length of several metres/yards, with a minute head little larger than a pin-head. More than 1,000 worms have been recorded from a single host. Numerous species have been recorded. *H. giardi* is found in Europe, Australia, and Africa and is from 1 m to 2 m (3 ft to 6 ft) long.

VetBooks.ir

A closely related form, *Thysanosoma actinoides*, is found in North America. It is about 30 cm (1 ft) long, and is found in the liver. The sheep show general signs of malnutrition.

Bovine cystercercosis in Denmark On 14 farms with a history of this disease the source of infection on six of the farms was sludge from septic tanks applied to pasture or crops. In two herds the cattle grazed pasture near a sewage plant; while on three farms people defecating on pasture was a possible source. Those findings are typical wherever the infestation occurs.

Tapeworms in poultry A number of tapeworms have been found in poultry, of which the commonest are *Davainea proglottina*, which has a larval stage in slugs and snails and is widely distributed, and several species of *Raillietina*, with the larvae in house-flies, dung beetles and ants. The following are also common in many countries: *Amoebotoenia*, with larvae in earthworms; and *Hymenolepis* of various species, some of which may be very numerous in individual birds.

'Measles' in beef due to the presence of the cyst stage (*Cysticercus bovis*) of the tapeworm *Taenia saginata*, which is a parasite of man. Cattle swallow the eggs of the adult tapeworm, and these hatch in the intestines, liberating young embryos, which burrow until they settle in muscle fibre or connective tissues. Here they appear as small oval cysts, containing fluid, and each possessing the head of a potential tapeworm.

'Measles' in pork is due to the presence of the cyst stage (*Cysticercus cellulosae*) of the tapeworm of man, *Taenia solium*. It is extremely common among pigs in eastern lands, which have access to garbage and human faeces, from whence they pick up the eggs passed through the human intestines. The eggs undergo a development similar to those of the beef-measles tapeworm. Man may also himself harbour the cystic stage. According to the FAO, it is one of the 10 food-borne parasites with the greatest global impact.

Cysticercosis in man Very high sporadic infection rates have been found in Africa with *Taenia saginata* and *T. solium*, the two tapeworms of major importance in man. Where *T. solium* is present, serious human infections with the cysticercus stage may be observed, as well as mild infections with the adult tapeworm. When it occurs in beef cattle, the cysticercus of *T. saginata* is a major economic problem and a serious obstacle to the export of meat.

A single human carrier of *T. saginata* led to an outbreak of cysticercosis among cattle on a large farm in the USA.

Coenurosis (gid or sturdy) in sheep and goats This disease is caused by the pressure of cysts of the tapeworm *Taenia multiceps* on cells of the brain (or spinal cord).

Sheep become infested by swallowing the unhatched eggs, excreted in a dog's faeces, while grazing. In the digestive tract the eggs hatch, and pass via the bloodstream to various parts of the body; only those reaching the central nervous system develop. Here they form small cysts, each containing one tapeworm head: this larval stage is known as *Coenurus cerebralis*. Over a period of months, each cyst increases in size, and more heads are budded from the lining membrane of the translucent cyst wall. Eventually a single coenurus may contain 50 or 100 or more tapeworm heads (scolices) projecting inwards.

The life-cycle is completed if a dog eats the head of an infested sheep.

Signs These include impairment of vision, a staggering or high-stepping gait, circling and standing with head lowered, raised, or pressed against an object. Backward somersaults have been recorded. Recumbency and opisthotonus may occur. A softening of the bone of the skull, due to internal pressure of the cysts, is found in a proportion of cases.

Diagnosis Where there is no softening of the skull, a guide to the location of the cyst may be given by interpretation of the neurological signs as indicated by the sheep's behaviour. An intradermal test has been used: 0.1 ml of cyst fluid is injected into a shaved area of skin. Thickening of the skin within 24 hours indicates the presence of a cyst in the animal.

Treatment Physical removal of the cyst may be attempted. The sheep is anaesthetised and, in the absence of any skull softening, a trephine used to remove a disc of bone 1.5 cm (0.6 in) in diameter. Draining the fluid from the cyst before its removal obviates the need to enlarge the hole. The cyst is then removed completely. (If this is not done, the remaining cyst wall is apparently capable of replacing the fluid.)

Hydatid disease is caused by the cystic larval stage of the microscopic tapeworm *Echinococcus granulosus* in Britain and *E. multilocularis* which is more severe and found especially in Eastern Europe. In both, the dog and fox are the usual hosts. Eggs released from tapeworm segments passed in the faeces by these animals are later swallowed by grazing cattle, sheep and horses, which may become infested also through drinking water contaminated by wind-blown eggs.

People become infested through swallowing eggs attached to inadequately washed vegetables, and

VetBooks.ir

possibly eggs may be inhaled in dust or carried by flies to uncovered food. The handling of infested dogs is an important source. In man and other intermediate hosts the larvae form cysts which can be found in different organs such as liver, lung, etc., leading to debilitating and often fatal disease. Medical treatment is usually ineffective and surgical incision is the best chance for success.

There have been successful campaigns to control human hydatid disease in both Cyprus and Iceland, by compulsory treatment and/or banning of dogs.

Swallowed eggs hatch in the intestines and are carried via the portal vein to the liver. Some remain there, developing into hydatid cysts; others may form cysts in the lungs or occasionally elsewhere, e.g. spleen, kidney, bone-marrow cavity, or brain. Inside the cysts, brood capsules containing the infective stage of the tapeworm develop and, after 5 or 6 months, can infest dog or fox.

In Wales, where the incidence of hydatid disease is relatively high, farm dogs and foxhounds are important in its spread.

About seven people are known to die from this disease in England and Wales each year – this figure would probably be higher if diagnosis were less difficult. Condemnation of sheep and cattle offal from this cause costs hundreds of thousands of pounds annually. Routine worming of dogs is essential for control. Infestation can be brought back to the EU from mainland Europe under the PET TRAVEL SCHEME. All dogs returning to the UK must be treated for tapeworms.

E. granulosus and *E. multilocularis* are far from being typical tapeworms, as they have only three or four segments and a total length of a mere 3 mm to 9 mm (0.12 in to 0.35 in), so that the dog-owner will not notice the voided segments.

A problem of diagnosis also arises, as this worm's eggs are indistinguishable from those of *Taenia* tapeworms. Examination of a dog's faeces following dosing with arecoline would reveal the intact tapeworm. However, this drug has now been replaced by more modern drugs which destroy the tapeworm but leave it unrecognisable.

DICHLOROPHEN, PRAZIQUANTEL, NITROSCANATE, and BENZIMADAZOLES are used for treatment.

Equine hydatidosis in Britain is caused by a strain of *Echinococcus granulosus* which has become specifically adapted to the horse as its intermediate host, and is often referred to now as *E. granulosus equinus*. This apparently is of low pathenogenicity for man.

In a survey covering 1388 horses and ponies examined at two abattoirs in the north of England, 8.7 per cent were infected. Prevalence of infection was closely related to age, rising from zero in animals up to 2 years old to over 20 per cent of those over 8 years old.

66 per cent of the infected animals had viable cysts.

Treatment of human patients According to the FAO, *E. granulosus* and *E. multilocularis* are two of the 10 food-borne parasites with the greatest global impact. Hydatid disease is one of the rare parasitic conditions that can be treated by surgery. However, the result is often incomplete, with frequent local recurrences or accidents of secondary dissemination. Repeated interventions are often mutilating and do not guarantee a definite cure. MEBENDAZOLE is reported to have been used successfully in patients. (See also HYDATID DISEASE.)

Tapping

(See ASPIRATION.)

Tar

Recently applied tar, in the form of asphalt on roads and pavements, often causes irritation between a dog's toes, causing the animal to lick or bite the part. The tar must be removed with a bland fat or oil. Crude tar should never be used on an animal's skin. (See also PITCH POISONING.)

Tarantulas

These include the Chilean rose spider (*Grammostola spatulatus*). If found lying on its back, this creature should not be assumed to be dead, but merely moulting. In the UK, tarantulas are being kept as pets; in Australia wild tarantulas ('red-back' spiders) bite a few hundred people each year. An antivenin is available. (See also PET ANIMALS ACT 1951; PETS, CHILDREN'S AND EXOTIC.)

Tarsometatarsus Bone

The bone of the bird's lower shank between the tibia and the bones of the foot, formed by the fusion of the tarsus and metatarsus bones. It is only found in birds, and from it in some species a SPUR is produced, which is the remnants of the fifth toe.

Tarsorraphy

An operation for producing union of upper and lower eyelids. It is performed as a permanent measure after enucleation of an eyeball; and sometimes as a temporary expedient to give protection to an ulcerated or perforated cornea. (But see LENSES, CONTACT)

Tarsus

The hock. (See under BONES.)

Tartar

Tartar is the concretion that often forms upon the crowns and upon the necks of teeth, as well as

upon exposed portions of the roots. The material is of a brownish, yellowish or greyish colour, and consists chiefly of phosphate of lime which has been deposited from the saliva, making plaque, with which are mixed numerous food particles and bacteria of a harmful nature. Tartar is most often seen in the mouths of dogs and cats, although the herbivorous animals may also be affected.

It is important that the formation of tartar is prevented by feeding a suitable diet and that accumulated tartar be removed from time to time; if it is allowed to collect for an indefinite period the gums shrink before the advancing deposit, the root becomes exposed and ultimately affected, and the tooth loosens and falls out. There are, also, generally signs of systemic disturbance, such as a bad smell from the breath, indigestion from inability to feed properly and, in bad cases, great irritability and loss of condition. Prevention in CARNIVOROUS animals is provided by supplying 'meat on the bone'. The animals use their teeth to pull muscle meat off the periosteum, which allows the fibrous connections to clean their teeth. (See TEETH, DISEASES OF.)

Tasmanian Grey Cattle

An Australian breed of beef cattle, similar to the Murray Grey but developed from Aberdeen Angus and White Shorthorns.

Tassel

The WATTLE of a goat.

Tassel Foot

(See CNEMIDOCOPTIASIS.)

Taste

This special sense is dependent upon the taste buds, located in the crevices of the papillae. The taste buds have minute projections – the endings of nerve fibres. It is necessary for the purpose of taste that the substance should be dissolved in a fluid, and it seems that this is one of the functions of the saliva. The sense of taste is closely associated with the sense of smell. (See TONGUE; SMELL; JACOBSON'S ORGAN.)

Tattooing

Identifying marks or numbers may be applied to animals by tattooing. On black skins, tattooing is not an effective method, and the use of nose prints has been tried for cattle. The tattooing of dogs is widely practised in France (where it is compulsory for the Kennel Club's register of pedigree dogs), and in Canada and the USA.

Tattooing, usually in the ear, is used to identify cattle, pigs, sheep and goats. It is not entirely free from the risk of introducing infection, e.g. blackquarter, tetanus. FREEZE-BRANDING and MICROCHIPPING are alternative methods. (See also DANGEROUS DOGS ACT 1991.)

Taurine

An amino acid essential to maintain the health of cats, and which must be provided in the food. In the USA, feeding of cats on canned dog foods is reported to have led to a taurine deficiency, resulting in degeneration of the cat's retina.

However, a level of taurine in the cat's diet sufficient to prevent degeneration of the retina may be insufficient to prevent the heart disease, dilated cardiomyopathy (DCM). Most modern proprietary cat diets contain adequate amounts of taurine. It may assist in preventing FELINE LOWER URINARY TRACT DISEASE (FLUTD).

Taurine supplementation may be required for large breeds of dogs. In zoos, maned wolves (*Chrysocyon brachyurus*) require extra taurine in the diet compared to similar-sized dogs.

Taxis

Taxis is the method of pushing back into the abdominal cavity a loop of bowel which has passed through the wall as the result of a rupture or hernia.

TB

(See TUBERCULOSIS.)

T Cells

LYMPHOCYTES from the thymus gland concerned with cell-mediated immunity. (See IMMUNE RESPONSE.)

Tears

(See EYE; for 'soapy' tears, see ALGAE POISONING; see also NAPHTHALENE POISONING.)

Tear-Staining

Tear-staining of the face in the dog may be due to atopic disease or (and also in rabbits) to blockage of a lacrimal duct.

'Teart' Pastures, Soils

(See under MOLYBDENUM; 'PEAT SCOURS'.)

Teaser

(See under VASECTOMY.)

Teat Canal

One of the most important defences against bovine mastitis, as almost all infection enters the cow's udder by this route. The constant production and shedding of cells lining the canal helps to remove pathogenic bacteria. (See also MASTITIS IN COWS; ORIFICES, IMMUNITY AT.)

Teat-Cup Liner

(See under LINER, TEAT-CUP.)

VetBooks.ir

Teat Dipping

First practised by a veterinary surgeon in 1916, this has proved a useful measure for the control of mastitis in cattle. Teats are dipped, usually after milking, to help prevent streptococcal and staphylococcal infection. However, pre-milking teat dipping has been advocated as a means of reducing coliform mastitis. Results in the UK are reported as variable.

The liquid chiefly used for the purpose is an iodophor, but good results can be obtained with hypochlorite teat dips containing 1 per cent available chlorine. (See under MASTITIS IN COWS.)

Teat Necrosis

This is seen in piglets reared under intensive conditions, and is sometimes accompanied by skin necrosis affecting the limbs. Inadequate bedding and abrasive concrete may be contributory factors.

Teats, Cow's

(See under MAMMARY GLAND; also VIRAL INFECTIONS OF COWS' TEATS; MASTITIS.)

Teats, Diseases of

(See BOVINE HERPES MAMMILLITIS; TEAT NECROSIS, VIRAL INFECTIONS OF COWS' TEATS.)

Teeswater Sheep

The breed is found mainly in the Teesdale area of County Durham, Northern England. It has been established for over 200 years and is found mainly in Britain and North America. It has long-stapled wool. The Teeswater ram was crossed with the DALESBRED ewe or SWALEDALE ewe to produce the MASHAM breed.

Teeth

Teeth are highly calcified structures that penetrate the lining of the mouth. Most mammals have two sets of teeth, baby/deciduous and adult/permanent; some just have adult teeth. These are attached to the underlying bone by a sheet of periodontal ligament surrounding each tooth root. The tooth support structures and alveolar bone can be destroyed by periodontal disease (see MOUTH, DISEASES OF) causing tooth loss. Carnivores and omnivores typically have smaller, shorter and fewer teeth than herbivores, some of which have prolonged tooth growth (e.g. large animals such as horses and cattle) or continuous tooth growth (rabbits, guinea pigs and chinchillas) allowing for considerable tooth wear from prolonged chewing. Some fishes and reptiles have teeth that are fused directly to the underlying bone, and which are shed and replaced at intervals throughout life.

Tooth patterns and shapes vary, but the basic mammalian arrangement is to have three incisor teeth, one canine tooth, four premolar teeth and three molar teeth in each quadrant of the mouth, making 44 teeth in total. The number is reduced in many species; dogs typically have 42, man 32 and cats 30, although there is individual variation — expected teeth may be missing and others can be duplicated producing 'supernumerary teeth'.

Teeth developed in connection with the mucous membrane of the mouth, being actually calcified papillae. They are implanted in sockets or 'alveoli' in the upper and lower jaws, being only separated from actual contact with the bone by a layer of 'alveolar periosteum'.

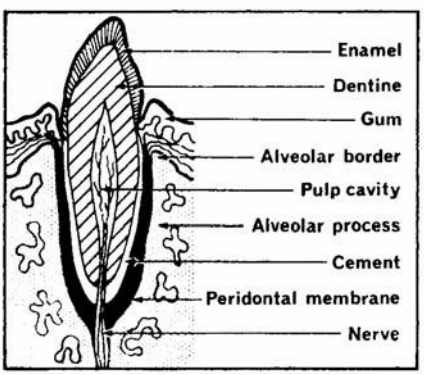
The incisors are implanted in the incisive bones of the upper jaw, and in the anterior part of the mandible; they are situated in the front of the mouth, and used for grasping and cutting. They are absent from the upper jaw of cattle, sheep, and goats, as well as other ruminating animals.

The canines are situated behind the incisors, and are used mainly for fighting purposes, being most developed in carnivores and omnivores. They are useless to the domesticated herbivorous animals, and in them are usually of small size. They are not present in the upper jaws of ruminants, and in the lower jaws have the shape and function of incisors.

The molars are the remaining teeth, situated further back in the mouth. They are used mainly for chewing, and are specially adapted for this purpose by having broad strong irregular tables or grinding surfaces. The term 'cheek teeth' is often applied to these teeth since, strictly speaking, they are composed of 'premolars', which are represented in the milk dentition, and 'molars', which are not so represented. (See DENTITION.)

Each tooth has a portion covered with enamel, the 'crown'; a portion covered with cement, the 'root'; and a line of union between these 2 parts known as the 'neck'. A constriction occurs at the neck in the temporary incisors of the horse, in the incisors of the ruminants, and in incisors and molars of the dog and cat; in the remaining teeth there is no such constriction.

Structure Teeth are described as having a crown and one or more roots, based on human dentition. Teeth consist of four tissues. In the middle of the tooth is the 'pulp', occupying the 'pulp cavity'. It is soft and gelatinous, well supplied with blood vessels and nerves, and is large in the young tooth. It nourishes the remaining tissues, and forms dentine for as long as the pulp cavity is open. In later life it is small or absent, the pulp cavity having filled with dentine formed from the pulp. The 'DENTINE' forms the bulk of the tooth. It is hard, yellowish, or yellowish-white in colour, and is surrounded in the crown by enamel, and in the root by cement. The 'enamel' consists of a comparatively thin layer of a brilliant white colour



VetBooks.ir

VetBooks.ir

and extremely dense and brittle, which forms a cap to the dentine, or, in hypsodont (high-crowned) teeth, it is arranged in layers throughout it. Carnivores and omnivores have brachydont (low-crowned) teeth. Herbivores have a mixture of hypsodont and brachydont teeth, e.g. in the horse, the incisors and the cheek teeth are hypsodont and the canines are brachyodont.

The 'cement' is always the outermost layer of a tooth, being formed on the outside of the dentine in the root, and of a bone-like tissue, filling up the irregular spaces and hollows of the crown. The implanted part of a tooth is fixed into the socket by a layer of vascular fibrous tissue, which serves as the periosteum both of the tooth root and of the lining of the alveolus. It is known as the 'alveolar periosteum'.

Enamel is the hardest tissue in the body, and consists mainly of phosphate of lime. It is composed of prisms placed side by side, with one end resting on the dentine and the other end towards the free surface in a simple tooth, such as the canine of a dog. Cement is practically of the same structure as bone, without possessing Haversian canals.

Tooth structure. (From de Coursey, *The Human Organism*, McGraw-Hill.)

Arrangement and form For times of cutting of the various teeth, see DENTITION.

Teeth, Diseases of

Most diseases or disorders affecting the teeth are associated with pain or discomfort, which results in absence of appetite, capriciousness in feeding, or other disturbances.

Irregularities In certain cases, the incisor or molar teeth develop out of their normal positions in the jaw, with the result that perfect apposition between the upper and lower teeth is not possible, and the rate of tooth wear is not uniform. In other instances, extra or 'supernumerary' teeth are formed; in the incisor region these are usually placed behind the arch of normal teeth, while extra molars may be found as projections from the gums on the inside or the outside of the line of normal teeth.

When the temporary teeth are shed, it sometimes happens that the permanent teeth erupt irregularly to one side or behind the temporaries, and are distorted accordingly. This frequently happens in puppies and, to a lesser extent, in the herbivores (cattle, sheep). In the former, trouble is likely to be experienced between 8 weeks and 5 or 6 months, and in young horses at 6 weeks and 3½ years of age. In such cases it is necessary to extract any temporaries which persist, so that the permanent teeth can arrive in their proper places in the mouth.

In dogs frequently, in sheep sometimes, and in other animals less commonly, there may be a discrepancy in length between the upper and lower jaws. When the upper jaw is too long, the condition is known as an 'overshot jaw', and when the lower jaw projects too far forward, it is popularly spoken of as an 'undershot jaw'. In bulldogs, pugs and other breeds of dogs with very short upper jaws the undershot condition is accepted as normal, while in certain breeds with extremely long upper jaws, such as the GREYHOUND and show collie, overshot jaws are very common.

Abnormal wear, which is due to malformations of the jaws, to excessive softness of the teeth, or to the direction of the teeth, is another mechanical cause of tooth disorder. (See SOIL-CONTAMINATED HERBAGE with reference to sheep.) Even though the main components of teeth, enamel and dentine, are hard, they wear away as they are used. Wear from functional use (attrition) should be quite slow in carnivores but is rapid in herbivores, particularly grass-eaters.

Abnormal wear is mainly a disorder of hypsodont teeth seen in herbivores, which are continuously erupting. This is most important in the cheek teeth of the horse, which erupt at approximately a tenth of an inch a year and in normal conditions are abraded at about the same rate by eating relatively hard silicates in herbage. Thus if a cheek tooth in as horse is lost or displaced, the tooth opposing the gap will not be worn down at the same rate as the rest of the cheek teeth in that row. The tooth will not only be worn down less but it will 'super erupt'. This creates a condition known as 'step mouth', where, instead of the teeth all being the same level, they are arranged with some higher than others, somewhat like steps.

The cheek tooth rows in the horse consist of six teeth, are continually being ground together to chew the food and are thus continuously being abraded. The cheek teeth tables are not flat but at an angle, where the buccal aspect of the upper

VetBooks.ir

cheek teeth is lower than the palatine aspect and the buccal aspect of the lower cheek teeth is higher than the lingual aspect. This creates a cheek teeth angle up to 35º in a normal horse. However, if the angle is greater than that there are problems of abnormal wear called 'shear mouth'. If the upper cheek teeth are not symmetrical with the lower cheek teeth rows in a rostral/caudal direction, there will be formation of a local dental overgrowth, as there is not accurate apposition between the rostral and caudal cheek teeth. These traditionally are known as 'hooks'. The most common foca dental overgrowths are linked with brachygnathia, commonly called 'parrot mouth' or 'overshot jaw'. The overgrowths are formed on the rostral upper cheek teeth and the lower cheek teeth. The opposite occurs with prognathia, commonly called 'sow mouth', 'monkey mouth' or 'undershot jaw'.

The horse has anisomatic cheek teeth rows. The occlusal surfaces of the upper cheek teeth rows are 25 per cent wider than the occlusal surfaces of the lower cheek tooth rows. If the diet of the horse does not contain sufficient long fibre requiring a wide excursion of the mandible during the chewing motion, sharp enamel points will be formed on the buccal aspects of the lower cheek tooth rows. These are self-perpetuating as the excursion of the mandible is then adversely affected and it will lead to cheek ulceration.

During the chewing motion the occlusal surfaces may not be worn evenly so that the occlusal surface will not be flat but will form a wave. The opposite occlusal surface will also wear unevenly as a mirror image. This is called 'wave mouth'.

Signs In most of these instances the animal affected (almost always a member of the horse tribe), instead of chewing its food and swallowing it in the usual way, rolls it round and round in the mouth until it collects into a sodden mass, often about the size of a couple of fingers, and puts it out of the mouth instead of swallowing it. (See QUIDDING) Pain may be shown when the hand is passed along the outside of the cheek, especially when pressure is put upon the line of teeth.

Quidding will also be shown by horses which have gaps between their cheek teeth, called DIASTEMA (plural diastemata). Food becomes packed into these gaps which causes gingivitis and eventual erosion of the alveolar socket. This is the most painful dental condition seen in the horse.

Treatment Rasping the teeth by means of a hand-held tooth-rasp will reduce small or minor irregularities, and bring the teeth back into their proper function. If the abnormal wear has been excessive, the correction will have to be made over time, normally at three-monthly intervals. As a rule, horses' teeth should be checked at least every 12 months. A shorter time interval should be advised in cases of more advanced dental disease, particularly in older horses. Diastemata, particularly in younger horses, which are causing quidding will need to be treated. This is usually carried out by 'widening the diastema' with a motorised burr. This has to be carried out with great care to ensure the burr does not enter the pulp cavity and cause death of the tooth. Tooth death can also be caused by excessive heat and so great care must always be taken when using motorised equipment.

Caries is **not** synonymous with tooth decay, although the term – borrowed from human dentistry – is often used in veterinary practice to include all tooth decay.

Caries is the destruction of the tooth enamel and invasion of the dentine by bacteria, which feed on carbohydrates, releasing acids which dissolve the minerals out of teeth allowing the bacteria to penetrate and destroy the inner tooth structure, resulting in the formation of a cavity. Caries cavities tend to form when there are free sugars in the diet, although starch can also support such bacteria.

Neck lesions in cats' teeth A painful condition affecting middle-aged to elderly cats, characterised by cavitation of the necks of teeth, out of sight as it is just below the gingival margin edge. This makes extraction difficult because of the risk of breakage of crowns.

Inflammations of the periosteum lining the root cavity of a tooth are common. They may be due to small particles of food getting forced down into the socket of the tooth, to fractures or fissures of the teeth, to caries, tumour formation, depositions of tartar, and to certain specific diseases, such as actinomycosis, etc.

Signs These vary from a slight redness of the gum around the root of the tooth, which is painful when pressed by the finger, to a large suppurating tract running alongside the root of the tooth down into its socket, and perhaps through the skin to the outside or into one or other of the sinuses. Abscess formation in the tooth socket may take place, and the abscess may burst into the mouth, to the outside through the skin, or up into a sinus. In many cases there is a distinct bulge of the surface above the diseased tooth, which may give to the face a one-sided appearance.

Treatment The affected tooth or teeth must be extracted, and the areas of suppuration cleansed and curetted if necessary. The cavity usually has to be packed with antiseptic gauze afterwards for a

VetBooks.ir

few days until it begins to fill by healthy granulation tissue.

Periodontal disease is a name for chronic infection of the periodontal membrane. It is one form of inflammation of the periosteum, or alveolar periostitis. It causes loosening and shedding of the teeth, pain, failure to masticate, and loss of weight. This is quite common in elderly cats and often leads to the extraction of all molars, premolars and incisors, with the retention of the canines to maintain the conformation of the jaws.

Odontomata are tumours formed in connection with the root of one tooth, or they may be found in the jaw, sinuses, or even involving part of the nasal passage, and be composite or compound, when multitudes of small rudimentary teeth are present. They cause swelling and bulging of the surface of the face, and can only be treated surgically.

'Broken mouth' is important in hill sheep. (See under 'BROKEN MOUTH'.)

Fractures of the canine teeth in dogs are not uncommon. If the pulp is exposed, subsequent infection can lead to a painful abscess. Extraction of the remainder of the tooth obviates this but, for show dogs or guard dogs, is undesirable. Metal crowns have been applied to dogs' teeth, but are liable to be dislodged. Apisectomy, or removal of the apex or end of the root of a canine tooth to seal the root canal, often acts as a successful salvage operation, even in a working dog.

Tooth transplantation has been used in veterinary practice but the results are seldom lasting, due to root resorption and bone replacement. Fracture of the transplanted tooth is likely after a couple of years or so.

Tooth deformities Teeth are easily damaged during their formation, resulting in misshapen (dilacerated) crowns or roots, or areas where the tooth surface has not formed properly. Enamel hypoplasia/dysplasia/aplasia causes partially formed, abnormally formed, or missing teeth. Similarly, the internal tooth structure may be abnormal (dentine dysplasia).

Tooth resorption is a more common cause of cavities in many species. While cats are predisposed to this, cases occur in dogs, rabbits, chinchillas and larger animals like deer and cattle. Some cases are due to inflammation but many are idiopathic (unknown cause). Resorption of the tooth surface in areas exposed in the mouth results in discomfort or pain in the sensitive dentine. Resorptions buried in the jaw and not exposed to the inside of the mouth do not appear to cause significant pain.

Tooth pulp disease Inside the tooth mineralised structure is living tissue containing nerves and blood vessels, the dental pulp. This can become damaged, infected and/or die, resulting in endodontic disease (endo = inside, odont = tooth). Injuries of the tooth can directly expose the pulp causing inflammation (pulpitis). A minor blow can disrupt the blood supply to the tooth causing it to die, with release of pigments; the tooth becomes discoloured. If not treated, infection may spread to the base of the tooth, resulting in an abscess.

Dental deposits There is a tendency for accumulation of deposits on teeth. Salivary glycoproteins attach to clean teeth creating an extremely thin layer termed pellicle. This can become stained by pigments from food. Pellicle allows the attachment of bacteria that secrete a slimy material creating DENTAL PLAQUE. Dental plaque is initially translucent, making it difficult to see, but it sometimes absorbs pigments making it visible; application of dyes (e.g. from disclosing tablets/solutions) allows it to be seen. Initially, the bacteria involved are mainly Gram-positive aerobes that do not cause significant inflammation in adjacent tissues. As undisturbed plaque matures, other bacteria become involved with a tendency for growth of Gram-negative and anaerobic organisms that act as periodontal pathogens, causing local inflammation and tissue damage (gingivitis and periodontal disease). Damage is progressive, especially if the human or animal has a weak or disordered immune system. Many bacteria die and become calcified, creating hard mineralised deposits known as DENTAL CALCULUS or TARTAR. Dental calculus is itself inert, but has a rough surface that allows further dental plaque accumulation.

Dental deposits can be prevented from becoming established by regular and thorough tooth brushing. Established dental deposits can be removed using a combination of TEETH SCALING and polishing. Antibiotics are not effective in preventing dental plaque as organisms growing in a biofilm are far less susceptible than those living planktonically (free floating in liquid).

Porphyria gives rise to a pink or brown discoloration of teeth. (See under BONE, DISEASES OF.)

Toothache common and very unpleasant. In the dog, it often rubs its mouth along the ground, paws at its nose or mouth, works its jaws, salivates, and may whine or moan. A veterinary surgeon will offer a diagnosis and initiate the necessary treatment.

VetBooks.ir

Tooth discolouration The teeth of most mammals are typically considered white, although there is considerable variation. Various things can result in discoloration including stains (almost any colour but mainly black and brown), deposits such as bacterial plaque (often difficult to detect unless the layer is thick) and tartar (dental calculus; mineralised dead dental plaque) which can be white or yellow/brown. External stains and deposits can be professionally removed and then dental hygiene measures and regular tooth brushing should help prevent return.

Internal tooth discoloration may be due to ageing (typically darkening in colour), injury with pulp death (grey/brown/purple particularly towards the tip of the tooth), metabolic disease (e.g. porphyria) and deposition or absorption of chemicals (yellow/brown teeth in dogs, cat and children given tetracyclines during tooth formation).

Teeth, Ewes', 'Trimming'

It has been estimated that between 60 per cent and 70 per cent of culling of ewes is on account of their teeth. A small percentage will involve loss of molars or incisor wear, but the vast majority will be incisor loss.

Ewes have been treated for 'bite correction' by means of an electric grinder, a practice that originated in Australia. The procedure has been strongly condemned on welfare grounds.

(See also 'BROKEN MOUTH'.)

Teeth Scaling, Dental Scaling

Deposits can be removed from teeth using a combination of scaling and polishing. Stained pellicle and immature dental plaque can be removed by tooth brushing or polishing. If dental calculus is present then the removal of the hard deposits is termed 'de-scaling' or 'scaling'. This can be done using hand instruments with small sharp blades, dental hand-scalers and curettes, and/or mechanical instruments such as sonic or ultrasonic scalers. Mechanical scalers reduce the effort required to clean off deposits but have the disadvantage, that during the scaling, an aerosol of water droplets is formed, with a variable amount of periodontal debris spattered from the patient's mouth, which may contain viruses and/or bacteria – a danger for operator, assistant, or subsequent patient unless precautions are taken. An aerosol of mouth flora can remain airborne for up to 30 minutes following scaling and can spread a significant distance.

It is recommended that: (1) the working area should be well ventilated – preferably with forced air extraction; (2) masks should be worn at all times by anyone in the working area; and (3) a 0.2 per cent chlorhexidine solution should be used as the coolant supplied to the scaling equipment.

Teflon

This is a polytetrafluoroethylene and produces fumes on heating that are given off by kitchen utensils during use. These can be lethal for birds. Bird cages must be kept away from kitchens, nor should birds be allowed to fly in kitchens. (See also 'FRYING PAN' DEATHS; 'KITCHEN DEATHS'.)

Teladorsagia

A genus of nematodes within the Family Trichostrongylidae, which was previously called OSTERTAGIA. There are three species: *Teladorsagia circumcincta* (formerly *O. circumcincta*) in sheep abomasum, *T. boreoarcticus* (muskoxen) and *T. davtiani* (Canadian Maritime sheep).

Telemetering Capsules

(See RADIO 'PILLS'.)

Telogen

The resting phase in the cycle of hair growth.

TEM

Triethylenemelemine, a gametocide which, in America, has been used in field trials for the control of birds. The chemical is mixed with corn, and has the effect of making the male bird infertile. The birds continue to defend their territories and nest, but do not produce any young.

TEME

(See THROMBOEMBOLIC MENINGOENCEPHALITIS.)

Temperament, Change in

This may follow a brain tumour or infection, as occurs in BOVINE SPONGIFORM ENCEPHALOPATHY and RABIES, for example. A horse may become bad-tempered as the result of EQUINE VERMINOUS ARTERITIS. Poisoning may cause frenzy or aggressiveness, e.g. BENZOIC ACID poisoning in the cat. (See also BRAIN DISEASES; STRESS; FUCOSIDOSIS.)

Temperature, Air

(See under HOUSING OF ANIMALS; HEAT EXHAUSTION; TROPICS, LIVESTOCK PRODUCTION IN THE.)

Temperature, Body

Body temperature is controlled by the heat-regulating centre in the brain – the hypothalamus, which also influences blood circulation, secretion of urine, and appetite – all three of which have a bearing on body temperature.

Heat is produced by the muscles and by the digestive organs, and during very cold weather or exercise, heat from the former increases, while that from the liver and other digestive organs decreases.

VetBooks.ir

The animal may also absorb heat from the sun's rays.

Heat is lost by evaporation of water, and by sensible heat loss (see under HEAT LOSS). Water loss is achieved via the lungs and the skin, e.g. by panting and sweating. (The dog is, for all practical purposes, a non-sweating animal apart from the pads of its feet, and has to rely mainly on panting.)

Diurnal variations in body temperature are normal; in the early hours of the morning it is usually at its lowest, and at its highest in the late afternoon.

For ordinary practical purposes the usual average temperatures of animals are given as follows:

Horses	38.0° C (100.5° F)
Cattle	38.9° C (102.0° F)
Sheep, goats	40.0° C (104.0° F)
Pigs	39.7° C (103.5° F)
Dogs	38.3° C (101.0° F)
Cats	38.6° C (102.0° F)
Rabbits	38.2° C (100.8° F)
Fowls	41.6° C (106.9° F)
Small birds	42.5° C (108.6° F)
Elephants	36.4° C (97.6° F)
Camels	37.5° C (99.5° F)

Temperature-taking The most satisfactory place is within the rectum. In females the thermometer may also be inserted into the external part of the genital canal; as a rule, the vaginal temperature is about half a degree higher than the rectal temperature, so that when a series of temperatures is to be taken, one site or the other should be selected.

With dogs and cats, one person should hold the animal, preferably on a table, while another inserts and holds the thermometer. In each animal, after the bulb of the thermometer has been lubricated with a little soap or Vaseline, etc., the tail is raised vertically by the left hand, and the thermometer is inserted through the anal ring and into the rectum, by a screwing movement if any resistance is encountered. It is held in position for 30 seconds, or one minute, according to the make of the thermometer, and then withdrawn. With a piece of cotton-wool any adherent faeces are wiped away, and the temperature is read off. Subsequently, the thermometer should be washed in cold water, and a cold solution of disinfectant used to disinfect it.

For purposes of temperature stress research, American scientists use a special ear thermometer in cattle. As in similar medical research, this tympanic thermometer is more reliable than the rectal thermometer, and can sense changes as small as 0.05° C (1/50° F). A device is available for cattle, which measures ruminal temperature remotely and transfers the data to a computer where it can be analysed. The temperature changes can be used to detect infection, the rise of OESTRUS and the fall at calving. (See PARTURITION.)

Temperature in disease A high temperature is one of the classic signs of fever, and in greater or less measure accompanies practically all acute cases of disease. A comparatively steady rise in temperature is as a rule succeeded by a correspondingly steady fall, and is to be looked upon as a more favourable sign of the natural course of a disease than when the temperature rises and falls with greater suddenness. The reduction of temperature in simple fevers is in almost all cases much slower than the rise. A wavering temperature, which shows little tendency to come down to normal, generally indicates that there is some active focus of disease, such as an abscess, which the body cannot overcome. A sudden rise in temperature in an animal which has shown a steady fall previously is an indication of a relapse or recurrence of the disease. (See also FEVER; HYPERTHERMIA; HEATSTROKE; TROPICS, LIVESTOCK PRODUCTION IN THE.)

A fall in temperature may be occasioned by great loss of blood, starvation, collapse, or coma; it is characteristic of certain forms of kidney disease. Certain chronic diseases in which emaciation is marked are also associated with a subnormal temperature. (See also HYPOTHERMIA.)

Temperature, near calving time A healthy cow – even though showing the familiar signs – is unlikely to calve during the next 12 hours if her temperature is 39° C (102° F). This is a useful guide to herdsmen. (See also under FEVER; HOUSING OF ANIMALS, etc.)

Temperature Control in Animal Housing

(See CONTROLLED ENVIRONMENT HOUSING.)

Temperature-Sensitive Viruses, TS Viruses

(See VACCINE.)

Tenderness

Tenderness is pain that is felt only when a diseased or injured part is handled.

Tendon

Tendon is the dense, fibrous, slightly elastic cord that attaches the end of a muscle to the bone or other structure upon which the muscle acts when it contracts. Tendons are composed of bundles of fibrous tissue, white in colour, and arranged in a very dense manner, so as to be capable of withstanding great strains. Some are rounded; some are flattened into ribbons; others are arranged

VetBooks.ir

in the form of sheets; while those of a fourth variety are very short, the muscle fibres being attached almost directly on to the bone or cartilage which they actuate. Most tendons are surrounded by sheaths lined with membrane similar to that found in joint cavities, i.e. synovial membrane. In this sheath the tendon glides smoothly over surrounding parts. The fibres of a tendon pass into the fibres of the periosteum covering a bone, and blend with them. One of the largest tendons in the animal body is the Achilles tendon, which runs from the large muscles at the back of the stifle down to the point of the hock; it is often called the 'hamstring', and is the structure that is injured in the condition known as 'hamstrung'.

Tendons, Diseases and Injuries of

(See also under MUSCLES; SPRAINED TENDONS.) In most cases the injuries to which tendons are liable are in the nature of minute lesions in which fibres have been torn across through over-extension of the tendon as a whole. Accompanying these there are often slight haemorrhages or extravasations of blood into the substance of the tendon, and the tendon itself is thickened at the injured part or, when severe, practically over the whole of its length. At the same time, a certain amount of damage has usually been sustained by the tendon sheath, or by its lining, and an unusually large amount of the lubricating synovial fluid is thrown out, which fills the tendon sheath to the point of dilatation, causing it to stand out on the surface of the limb.

When recovery occurs, the swelling subsides, fluid is absorbed, and the broken ends of the fibres become attached by strands of fibrous tissue to other intact fibres nearby. Pain disappears, and the animal becomes sound. Sometimes, however, permanent thickening results. (See also KNUCKLING.)

Certain of the tendons of the horse's limb are liable to become ruptured when subjected to great or sudden strains. Suture of the ruptured ends of the tendon has given good results when performed early, and when a sufficient amount of support can be provided by splints or other means. (See CARBON FIBRE IMPLANTS.)

Severing of tendons in dogs' legs has been successfully treated. (See also TENOSYNOVITIS.)

Tenesmus

Straining to pass urine or faeces with little or no result.

Tenosynovitis

Tenosynovitis is inflammation of the tendon and its sheath. It affects the legs of broiler chickens and is usually caused by a virus. Tendons may enlarge and cease to function. (See also SYNOVITIS.)

Tenotomy

The surgical severing of a tendon.

Tepoxalin

A new NSAID which inhibits two enzyme pathways and is, therefore, more effective in certain circumstances than the usual NSAIDs.

TEPP

Tetra-ethyl pyrophosphate, used in agriculture as a pesticide, is a potential danger to livestock. A Texas rancher diluted one volume of TEPP with water to make 120 volumes, and sprayed 20 head of cattle. All were dead within three-quarters of an hour. Signs of poisoning in a puppy comprised drowsiness, muscular incoordination and vomiting. The antidote is ATROPINE sulphate.

Teras

(See MONSTER.)

Teratogen

An agent which has effects on the dam resulting in congenital abnormalities in the offspring. It may be chemical, environmental, plant or infectious. (See TERATOGENIC.)

Teratogenic

Teratogenic agents, called teratogens, are those known to cause congenital defects when the pregnant mother is exposed to them. The most notorious is thalidomide but there are many others, not all of them drugs: alkaloids found in some plants, e.g. hemlock, viruses and radiation can all be teratogenic.

Teratoma

Teratoma is a developmental irregularity in which the embryo, instead of growing normally in the uterus, develops structural defects or, in extreme cases, develops into a seriously deformed fetus. The latter are comparatively common in cattle, and give rise to difficulty at parturition. 'Teratology' is the study of congenital deformities. (See also under TUMOURS.)

Terminal Ileitis in Hamsters

A relatively common condition. (See under ILEITIS; 'WET TAIL' IN HAMSTERS.)

Terminal Sire

A term especially used in sheep but also cattle. It often involves a ram with good meat potential serving usually a cross-bred animal developed for size and milk to produce offspring specifically designed to be raised for meat but not for breeding. In sheep, terminal sires are especially rams of the CHAROLLAIS SHEEP, SUFFOLK SHEEP and TEXEL SHEEP breeds. In cattle, terminal sires include

bulls of the CHAROLAIS, BRITISH BLUE and LIMOUSIN breeds.

Termites
Whitish, ant-like insects of the tropics. Some species feed on wood, damaging buildings.

Control Heptachlor and chlordane.

Terrapins
A small aquatic turtle, of which the diamond-backed terrapin (*Malaclemys terrapin*) or the red-eared terrapin (in USA called 'slider') (*Pseudoemys scripta*) is typical. Males are smaller than females, with the diamond-backed reaching about 14 cm (5½ in) to the female's 32 cm (9 in), and the red-eared reaching 20 cm (8 in) in the male and 32 cm (22 ins) in the female. They are popular domestic aquarium pets; however, they should be handled with care as cases of salmonella poisoning in members of households in which they are kept have occurred.

Tervueren
A breed of dog originally from Flanders. EPILEPSY has been recorded in some individual dogs.

Teschen Disease
(See TALFAN DISEASE.)

Testicle, Testis
Testicle (testis) is the essential male generative gland or gonad which, along with the epididymis and its associated structures, lies in the scrotum in each of the domesticated animals.

Normally, in the fetus or soon after birth, the testicle, guided by the fibrous cord known as the gubernaculum, moves down from a position close to the kidney to a 'cooler climate' in the scrotum. Into this it is pulled by the gubernaculum, which either fails to lengthen or actually shortens.

In some animals, e.g. foals, one or both testicles may re-ascend through the inguinal canal. This occurs occasionally in pigs, in which a returning testicle has been known to become vestigial or atrophied by the age of six months.

In certain of the wild animals, such as the rat, rabbit and chinchilla, and in many tropical animals, e.g. the elephant, the testes are found in the abdominal cavity, either permanently or temporarily between periods of sexual activity. In the foal the testes appear in the scrotum usually very soon after birth, but they are subsequently drawn up into the abdomen, and do not reappear until between 5 or 6 months and 10 to 12 months. In a certain proportion of cases the testes are retained in the abdomen until 2 years of age, and then descend into the scrotum; in a number of cases they do not descend at all. The name 'rig', or 'cryptorchid', is applied to such animals, and the condition is known as 'cryptorchidism'. (See CRYPTORCHID.)

The testis consists of a dense fibrous coat, the 'tunica albuginea'. Blood vessels run throughout the fibrous tissue, and nourish microscopic tubules, lined by layers of specialised cells which form the spermatozoa. The tubules, known as 'seminiferous tubules', are connected with each other near the centre of the testes, and communicate with the coiled tubes of the epididymis, from which the vas deferens connects with the urethra at the opposite end. In the epididymis the sperms mature. The 'SPERMATIC CORD', which consists of the vas deferens, spermatic artery, veins and nerves, enclosed in the layer of serous membrane (tunica vaginalis), passes upwards through the inguinal canal and enters the abdomen, where it runs back to the region of the neck of the urinary bladder, where it opens into the urethra. Along the course of the urethra are the openings of the ducts from the secondary sexual glands – seminal vesicles, prostate, and bulbo-urethral glands – which pour out a secretion which mixes with, nourishes and protects the masses of spermatozoa coming from the testes.

Externally, the testicle is covered by a layer of serous membrane, lying immediately outside the tunica albuginea, and known as the tunica vaginalis propria, which also covers the epididymis. On the outside of this tunic is the tunica vaginalis communis, or the parietal layer. Outside this is a fairly thick layer of scrotal fascia, in which is deposited the 'cod-fat' of the bullock and wedder. A strong reddish, fibro-elastic tunica dartos forms the next outermost layer, and provides the septum between the right and left pouches of the scrotum. Finally, on the outside, there is the practically hairless, thin, elastic, oily-feeling skin of the scrotum.

Functions The essential function of the testis is to produce sperms. (See SPERMATOZOA) Between 60 and 80 million sperms are discharged at each copulatory act by the stallion at the beginning of the breeding season. Since a stallion may serve more than 100 mares during the season, many of them upon two separate occasions, the testes are, obviously, extremely active organs, and make a considerable demand upon the vitality of the body generally. The necessity for a recuperative period in breeding males will also be obvious.

The other function of the testis is that associated with the male sex-hormones, which produce the secondary sexual characteristics, such as the arched neck and great body size of the stallion, the broad forehead, massive development of horns, and deep voice of the bull, the horns of the ram, and the tusks of the boar, etc., as well as the desire for sexual intercourse. The chief hormone is testosterone.

VetBooks.ir

(See also REPRODUCTION; ENDOCRINE GLANDS; ARTIFICIAL INSEMINATION.)

Testicle, Diseases of

During service, an irritable mare may kick a stallion and rupture one of the testes, or seriously injure it. Damage may also be occasioned to these organs by the bites of dogs when fighting, by gores from cattle, or by injuries from the tusks of boars, gunshots, etc. However, infection is probably most common.

Orchitis, or inflammation of the testis, may be the result of infection (e.g. by *Actinobacillus seminis*, *Brucella abortus*, *B. suis*, *Corynebacterium pseudotuberculosis*, tuberculosis) or of trauma which – if the skin is broken – may itself lead to infection. Necrotic orchitis in the bull has been caused in Britain by actinobacillosis. The testis, being enclosed in a fibrous, comparatively non-elastic capsule, is not able to swell to a great extent, although the loose tissues of the scrotum often do. The scrotum becomes reddened in animals which have unpigmented skin in the inguinal region, and the whole area is very painful to the touch.

In rabbits, abscessation of the testicle is commonly encountered after fights between rival bucks, due to infection with the ubiquitous *Pasteurella multocida*.

Treatment Antibiotics or other therapy may be needed to deal with an infection. However, castration may be necessary to prevent infection spreading internally.

Epididimytis (See under main dictionary heading and RAM EPIDIDYMITIS.)

Hydrocele is a local oedema affecting usually one tunica vaginalis, and distending that side of the scrotum with fluid, but painless. It is most frequently encountered in the dog, although it may affect other animals.

Hypoplasia (See under INFERTILITY.)

Tumours affecting the testicle and/or scrotum include CARCINOMA, SARCOMA, FIBROMA, PAPILLOMA, SEMINOMA and SERTOLI-CELL TUMOUR.

Torsion (See under SPERMATIC CORD, TORSION OF.)

Testosterone

The hormone, secreted by the testicle, which controls development of the secondary sex organs, sex characteristics and libido. (See ENDOCRINE GLANDS; HORMONES.)

Tests

(See LABORATORY TESTS.)

Tetanus, Lockjaw

Tetanus (lockjaw) is a specific disease of the domesticated animals and man, caused by *Clostridium tetani*, which obtains access to the tissues through a wound. Horses are most commonly affected. The organism is present in most cultivated soils, especially those that have received heavy dressings of farmyard manure.

In certain districts, tetanus is so common that it is usual to take precautions by inoculating horses with antitoxin whenever they receive even comparatively slight wounds, and always before castration or major operations. Unvaccinated lambs born to unvaccinated ewes are lost each year after docking and castration, or before the umbilicus (navel) has closed after birth, from tetanus.

Cl. tetani is an anaerobe, i.e. it thrives only in an absence of oxygen. Its serious effects are produced by a toxin, which is absorbed into the general circulation and exerts its effects upon the nervous system of the brain and spinal cord. This toxin is one of the most powerful known.

Deeply punctured wounds, from which oxygen is excluded, are much more serious than even large superficial wounds, the surfaces of which are exposed to the action of sunlight and fresh air. Wounds from picked-up nail wounds, cracked heels, injuries from the tines of stable-forks, pitch forks, etc., are examples of wounds which often become contaminated with *Cl. tetani*. Tetanus may occur in an animal which has had a slight wound which appeared to heal without any complication. It may follow tattooing. Cases are encountered where no wound can be found on the surface of the body, nor is there any history of an accident; such cases are probably the sequel to injuries inflicted by worms in the intestinal wall, or to slight scratches from unusually hard or rough herbage.

Intramuscular injections are a potential route of infection when sterile precautions are neglected.

Signs

Horses become stiff and disinclined to move. There is difficulty in turning the head round to the side, and the fore-legs are splayed outwards as though to enable the unfortunate animal better to retain its balance.

The ears may be turned in towards each other.

If the head is lifted sharply up, by placing the hand under the chin, the haw or third eyelid (nictitating membrane) is seen to flicker across the eye to an extent much greater than usual.

Fixed clenching of the jaws, or trismus, which has been responsible for the popular name given to

VetBooks.ir

tetanus (i.e. lockjaw), is not always in evidence in the early stages of an attack.

The tail may be held out quivering and OPISTHOTONOS may be evident.

During the course of an attack, faeces and urine are usually withheld, and digestive disturbances may occur, sometimes resulting in fatal collections of gas in the large intestines.

(See HYPERAESTHESIA.)

Cattle Early signs include a raising of the tail-head and, in some cases, bloat. The gait becomes stiff and the animal may have difficulty in feeding because it cannot easily lower its head because of stiffness in the neck. Trismus (lockjaw) is a late sign. Tetanus in cattle is not, however, at all common; occasionally outbreaks occur, possibly due to rough, abrasive feed which allows entry of the infection through the gut.

Sheep The signs are similar to those in cattle. As the disease progresses, standing is difficult; the affected animals lie on their sides, rapidly become tympanitic, and die after a very short illness. In lambs after castration or docking, the disease is very rapid in its effects, and several are affected at the same time.

Pigs Tetanus is not common.

Dogs The owner may notice something peculiar about the eyes and mouth, and either stiffness or recent lameness. Later, the limbs are usually stretched out as far from each other as possible, in a sawhorse position. Squinting and grinning are common, but closure of the jaws is not always in evidence. When it is present it is complete, and death practically always follows. Hyperaesthesia is also very marked. The ears may be bent inwards (as in the horse).

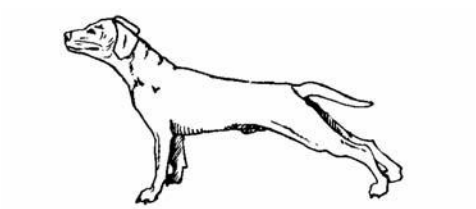


Diagram of attitude assumed by a dog affected with tetanus. The hind-limbs are kept well out behind the body, the tail is held rigidly or quivering, and the muscles of the face are drawn into a sardonic grin – the *'risus sardonicus'* of ancient authors.

Treatment Farm animals should be placed in a darkened loose-box, away from noise, and with food and water placed at a new level which they can reach despite their stiffness.

If nursed at home, a dog should be in a room where there are no bright lights, noise, television, or family activity.

Tetanus antiserum, penicillin and muscle relaxants (such as acepromazine, which can obviate exhaustion and save life) are all needed. Treatment must also include glucose saline injections, e.g. in a dog which cannot drink or eat; and large animals similarly. (See DEHYDRATION, NORMAL SALINE.)

Prevention Vaccination is effective, and should be used in all horses, sheep, goats and camelids as the infection is common worldwide. Injection of pregnant dams will allow antibodies in the colostrum to be passed to the offspring so that when it is ingested passive immunity will be provided to the offspring. On land where tetanus is rife, cattle should also be immunised.

Lambs are given antitoxin on the day of docking or castration. Vaccine can be injected at a different site on the same occasion.

Horses The usual practice is to give 2 injections at an interval of 4 to 6 weeks, with a booster dose 6 or 12 months later. Further booster doses may be required. It is practicable to vaccinate pregnant mares so that later their newborn foals will be protected against tetanus infection via the navel. (See also under IMMUNITY.)

Prognosis In the absence of first-class nursing and intensive care, not many animals (other than cattle) recover from tetanus.

If an animal regains the ability to drink, that can be regarded as a favourable sign.

Tetanus Antitoxin (TAT)

(See ANTITETANIC SERUM.)

Tetany

Tetany is a condition in which localised spasmodic contraction of muscles takes place. There may be twitching or convulsions. Tetany occurs when the level of blood calcium falls below normal. (See also under PARATHYROID GLANDS; HYPOMAGNESAEMIA; TRANSIT TETANY; MILK FEVER; RABIES.)

Tethering

The Cruel Tethering Act 1988 made it illegal to tether a horse, ass or mule in such a way as to cause suffering. The animal must have enough to eat and be supplied with fresh water regularly. The tether must not be able to cause injury, e.g. by being too tight or too short. This is now covered by the Animal Welfare Act 2006. These acts cover unnecessary suffering, supply of feed and water and the question of the tether causing harm. In

some situations, abandonment may be considered. In comparison with free-range horses, those tethered were more likely to have eye lesions, vertical hoof cracks, lameness and limb pain, and less likely to have a low condition score or tangled mane and tail. In the same study tethered horses were less likely to have shelter or access to water.

Tetracyclines

Tetracyclines are bacteriostatic antibiotics with a wide range of activity which includes Gram-positive and Gram-negative bacteria, certain protozoa, Rickettsia, and Mycoplasma. Tetracyclines are absorbed from the gut, but oral administration may upset the gut flora. They are irritant when injected.

Tetracyclines cause fluorescence in bone and teeth. In late pregnancy or in young growing animals, high dosage can result in teeth discoloration and can interfere with the formation of enamel. (See CHLORTETRACYCLINE, DOXYCYCLINE, OXYTETRACYCLINE.)

Tetrahydrozoline

(See IMIDAZOLINE COMPOUNDS.)

Tetrahymena

A transparent and nearly invisible protozoan living in water. It is able to digest and so remove *Listeria monocytogenes*. It can also ingest but not digest *Salmonella* spp.

Tetraiodophenolphthalein

Tetraiodophenolphthalein is used in radiography of the gall-bladder and bile-ducts for diagnostic purposes.

Tetralogy of Fallot

A complex congenital heart condition which consists of:

1. stenosis of the pulmonary valve;
2. a defect of the septum which separates the two ventricles;
3. the aorta overriding both ventricles;
4. marked hypertrophy of the right ventricle.

The condition can occur in all species but is rare and the signs can be quite vague, for example, in kittens there may be failure to thrive and inability to cope with exercise. More serious defects result in death of the animals soon after birth. The incidence is high in some dog breeds such as KEESHONDS.

Tetraplegia
(adjective, Tetraplegic)

(See QUADRIPLEGIA.)

Tetrapyrroles

Compounds containing four pyrrole rings. They can have three carbon bridges (linear tetrapyrroles - bilanes) such as HAEM breakdown products (BILIRUBIN); and phycobilins (found in CYANOBACTERIA) of four carbon bridges (cyclic tetrapyrroles) for example PORPHYRINS (HAEM); chlorines (CHLOROPHYLL); and corrins that have three carbon bridges and a direct connection between two pyrrole rings.

Texas Fever

Texas fever is a tick-borne disease. (See BABESIA - BABESIOSIS.)

Signs Stained urine (red-water), high temperature, no appetite, and constipation followed by diarrhoea. Cerebral signs may be evident. The animal dies within three to 10 days. On post-mortem examination the blood is bright red and abnormally fluid, while the tissues are paler. The spleen is enlarged from two to four times its normal size and is reddish-brown ('anthrax spleen'). The liver is swollen and pale and the gall-bladder is distended with thick, viscid, dark-coloured bile. The muscles are normal.

The chronic form is similar but milder, and occurs in late autumn. Recovery is frequent, but convalescence is long (although it is stated to be very short in Argentine cattle).

Treatment is fairly effective. Imidocarb is one of several proprietary preparations that have replaced the trypan blue formerly used.

Transmission is by the following ticks:
Boophilus (Margaropus) annulatus (North America)
B. microplus (South America)
B. australis (many countries)
B. argentinus (South America)
B. calcaratus (Asia)
B. decoloratus (South Africa)
Rhipicephalus appendiculatus (South Africa)
R. evertsi (South Africa)
R. bursa (North Africa)
Haemaphysalis punctata (Europe)

Texel Sheep

A Dutch breed of sheep from Texel, and the most common breed in Europe. Noted for its milk production, it has good growth rate and meat potential. It has a white fleece with no wool on head or legs and no horns. It has a white face with a black nose. It is thick set and used as a TERMINAL SIRE for meat, fleece weight is 3.5 kg to 5.5 kg.

TGE

(See TRANSMISSIBLE GASTROENTERITIS OF PIGS.)

Thalamus
A part of the brain consisting of two large ovoid structures at the base of the cerebrum. (See under BRAIN.)

Thallium (Tl)
Thallium sulphate has been used in poison baits to destroy rats, ants and other pests, and accidental poisoning in domestic animals may occur. Less dangerous substances have largely replaced it. Thallium poisoning in dogs gives rise to gastroenteritis, profuse vomiting and severe pain. If death does not immediately follow, there may be a brick-red discoloration of lips, skin of groin or axilla. Hair begins to fall out. In human medicine, thallium poisoning has been successfully treated with prussian-blue.

Theave
A sheep between first and second shearing. (See under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC.)

Theileriosis
Infection with tick-borne parasites of the *Theileridae*.

The parasites vary in shape, some being spherical, others ovoid, pear-shaped, or elongated rod-like. Division by binary fission within the blood corpuscle may occur. Sexual multiplication occurs within the tick which transmits the parasite when it bites a new host.

There are several species in cattle and in sheep, including:

T. parva (EAST COAST FEVER in tropical Africa).

T. mutans (Benign bovine theileriosis).

T. lawrencei, causing CORRIDOR DISEASE.

T. annulata, causing MEDITERRANEAN FEVER.

(See also TZANEEN DISEASE.)

Theileriosis of Goats and Sheep
(See MALIGNANT THEILERIOSIS OF SHEEP AND GOATS.)

Theine
Theine is the alkaloid which gives its stimulant properties to tea. It is the equivalent of CAFFEINE.

Thelazia
(See EYEWORMS.)

Theobromine
Theobromine is the alkaloid upon which the stimulant action of cocoa and chocolate depends. It stimulates heart muscle and the central nervous system, causing increased activity and raised heart rate. Horses fed a supplement of vitamins and minerals incorporated in a material containing ground cocoa shells have tested positive for this alkaloid. CHOCOLATE POISONING is not uncommon in dogs.

Theophylline
A stimulant found naturally in tea leaves. It is available in tablet form for the treatment of BRONCHITIS and CONGESTIVE HEART FAILURE in dogs.

Thermography
The mapping of temperature over surfaces. Infra-red thermography, using a camera, has been tested in the diagnosis of orthopaedic lesions in horses.

Thermolabile
Subject to the loss of characteristic properties when heated.

Thiabendazole
This was the first of the benzimidazoles to become widely available in the 1960s in the UK for farm animals. (See ANTHELMINTICS.)

Thiamazole
A product licensed for the stabilisation of feline hyperthyroidism. Prior to surgery or for the long-term treatment of hyperthyroidism. It controls the production of thyroxine and triiodothyronine.

Thiamin, Thiamine
Thiamine hydrochloride, or vitamin B_1. A secondary deficiency occurs in bracken poisoning and horse-tails poisoning in horses, and in pigs due to the enzyme, thiaminase. Thiaminase-producing bacteria have been isolated from sheep dying from polioencephalomalacia (cerebro-cortical necrosis (CNN)). (See also 'CHASTEK PARALYSIS'.)

Thiaminase is present to a varying degree in raw fish. Accordingly, fish should be cooked before it is fed to cats, etc.

Signs of thiamin deficiency include loss of appetite, a staggering gait and muscular spasms.

Treatment Thiamin injections are often effective in CCN.

Thin Layer Chromatography (TLC)
A technique widely used to separate out mixtures of different substances. It is performed using a sheet of plastic, glass or aluminium foil coated with a thin layer of absorbent material such as silica gel, aluminium oxide or cellulose (blotting paper). The technique is usually used to identify compounds present in a mixture or to establish the purity of a substance.

VetBooks.ir

VetBooks.ir

Thin Sow Syndrome

Groups of sows or gilts lose weight, usually in the middle or later stages of pregnancy, and remain emaciated for perhaps six months or more. Prolonged under-feeding may eventually result in some sows being unable to cope with adverse conditions encountered at times of stress, e.g. weaning. It has also been suggested that infestation with the stomach worm *Hyostrongylus* or with the nodular worm *Oesophagostomum* may be a cause. The use of sow stalls, in which animals cannot move away to escape draughts, is another possible cause.

Thiocyanate

A relatively non-toxic salt, which is similar to cyanide but contains sulphur instead of oxygen. It is produced in the body as a detoxicating mechanism. It occurs in brassicas and continued ingestion by herbivores (ruminants, tortoises) can cause toxicity by producing GOITRE.

Thiopental

This was a widely used anaesthetic for horses, dogs and cats but has been superseded by more modern anaesthetics. It is administered intravenously, as an aqueous solution of the sodium salt; other routes cause necrosis of the tissues.

Thiophanate

A benzimidazole anthelmintic not now available in the EU and USA.

Thiostrepton

An antibiotic used as a topical application for the treatment of conditions involving such bacteria as *E. coli*, *Pseudomonas* spp. and *Proteus* spp.

Thiouracil

An antithyroid agent which lowers the rate of metabolism by inhibiting the oxidation of iodine thus preventing the formation of THYROXINE. It has been used as a growth promoter; such use is banned in the EU. It has used as a thyroid depressant in HYPERTHYROIDISM.

Thiourea

A goitrogenic agent whose action on the thyroid is the same as for THIOURACIL. It is used in industry as a photographic fixative. It is also known as naphythyl antu, a rat poison, which causes oedema of the lungs. It is dangerous to domestic animals and birds.

Thirst

(See WATER AND WATERING OF ANIMALS; DIABETES MELLITUS; SALT POISONING; COMPULSIVE POLYDIPSIA.)

Thogoto Virus

Thogoto virus is a cause of abortion in ewes in Africa. It was first isolated from a tick, *Rhipicephalus appendiculatus*, near Thogoto in Kenya. In one flock of some 600 Dorper ewes, more than 200 aborted over a two-month period.

Thoracic Duct

The thoracic duct is the large lymph vessel which collects the contents of the lymphatics proceeding from the abdomen, hind-limbs, part of the thorax, etc., and which discharges its contents into the left innominate vein. (See aspiration under PARACENTESIS.)

Thoracocentesis

Draining off from the thorax of the fluid found in certain diseases of the chest. (See aspiration under PARACENTESIS.)

Thoracopagus

A congenital abnormality where two malformed fetuses joined at the thorax.

Thoracoschisis

A congenital fissure in the chest wall. (See CHEST.)

Thoracotomy

A surgical operation involving opening of the chest cavity.

Thorax

(See CHEST.)

Thorn Apple

(See STRAMONIUM.)

Thoroughbred Horses

This is the breed used for racing. All thoroughbreds are descended from three famous Middle Eastern sires, bought to England in the 17th and 18th centuries. The thoroughbred stud book is closed and no artificial insemination is allowed. Thoroughbreds are normally 15 to 17 HANDS high. They are commonly bay, chestnut or grey in colour, although black animals are sometimes seen. They normally start racing at about two-years-old. The Derby is a race for three-year-olds. All animals are said to be born on 1 January of the year in which they are born. Therefore, in the UK, thoroughbred breeders try to breed foals as early as possible in the year so that they are well developed as soon as they are sold or start to race. The stud season historically starts on St Valentine's day (14 February).

Thorough-Pin

Thorough-pin is a distension of the sheath of the deep flexor tendon in horses and ponies where it

VetBooks.ir

passes over the arch of the tarsus (hock). It is characterised by swellings, one on either side of the hock, about the level of the 'point of the hock' (summit of the tuber calcis), and lying in front of the strong Achilles tendon.

Thread-Worm

Thread-worm is a popular term for *oxyuris* worms. (See ROUNDWORMS.)

Three-Day Sickness

(See EPHEMERAL FEVER.)

Threonine

One of the essential amino acids. It is found in low quantities in feed ingredients of plant origin. It is an important component of collagen and elastin fibres.

Throat

(See PHARYNX; also under LARYNX; NOSE AND NASAL PASSAGES.)

Throat diseases Most of these will be found under separate headings such as choking; larynx, diseases of; tonsillitis. For 'sore throat', see PHARYNGITIS.

Thrombasthenia

This is a rare, congenital disorder of the blood, occurring in man and dogs, in both sexes (compare HAEMOPHILIA). It arises from a defect of the platelets, and gives rise to prolonged bleeding resulting in anaemia. It has been described in foxhounds, otterhounds, etc.

Thrombiculosis

Infestation with mites from the Family *Thrombiculidae*. The most common is *Neotrombicula autumnalis* (formerly *Thrombicula autumnali*), the HARVEST MITE. Their orange larvae parasitise animals, man and some ground nesting birds, and may also cause CANINE SEASONAL ILLNESS (See MITES, PARASITIC.)

Thrombocyte

These are the blood PLATELETS that are involved in clotting. (See BLOOD.)

Thrombocytopenia

A condition of the blood in which the number of platelets is below normal. Causes include viral infections, poisoning, auto-immune disease. The signs may include petechial haemorrhages and fever.

Thromboembolic Meningoencephalitis (TEME)

An infection caused by *Histophilus somni* (previously *Haemophilus somnus*) in growing calves, resulting in them appearing dull, sleepy and usually dying. It is often called the 'SLEEPER' SYNDROME.

Thromboembolism

The formation of a blood clot (THROMBUS) which detaches itself from its point of formation and then moves on to other blood vessels, where it lodges when it cannot pass through them. The sites vary but can be the brain, heart, lungs, kidney, limbs or other tissues or organs. This then plugs the circulation to part or all of an organ (an EMBOLISM) and can lead to other signs. The damage depend on whether or not there is a sufficient COLLATERAL CIRCULATION. If there is any infection in the blood clot, it will also be spread to the other organ(s).

Thrombopathia

A coagulation disorder caused by a failure of ADENOSINE DIPHOSPHATE release from blood platelets. A condition seen in BASSET HOUNDS.

Thrombosis

The blocking of a blood vessel by a blood clot. It may follow atheroma, or some injury to the vessel. In cats, thrombosis of the femoral arteries is by no means rare, and causes paralysis of the hind-legs and often pain. There is complete absence of pulse in the arteries. In dogs, thrombosis of the iliac and femoral arteries occurs occasionally. Euthanasia is nearly always necessary. (See also PARAPLEGIA.)

Aortic-iliac thrombosis is seen in the horse; the worm *Strongylus vulgaris* may be a cause.

Thrombosis of a blood vessel in the brain is a cause of apoplexy (in human medicine a stroke). (For thrombosis of the vena cava in cattle, see under VENA CAVA) (See also under ANTICOAGULANTS.)

Thrombus

A blood clot in a blood vessel or the heart.

Thunderstorms

Most animals used to living outside are usually unaffected by storms. The main exception is some horses which can become overanxious and excited. There is no complete answer to this, but it is probably best to keep the animals where they are most familiar. Horses used to being stabled should be placed in their familiar surroundings. Staying with them can also be helpful provided the person is calm. Some pets have problems, particularly dogs because of their exceptional hearing. If the owner knows that their animals are susceptible, they should be kept in a familiar place which is quiet and preferably relatively dark where they cannot cause damage or injure themselves. Sedatives can be used but it is better to try and accustom animals to the noises by means of

specific CDs. (See also CHINESE LANTERNS; FIREWORKS; LIGHTNING STRIKE.)

Thymine
One of the pyrimidine bases of DNA.

Thymus Gland
Situated in the anterior part of the chest cavity, and along the trachea in birds, this gland attains its largest size during early life and thereafter gradually dwindles in mammals as they mature. However, it is still prominent in adult rabbits. It has a role in immunity, as it removes young T-cells that happen to recognise the body's own components as foreign. Failure of this function can result in auto-immune disease. (See T CELLS, which are thymus derived; also LEUKAEMIA.)

Thyroid Cartilage
The thyroid cartilage is the largest cartilage of the larynx, and forms a well-marked prominence at the upper end of the trachea. It gives attachment to one end of each of the vocal folds, which are concerned in the production of voice. (See LARYNX.)

Thyroidectomy
The surgical removal of all or part of the thyroid gland and undertaken in hyperthyroidism. (See under HYPERTHYROIDISM, THYROID GLAND, DISEASES OF.)

Thyroid Gland
This is a very highly vascular ENDOCRINE GLAND, situated near the thyroid cartilage of the larynx. The gland usually consists of two lobes, one on either side of the larynx, joined by an isthmus in some species and individuals.

Located within or near the thyroid gland are the PARATHYROID GLANDS.

Minute structure Each lobe is enveloped in a thin capsule of fibrous tissue, strands from which pass into the organ, dividing it into lobules.

Function The most important hormone secreted by the thyroid gland is an iodine-containing compound called thyroxin. This increases the rate of metabolism, and is released when an animal is exposed to cold, for example. In hot weather, thyroid activity is reduced. Thyroxin is essential for growth and reproduction, and influences lactation.

Secretion of the hormone is controlled wholly or in part by a hormone from the anterior lobe of the pituitary gland. (See also PARATHYROID GLANDS.)

Thyroid Gland, Diseases of
Enlargement of the thyroid gland is known as GOITRE. Goitre may occur when there is either too little or too much of the thyroid hormone, thyroxin, produced.

Dwarfism in young animals (cretinism) can result from failure of the gland to produce sufficient thyroxin.

Hypothyroidism An insufficiency of thyroxin is known as hypothyroidism, and may be associated with insufficiency of iodine in the diet (see GOITRE). The rate of metabolism is slowed, while there is an increase in body weight, loss of hair, and lethargy.

One form of hypothyroidism, MYXOEDEMA, affects the skin, causing its deterioration.

Treatment includes the use of thyroid extract; and iodides if appropriate.

Hyperthyroidism, or excess thyroxin in the blood, is characterised by loss of weight, sometimes an increase in appetite, polyuria, thirst, increased rate of metabolism and heartbeat. Enlargement of the gland may be detected on palpation. The animal may become restless or irritable. Protrusion of the eyeballs (exophthalmic goitre) may occur.

Hyperthyroidism is seen in elderly cats. They are mostly thin, and it is this loss of weight which causes the owner to seek veterinary advice in many instances. In addition to the signs mentioned above, diarrhoea may occur.

Treatment is surgical: removal of one gland, or ligation of the anterior arteries; alternatively, the use of drugs such as sodium fluoride or methylthiouracil.

Tumours of the gland include ADENOMA; sarcoma and carcinoma (see under CANCER), and EPITHELIOMA).

Thyroxine (T4)
The chemical name is tetraiodothyroxine (T4); it is the active principle of the THYROID GLAND. It contains IODINE and is a derivative of the amino acid TYROSINE. It is used in pharmaceutical preparations to correct hypothyroidism, a common endocrine deficiency in dogs.

Tiamulin
A MACROLIDE antibiotic active against *Treponema hyodysenteriae* (swine dysentery), various Gram-positive organisms, and *Mycoplasma hyosinoviae* (a cause of arthritis in pigs). It must not be used at the same time as MONENSIN SODIUM or SALINOMYCIN.

Tiapost
A semi-synthetic prostaglandin preparation used to induce parturition in sows. It should not be administered before the 111th day of pregnancy.

VetBooks.ir

Tibetan Terrier
A small breed of dog in which LENS LUXATION and PROGRESSIVE RETINAL ATROPHY are inherited as recessive genes.

Tibia
The tibia is the larger of the two bones which lie between the stifle and the hock. In animals which possess fewer than five digits in their hind-limbs, the tibia has become modified so that it sustains the greater part of the weight borne by the limb – the fibula, its complementary bone, having become reduced in size and importance. The tibia lies just below the skin on the inside of the limb, in such a position that it is liable to be injured by kicks, blows, etc., and in this connection is of more importance than those bones that are surrounded by massive muscles which afford some protection. It is not uncommon for the tibia to become fractured, but the parts remain held together by the very dense periosteum that covers the bone. In the smaller animals, the setting of the fractured bone is a routine. (See BONES; FRACTURES.)

Tibial dyschondroplasia A crippling deformity occurring in certain strains of chickens, ducks, and turkeys selected for high growth rates. It is due to a cartilage abnormality.

Tibial Hemimelia
The complete or partial absence of the tibia. It can occur in all species but is reported in the GALLOWAY and BEEF SHORTHORN breeds of cattle.

Tick-Bite Fever of Man in Africa

Cause A RICKETTSIA. Local reactions and swelling of lymph nodes occur in some individuals. So far as is known, tick-bite fever is not fatal.

The bont tick, bont-legged blue tick, yellow dog tick, and the brown tick – all common in East Africa – transmit this disease. It can be transmitted to the guinea-pig by inoculation of blood.

Tick-Borne Encephalitis (TBE)
A meningoencephalitis following infection by a flavivirus transmitted by the sheep/cattle tick *Ixodes ricinus*. The ticks become infected by field mice, voles, shrews and, occasionally, moles. It occurs throughout continental Europe, being especially prevalent in mountainous regions with coniferous forests. It is more common in humans than in animals, but the infection in dogs has been confused with rabies.

The human illness resembles influenza in its signs, with a high fever. This may be followed by meningitis. Mortality is about 1 per cent.

In differential diagnosis, the flavivirus causing TBE has to be distinguished from louping-ill virus.

Tick-Borne Fever in Deer
The disease occurs but is usually less severe than in cattle unless the animal is debilitated.

Tick-Borne Fever of Cattle
Tick-borne fever of cattle is caused by *Cytoecetes (Erlichia) phagocytophila*, transmitted by the common sheep tick, *Ixodes ricinus*. Signs of this infection are high but transient fever, and a considerable reduction in milk yield. Abortion may also occur. Oxytetracycline is used in treatment. (Red-water, caused by *Babesia divergens*, often occurs simultaneously.)

Tick-Borne Fever of Deer
The disease occurs but is usually less severe than in cattle unless the animal is debilitated.

Tick-Borne Fever of Sheep
Tick-borne fever of sheep is a disease caused by *Cytoecetes phagocytophila* transmitted by the tick *Ixodes ricinus*.

Tick-borne fever is a mild febrile disease of sheep in which the essential sign is a rise in temperature occurring after an incubation period of four to eight days, and lasting about 10 days, when it subsides. During this period (which may be prolonged) there is dullness and listlessness, and a considerable loss of weight may occur. Death occurs in only a small percentage of cases; most sheep recover unless some other complicating condition such as louping-ill supervenes. Abortion is an important result of infection in many instances, and may affect 50 per cent of breeding stock introduced from tick-free areas.

Rickettsiae can be demonstrated in the polymorphonuclear white cells of the blood.

The importance of tick-borne fever is that it is capable of rendering the vasculo-meningeal barrier of the central nervous system vulnerable to the virus of louping-ill. Without its presence, though the louping-ill virus may be introduced into the bloodstream (by the bite of a tick), it cannot pass this barrier to attack the nerve cells and so produce the typical nervous signs. It has been shown that both infective agents – that of tick-borne fever and of louping-ill – frequently exist together in ticks found on animals on farms where louping-ill is common, and it is probable that under natural conditions the great majority of adult sheep on such farms have been infected with tick-borne fever infection and have recovered.

Tick-borne fever increases the susceptibility of lambs to tick pyaemia, often caused by infection with *Staphylococcus aureus* following tick bites.

Abscesses occur in the joints and elsewhere, causing lameness, unthriftiness and death.

Tick Paralysis

Tick paralysis affects man, cattle, sheep, horses, pigs, dogs, cats and poultry.

It occurs in Africa, Australia, and Canada, and is caused by the presence on the animal of various species of *Ixodes* (especially the dog tick) in South Africa and Australia, and *Dermacentor* in America. In East Africa, the bont-legged tick (*Hyalomma spp.*) and possibly the Red tick (*Rhipicephalus evertsi*) cause paralysis.

The paralysis is caused by toxin(s) present in the saliva of ticks.

In human beings, three or four days after the ticks attach themselves, paralysis of the legs occurs, then paralysis of the arms takes place, later the chest and neck become involved and, ultimately, the heart and respiratory centres are attacked. In the sheep, the parts are affected in the same general sequence.

This form of paralysis is peculiar in that signs disappear within two to six days after the ticks are removed, and recovery takes place subsequently. Individual lambs, for example, can be reinfected and recover more than once, if the ticks are removed by hand. They are usually not easily seen unless a deliberate search is made in the wool over the vertebral column from the base of the skull back to the tail.

In the dog, they may cause QUADRIPLEGIA.

Tick Pyaemia

(See TICKS; TICK-BORNE FEVER OF SHEEP.)

Ticks

These are among the most serious parasites of domestic animals. In the tropics they transmit bacterial, protozoal and viral diseases; in the UK, tick-borne fever, red-water fever and louping-ill. Tick pyaemia is caused in sheep by the transfer of staphylococcal infection. Lyme disease is considered to be partly tick spread.

Common Ticks of East Africa

Tick Species	Number of Hosts	Preferred site of attachment	Animal affected	Parasite	Disease transmitted
Brown-ear tick (*Rhipicephalus appendiculatus*)	3	Ears, base of horns, around eyes, tail brush, and heels	Cattle Cattle Cattle Cattle Sheep and goats Sheep, cattle, and goats Man	*Theileria parva* *Theileria lawrencei* *Theileria mutans* *Babesia bigemina* *Virus* *Rickettsia*	East Coast fever Corridor disease Mild gall-sickness Red-water Nairobi sheep disease Louping-ill Tick-bite fever
Red-legged tick (*Rhipicephalus evertsi*)	2	Larvae and nymphae in ears Adults perineal region	Cattle Cattle Cattle Horses Cattle, horses, sheep, and goats Lambs	*Babesia bigemina* *Theileria parva* *Theileria mutans* *Babesia nuttali* *Babesia caballi* *Spirochaeta theileri* *?Tick toxin*	Red-water East Coast fever Mild gall-sickness Biliary fever Spirochaetosis ?Paralysis
Yellow dog tick (*Haemaphysalis leach*)	3	Whole body	Dogs Man and animals Man	*Babesia canis* *Virus* *Rickettsia*	Biliary fever Q fever Tick-bite fever
Blue tick (*Boophilus decoloratus*)	1	Face, neck, dewlap, and sides of the body	Cattle Cattle Man Horses, cattle, goats and sheep	*Babesia bigemina* *Anaplasma marginale* *Rickettsia* *Spirochaeta theileri*	Red-water Gall-sickness Tick-bite fever
Bont tick (*Amblyomma* spp.)	3	Larvae and nymphae on head and ears Nymphae and adults on perineum, udder, scrotum, and tail	Cattle/Sheep/Goats Sheep Man and animals Man	*Rickettsia ruminantium* *Virus* *Virus* *Rickettsia*	Heartwater Nairobi sheep disease Q fever Tick-bite fever
Bont-legged tick (*Hyalomma* spp.)	2 or 3	Adults on perineum, udder, scrotum, and tail brush	Cattle, sheep, goats, and pigs Man and animals Man Man	*Tick toxin* *Virus* *Tick toxin* *Rickettsia*	Sweating sickness Q fever Tick paralysis Tick-bite fever

T

Some cause illness by means of a toxin, while all feed on the host's blood – which can result in a serious anaemia. Large numbers of ticks also worry the host and cause unthriftiness. Suppurating wounds may also result. In the British Isles, *Ixodes ricinus* is the main tick found, although *Haemophysalis punctata* is present in some southern coastal areas.

Life-cycles On this basis, ticks can be divided into three groups:

One-host ticks, such as *Boophilus*, which spend all three stages of their life-cycle on the same animal. Larvae having attached themselves to the host, they feed on it, moult, feed again on it as nymphs, moult, and the adult ticks also feed on it – the females subsequently dropping to the ground to lay their eggs.

Two-host ticks: these, such as some *Hyalomma* species, feed as both larvae and nymphs on the same host, but then moult on the ground; emerging adults find and feed on a second host.

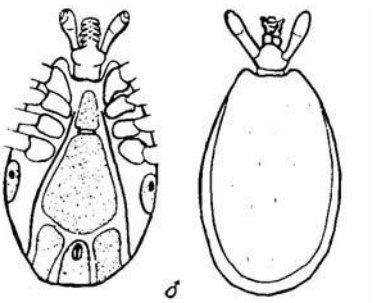
Three-host ticks: larva, nymph and adult each feeds on a different host, with moulting taking place on the ground between each stage in the life-cycle. *Ixodes* and *Dermacentor* species are included in this group.

Family Ixodidae (hard ticks) In this family the dorsum of the body is more or less protected by a hard shield of chitin, and in some species the male has ventral plates also.

The principal species attacking the domestic animals are dealt with below. (See also DOG TICKS for those occurring in Britain.)

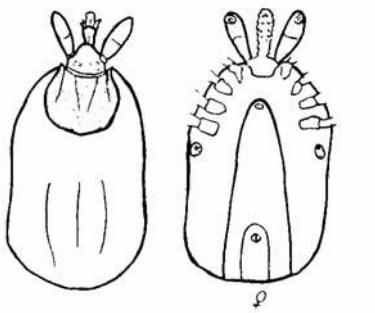
Ixodes There are over 50 species in this genus, including the following:

(a) *I. ricinus* attacks all the domesticated animals and is found in most parts of the world. It is known locally as the castor-bean tick, or European sheep tick. A three-host tick, it leaves its host before each moult, and then seeks a new host. In this way, three animals are attacked by the same tick: one as a larva, one as a nymph, and one as an adult. The animals attacked need not be of the same species. This tick transmits TICK-BORNE FEVER OF SHEEP, LOUPING-ILL, and causes TICK PARALYSIS in sheep and cattle. It can also transmit BABESIA, the cause of RED-WATER FEVER.



(b) *I. hexagonus* attacks especially the dog, but is found on other hosts, notably sheep. It occurs in Europe, North Africa and America; it is common on hunting dogs in France. In addition it is a transmitter of BABESIOSIS.

(c) *I. canisuga* is the common species found on the dog in Britain. It occurs also in Western Europe and North America. Like the last species, only females are found on the host. It is known popularly as the British dog tick.

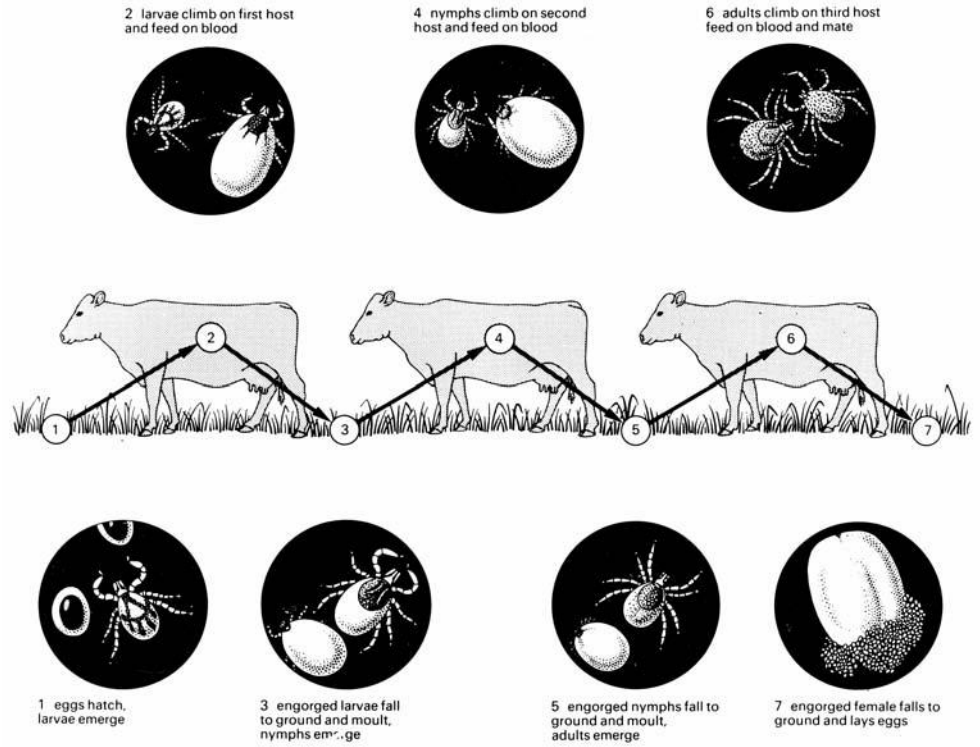


(d) *I. pilosus* attacks all the domestic mammals in South Africa. It is a reddish-brown tick, with the body larger behind than in front. It is known locally as the russet tick, and is a causal agent of tick paralysis.

(e) *I. rubicundus*, another South African tick, which is found only on sheep, also causes tick paralysis.

(f) *I. holocyclus*, in Australia and India, is found on ruminants, dogs, and pigs. It is the cause of Australian tick paralysis, signs of which may appear within an hour of attachment. It transmits Q fever.

Ixodes. (Ventral and dorsal views of male. × 12.)



Ixodes. (Dorsal and ventral views of a small female. × 8.) In this and subsequent drawings of ticks only the fore parts of the legs are shown in diagrams of the ventral surface.

Haemaphysalis The following species are important:

(a) *H. punctata* (*H. cinnabarina* var. *punctata*) is a common tick in Europe, North America and North Africa on all the domestic animals. The life-history is identical with that of *H. leachii*. It transmits *Babesia bovis* in Britain.

(b) *H. leachii* is a three-host African species which has been found in Western Asia and Australia. It attacks carnivores, but is sometimes found

Life-cycle of a 3-host tick, *Ixodes ricinus*. (Reproduced with permission from H. T. B. Hall, *Diseases and Parasites of Livestock in the Tropics*, Longman.)

on ruminants. In East Africa it is called the yellow dog tick; it is also known as the South African dog tick. It transmits canine babesiosis, Q fever, and tick-bite fever.

Dermacentor The following species are important:

(a) *D. reticulatus* is common in Europe, but also occurs in North Asia. It attacks ruminants, and also the dog and the horse. It is occasionally found in Western England. It transmits equine and canine babesiosis.
(b) *D. variabilis* (*D. electus*) is found on dogs in North America. It also occurs on cattle and horses. It is known as the American dog tick.
(c) *D. occidentalis* occurs in western North America on various domestic mammals. It is considered by some authorities to be *D. reticulatus*.
(d) *D. venestus* is found in the Rocky Mountain District of North America and is called the Pacific Coast tick. Adults are found on various mammals, including man. It is the transmitter of Rocky Mountain spotted fever in man, and of canine babesiosis. It is the cause of American tick paralysis. It is a three-host tick.

Rhipicephalus The following species are important:

(a) *R. sanguineus* is found in all parts of the world on dogs and ruminants. It is brown in colour. It is known as the European brown tick and also as the European dog tick – a name shared with *Ixodes hexagonus*.
(b) *R. appendiculatus* is found in Africa, where it attacks cattle, sheep, goats. It is called the brown tick, and is a three-host tick. This species transmits EAST COAST FEVER, CORRIDOR DISEASE, mild gall sickness (ANAPLASMOSIS), RED-WATER FEVER, NAIROBI SHEEP DISEASE.
(c) *R. bursa* is found in North Africa and Southern Europe on all animals. It is a two-host tick. It transmits ovine BABESIOSIS in Europe.
(d) *R. capensis* is found in South Africa on cattle, horses and dogs. It is called the Cape brown tick. The life-cycle is similar to the second species. It can transmit *Theileria parva*.
(e) *R. simus* is found in Africa on dogs and herbivores. It is called the dark pitted tick. Its life-cycle is similar to the second species. It can transmit *Theileria parva, Anaplasma marginale, T. mutans*.

(f) *R. evertsi* in Africa may be found on all the domestic mammals except pigs. It has orange-red legs with round convex distinct eyes. The scutum is black and densely pitted. The underside of the male is red; the females are brown or reddish brown. It is called the red tick or the red-legged tick. This two-host species transmits *Nuttallia equi* and *T. parva,* causing EAST COAST FEVER, BABESIOSIS and SPIROCHAETOSIS OF FOWLS.

Boophilus

(a) *B. decoloratus* is found on cattle and other animals in Africa. It is a one-host tick, called the blue tick. This tick, which may be a variety of *B. annulatus*, transmits *Babesia bigemina, Anaplasma marginale* and *Spirochaeta theileri*.
(b) *B. australis* is found in Australia, India, Africa and tropical America. It is called the Australian blue tick. It also is probably a variety.
(c) *B. annulatus* is the Texas fever tick, and is found in southern North America.

The tick remains on the host for three to nine weeks. It transmits *B. bigemina*.

Hyalomma This genus has an oval body with longish pedipalps and distinct eyes.

(a) *H. aegyptium* is found on all the domestic animals in Africa, Southern Europe, and Asia. It has a brown scutum. Only adults are found on the domestic animals, the younger stages being found on small mammals. It is called the striped-leg tick, or the bont-leg tick. The tick produces ulcerating sores in cattle, and is frequently the cause of lameness in sheep and goats owing to its attachment between the claws. It is believed to transmit both species of *Theileria*, and equine and bovine babesiosis.
(b) *H. truncatum*, the African bont-legged tick, is usually a two-host, occasionally a three-host parasite. Cattle and goats are the main hosts. It transmits SWEATING SICKNESS and Q FEVER. A toxin is thought to be produced by this species capable of causing necrosis of skin and mucous membrane at the site of bites, as well as some degree of paralysis. The necrosis may be extensive. In one case, in a terrier bitch, it extended from vulva to umbilicus, with exposure of the urethra and much sloughing.

Amblyomma In this genus the body is broadly oval.

(a) *A. hebraeum* is an African tick attacking all the domestic mammals. It has a conspicuously marked scutum, yellowish with a red and blue tinge, and brown or black markings. The eyes are flat and flush with the body. It is called the bont tick. This species causes ulcerating sores at the points for attachment, and is a frequent cause of sore teats. It conveys HEARTWATER to ruminants.
(b) *A. variegatum* is an African species attacking herbivores. It has distinct convex eyes. The scutum is reddish yellow bordered with green with black markings. It is called the variegated tick. Its life-history is as above. It also transmits HEARTWATER, NAIROBI SHEEP DISEASE and Q FEVER.
(c) *A. lepidum*, an African three-host bont tick, apparently transmits no diseases but gives rise to unpleasant sores.
(d) *A. gemma*, an African three-host bont tick which infests cattle, camels and other domestic animals. It can transmit both heartwater and Nairobi sheep disease.
(e) *A. cayannense* in South and Central America attacks all the domestic mammals. It is a most vicious biter, and transmits equine nuttalliosis. (See *Nuttallia*.)
(f) *A. americanum* is similar to the last species, but the scutum has a silvery white spot, giving it its popular name of the lone star tick.

An American species of *Amblyomma* transmits *Anaplasma argentinum*.

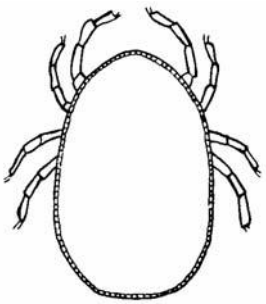
Family Argasidae (soft ticks) This family is distinguished from the hard ticks by the absence of a scutum and by the fact that the males and females are almost indistinguishable. Looked at from above, the capitulum is invisible in the adult, whereas in the Ixodidae the head is always visible.

Only two genera exist in this family, *Argas* and *Ornithodorus*. The adults do not permanently attach themselves to one host, like the hard ticks, but resemble the bed-bug in habits. The female also generally lays more than one batch of eggs.

Some ticks in this family are carriers of SPIROCHAETAL diseases to man and birds.

Argas

(a) *A. persicus* (*A. miniatus*) is the well-known fowl tick, or blue bug, or tampan. It is practically cosmopolitan in its distribution.



It is essentially a bird tick, but will bite man and other mammals (horses and cattle) on occasion. It particularly attacks chickens. A large number on a fowl will suck so much blood that the bird will die from anaemia. It is the carrier of SPIROCHAETOSIS OF FOWLS, and fowl PIROPLASMS.

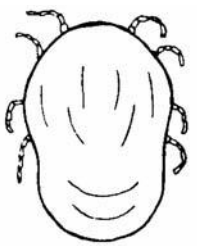
The tick normally feeds at night, spending the day in crevices, and accordingly is seldom seen – as is the case with bed-bugs, which also attack chickens. It is easily distinguished from this pest by the presence of eight legs – the bed-bug being an insect, and in consequence having only six legs.

VetBooks.ir

The larval tick (seed tick) remains several days on the host, and is more frequently seen. The adults can live for two years without food.

(b) *A. reflexus*, a closely related species, is found mainly on pigeons, but also attacks poultry and man. It is found in Europe, Africa, and America.

Argas. × 4.



Ornithodorus

(a) *O. savignyi*, the sand tampan, is a soft tick of great economic importance in Africa, Asia and the Near East. The tick lives below the surface of the sand, emerging to feed on the blood of cattle, other domesticated stock, wild animals, and man. The tick's saliva contains a potent toxin and this, together with massive blood loss, readily kills young or debilitated animals. AMITRAZ, CYPERMETHRIN and IVERMECTIN are among effective controlling agents.

(b) *O. megninii* is the spinose ear tick of America and South Africa. The larvae creep into the ear of some mammalian host, and in a few days moult. The nymphs, which are covered with minute spines, may live for one to seven months in the ear, increasing in size from 3 mm to 17 mm (⅛ to ⅔ in). They finally drop to the ground, moult, mate, lay their eggs, and die. The adult is not parasitic. The eggs hatch in about 10 days. As many as 80 ticks have been found in a single ear. The irritation is considerable and heavy losses may result. A modern treatment is IVERMECTIN.

(c) *O. coriaceus* (pajaroello) is a venomous species (found in North America) which causes a very painful bite.

Transmission of disease When an infected tick feeds upon a calf, it transmits the parasites – or causal organisms – of the tick-borne disease in question. The calf soon becomes ill, and either dies or recovers. As a rule, recovery is associated with immunity. However, relapses may occur in animals thought to be immune to red-water, for example.

Ornithodorus. × 3.

With the exception of ticks of the *Boophilus* species, larvae hatching from a tick's eggs will not immediately be infective because these larvae have not yet fed on any host; but as soon as they start feeding they may ingest the causal organisms of a tick-borne disease. When they moult and become nymphs, they may then be capable of transmitting disease. Similarly, when the nymph, on moulting, becomes an adult tick, it will be infective if there were already parasites in its blood.

Not all tick vectors will transmit all causal organisms; and, of course, not all species of host are susceptible to the same causal organisms.

An infective three-host tick feeding on a non-susceptible host 'cleans' itself of infection and will not transmit disease in the next stage of its life-cycle. This fact provides a useful control measure.

The specific parasites transmitted by the ticks are not passed on mechanically, but must undergo a special development in the tick. This is easily understood when it is realised that any one stage in the life-history of a hard tick bites only one animal. Accordingly, a tick infected in one stage must be capable of producing the disease in some succeeding stage, which depends on the tick.

Control of ticks In many tropical countries, energetic measures for the regular and frequent dipping of cattle and sheep are necessary. In order to achieve adequate control of the tick-borne diseases, it is important that hand-dressing of certain parts of the body should be carried out in addition to the dipping or spraying. This applies to inside the ears, around the base of the horns, around the eyes, anus, etc.

The acaricides, or tick-killing chemicals, have comprised: (1) arsenical compounds; (2) chlorinated hydrocarbon compounds; (3) the ORGANOPHOSPHORUS COMPOUNDS; and (4) AVERMECTIN compounds. Some countries do not use some of these treatments.

Dipwashes containing arsenic are unsuitable for spraying because of the danger of pasture contamination. Although cheap, stable and soluble, arsenic compounds are very poisonous: another disadvantage is that some species of ticks acquire a resistance to arsenic preparations. Accordingly, a change

VetBooks.ir

to chlorinated hydrocarbons followed. Of these, BHC and toxaphene have been widely used. Unfortunately, ticks can become resistant to these too. (See also BHC.)

Organophosphorus compounds tend to be expensive, and are used mostly against ticks resistant to other acaricides.

Coumaphos; cypermethrin, a synthetic pyrethroid; diazinon, an organophosphorus compound – these are among a range of substances formulated for application against ticks

For tick control in temperate regions, see also DIPS AND DIPPING and DOG TICKS.

Systemic Acaricides are a useful alternative to spraying or dipping. 'Pour-on' or 'spot-on' formulations of acaricides such as AMITRAZ and IVERMECTIN are applied along the dorsal ridge (pour-on) or to the base of the head, between the shoulder blades (spot-on). The drug is absorbed through the skin and carried by the blood circulation to all parts of the body.

Ticks in Buildings

Ticks in buildings, such as quarantine premises, kennels in the tropics, private houses, etc., can be eradicated by placing a block of dry ice on the floor and closing all doors and windows. Adults, nymphs, and larval ticks will be found, after a time, clustering around this source of CO_2 and can then be easily collected and destroyed.

Tildipirosin

A macrolide antibiotic which used by injection for the treatment and prevention of bovine respiratory disease associated with *Mannheimia haemolytica*, *Pasteurella multocida* and *Histophilus somni*. There is rapid concentration in the lungs with a high lung concentration within four hours and it can have activity in the lungs for up to 28 days.

Tilmicosin

A semi-synthetic macrolide for use by injection in cattle and sheep only. It can be fatal in other species including man. It must not be given intravenously. It is active against *Mannheimia haemolytica*, *Pasteurella mutocida*, *Staphylococcus aureus* and *Mycoplasma agalactiae* and is used in treating FOUL-IN-THE-FOOT in cattle. It can be given to poultry in drinking water for the treatment of infections due to *Mycoplasma gallisepticum*, (some turkeys and chickens may resistant), *M. synoviae*, and *Ornithobacterium rhinotracheale*. In pigs it can be used to treat infections caused by *Actinobacillus pleuropneumoniae*, *Mycoplasma hyopneumoniae*, *Pasteurella multocida* and other sensitive organisms. **The injection must only be administered by a veterinary surgeon**.

Tiludronic Acid

A drug licensed for horses over three years old suffering from lameness associated with BONE SPAVIN. It blocks osteoclastic activity and it helps in bone remodelling. It is used intravenously and is rapidly cleared from the blood.

Timber

(See WOOD PRESERVATIVES; BEDDING AND BEDDING MATERIALS.)

Timothy Grass

An old-fashioned grass species (*Phleum pratense*). It is an old-fashioned grass but still popular although its yield is poorer than more modern grasses such as perennial ryegrass. It is used for hay and can carry the fungus CLAVICEPS which may result in ERGOT POISONING.

Tin (Sn)

A TRACE ELEMENT found to have growth-promoting properties when fed to rats.

Tincture

Tincture is an alcoholic solution, e.g. tincture of iodine.

Tinea

(See RINGWORM.)

Tissue Culture Vaccines

(See VACCINES.)

Tissues of the Body

Tissues of the body include 5 groups:

1. Epithelial tissues, including the cells covering the skin, those lining the alimentary canal, those forming the glands, etc. (See EPITHELIUM.)
2. Connective tissues, including FIBROUS TISSUE, FAT (adipose tissue), BONE and CARTILAGE. (See main dictionary headings.)
3. Muscular tissues. (See MUSCLES.)
4. Nervous tissues. (See NERVES.)
5. Fluid tissues. (See BLOOD; LYMPH.)

Titanium (Ti)

This is commonly used in nanoparticles in some consumer goods. If these particles enter the water supply or a water environment, they cause gill damage in fish. The fish show an increase in blood HAEMOGLOBIN and a decrease in activity of the SPLEEN, indicating that they are having difficulty in coping. As a result, fish swim slowly and show reduced activity, for example to avoid predators. (See NANOPARTICLES.)

VetBooks.ir

Titre
The extent to which an antibody-containing biological substance can be diluted before losing its power of reacting with a specific antigen. 'High titres' indicate, in practical terms, that a patient's blood serum contains high levels of antibody, e.g. to the RABIES virus.

TLC
1. 'tender loving care' – the indefinable quality that good nursing brings to recovery. Often resulting from attention to detail and anticipating the likely progress of a disease, and dealing with the consequences before they are apparent or in the early stages.
2. thin layer chromatography. (See THIN LAYER CHROMATOGRAPHY.)

Toadfish, Puffer Fish
Members of the Tetraodontidae which contain a poison, tetrodotoxin; if eaten, can cause paralysis.

Toads
Toads (*Bufa vulgaris*) have a defensive venom which is secreted by skin-glands and by the parotid salivary gland. The principal toxic substance is BUFOTALIN. Signs of poisoning in the dog are profuse vomiting followed by the emission of ropy saliva and by loss of consciousness, which may persist for a couple of hours. ADRENALIN has been used in treatment.

The Central American toad, *Bufo marinas*, is also known as the Cane Toad, Giant Neotropical Toad or the Marine Toad. It is very large and has a powerful venom which can cause prostration, convulsions and death within 15 minutes. It is a serious pest in Australia, where it has caused deaths in wildlife, domestic dogs and cats.

Toadstools
Toadstools can cause severe poisoning if eaten. In one recorded instance, a cairn terrier died after eating *Nolanea sericeum* toadstools growing on a lawn. Death occurred within three hours.

Signs of poisoning by this fungus are severe vomiting and abdominal pain.

Tobacco
(See NICOTINE POISONING) Stalks of tobacco plants fed to pigs have resulted in piglets born with limb deformities.

Tocopherol
Vitamin E.

Toes, Curly
Also called curly toe disease and curled toe paralysis, it is a condition arising in chicks from a deficiency of riboflavin. The toes curl underneath the feet. (See VITAMINS.)

Toes, Twisted
Also called crooked toes, it is a condition seen in chicks – one or more toes twisting inwards or outwards. There is, at least, a hereditary disposition to this abnormality, but it may occur in temporary and reversible form where infra-red brooders are in use.

Togaviruses
Formerly known as arboviruses, this group includes ALPHAVIRUSES, BUNYAVIRIDAE, ORBIVIRUSES, and PESTIVIRUSES. (See table under VIRUSES.)

Toggenburg Goats
These dairy goats originated in the Obertoggenburg and Werdenburg Valleys of Switzerland. They were imported into the UK from 1882 onwards. The goat is slightly smaller than the BRITISH TOGGENBURG with mid brown, fawn or grey markings and white with variable length hair; there is usually fringing and a 'dished' face. The daily milk yield is about 3.6 kg (8 lb) with 3.7 per cent butterfat and 2.7 per cent protein.

Toldimphos
An organic source of phosphorus. It is given by injection to cattle and dogs and used to treat rickets, OSTEOMALACIA, promote rapid healing of bone fractures, tetany, PARESIS and as a general treatment for metabolic disorders.

Tolfenamic Acid
A non-steroidal anti-inflammatory agent with analgesic and antipyretic properties. In tablet form it is used in acute episodes of chronic locomotor disease in dogs and as an antipyretic in cats. As an injection it is given intravenously in cattle to support antibacterial therapy and to control the inflammation associated with infectious disease. In pigs it is given intramuscularly in the control of MASTITIS METRITIS AGALACTIA SYNDROME together with ANTIBIOTICS.

Tolt
In horses, this is a fifth pace of movement, and is between the trot and canter. It is seen in ICELANDIC HORSES and PONIES.

Toltrazuril
A treatment for coccidiosis in broilers and layer replacements. It is used as a two-day course and can be used in the presence of coccidiostats where disease has occurred. In severe problems treatment can be repeated after five days.

Tom
A male cat. In North America, male turkeys are also called toms.

Tomato Pumace
This is the residue from production of tomato sauce, ketchup and puree. It contains 20 to 25 per cent crude protein, is a good source of B vitamins, and contains vitamin A. It has been used in cattle and chicken rations. In the latter, the birds had decreased susceptibility to diarrhoea and other intestinal disorders.

Tomium
(plural, Tomia)
The cutting edge of the beak or bill of a bird. In some species, especially birds of prey, these are developed into protuberances, sometimes referred to as tomial teeth.

Tomography
Body section radiography. A type of radiation in which the X-RAYS are focused more specifically on the part of interest to the investigating clinician. The procedure is usually assisted by a computer and so it is often called COMPUTED TOMOGRAPHY (CT SCANNING). (See X-RAYS - COMPUTED TOMOGRAPHY; DIAGNOSTIC IMAGING.)

-tomy
-tomy is a suffix indicating an operation by cutting.

Tongue
A muscular and fibrous organ, richly supplied with blood vessels and nerves, and covered with a highly specialised mucous membrane. Its shape varies in the different animals, but in all it consists of a free part or 'tip'; a middle part, the 'body'; and a hinder part, the 'root'. In the horse the tongue is long and spatulate, with a blunt tip, freely movable, and there is a definite narrowing just behind the tip. In the ox the tip is short, and pointed or conical; mobility and pliability are not so great, and on the upper surface is a hump-like eminence or 'dorsum', divided from the tip by a distinct, deep, transverse groove. The dorsum is of the greatest use in swallowing, and in bringing the small balls of cud from the back of the mouth forward for chewing by the cheek teeth.

Tongue, Diseases of
(See under MOUTH, DISEASES OF; SALIVATION; RANULA; 'CURLED TONGUE' in turkey poults.)

Condition of the tongue The tongue of any animal in health should be of a pink glistening appearance, soft and moist to the touch in the horse, sheep, pig and dog; rough in the cow and cat. (There are a few breeds of dogs, such as the chow, in which the tongue is normally black or bluish.) When handled the tongue should possess a considerable power of retraction; a weak flabby tongue usually indicates general muscular weakness. When at rest the tongue should touch the inner edges of all the lower teeth. When it becomes greatly swollen it presses against the teeth and these leave indentations around its margin. In cattle there is a raised part or 'dorsum' behind the free tip, which is instrumental in forming the food into boluses for swallowing.

Inflammation of the tongue (GLOSSITIS) is usually accompanied by SALIVATION, and may result from injuries, irritant or corrosive poisons, infections and vitamin deficiencies.

Glossitis may be accompanied by the formation of vesicles which burst, leaving ulcerated areas. (See FOOT-AND-MOUTH DISEASE; SWINE VESICULAR DISEASE.) Ulcers are also a sign of cattle plague (see RINDERPEST), MUCOSAL DISEASE and ORF in sheep. FELINE CALICIVIRUS may cause tongue ulcers in the cat.

Raised irregular swellings or abscesses on the tongues of cattle suggest ACTINOBACILLOSIS.

Ulcers along the free edges of the tongue may be produced by diseased teeth.

In the disease called calf diphtheria (necrosis of the pharynx), the tongue may be the seat of raised areas of false membrane which will also be seen in other parts of the mouth.

The tongue may be injured or wounded from too severe a bit in the horse, or from carelessness in breaking in a young colt. In such cases there is usually a distinct mark across the tongue's upper surface, behind which the organ appears normal, and in front of which it is reddened and swollen.

Foreign bodies, such as fish-hooks, needles, wire, splinters of bone, etc., may become fixed in the tongue, and lead to protrusion of the organ, difficulty in swallowing, salivation, and a disinclination on the part of the animal to allow the mouth to be handled or examined.

In canine LEPTOSPIROSIS/kidney failure there are often areas of necrosis around the tip (which may slough off), and a foul odour.

A brown discoloration may be present in the above condition. (See also 'BROWN MOUTH'.) A soapy-white appearance of the tongue, again accompanied by an unpleasant odour, often indicates some digestive disorder.

'CURLED TONGUE' is an inherited defect in turkeys which has largely disappeared from the main hybrids. It may, however, still surface in the more traditional types – for example, BROAD-BREASTED BRONZE or NORFOLK BLACK. (See also 'BLACK TONGUE'; BLUETONGUE (a specific

disease of sheep and cattle); MYOTONIA; ASPHYXIA.)

'Tongue Worm'

'Tongue worm' is the colloquial name for *Linguatula serrata*, a parasite of the nose of the dog and other animals. (See MITES, PARASITIC.)

Tonic

Tonic means, in one sense, a continuous muscular spasm, as compared with CLONIC. (See also TONICS.)

Tonics

A name applied to a variety of medicines or other substances believed to help improve health. In human medicine, the term is often applied to bitter herbal extracts that may stimulate the appetite.

Turning out to grass is itself a tonic to animals that have been confined indoors. (See also under PROTEIN, HYDROLISED; VITAMINS.)

Tonkinese Cats

This is a breed of foreign short-haired cats. Congenital Unilateral Peripheral Vestibular Disease may be seen in individuals shortly after birth. However, many individuals adapt well and lead a comparatively normal life.

Tonsillitis

Inflammation of the tonsils, a sign of e.g. canine viral hepatitis. The dog may retch or cough, and be slightly feverish.

Tonsils

Tonsils are collections of lymphoid tissue, situated between the anterior and posterior pillars of the soft palate at the back of the throat. In the horse there is not a compact tonsil, as in man, the dog, etc., but a diffuse collection of lymphoid tissue, mucus glands, etc., causing elevations on the surface, in which are seen the numerous depressions or crypts which characterise the tonsil and differentiate it from other lymphoid tissue. In the sheep the tonsil is bean-shaped and does not project into the throat, as in most other animals. In health, the dog's tonsils are not conspicuous, being situated in a depression; but when inflamed they appear as two bright red lumps. The tonsillar area is an important organ to diagnose virus in FOOT-AND-MOUTH DISEASE.

Toothache

(See TEETH, DISEASES OF.)

Tooth Problems

(See TEETH, DISEASES OF.)

Top Dressed Seed

(See TOP DRESSING.)

Top dressing

The application of medication to the seed, usually whole seeds. It is mainly used for pet birds. There is a disadvantage in this type of medication in birds that dehusk their seeds, as most of the medication is discarded with the husk. (See IMPREGNATED SEED.)

Topical Applications

Topical applications of a drug are those made locally to the outside of the body.

Topping of Pastures

Mowing the top growth on an overgrown pasture. This practice is beneficial from a veterinary point of view in that it is unfavourable to the survival of parasitic worm larvae.

Torsion, Twisting

Torsion (twisting) occasionally involves the intestine (see VOLVULUS); the pedicle of the spleen; the stomach; uterus; and spermatic cords. (See also GASTRIC TORSION.)

Torticollis

A lateral deviation of the neck. It is seen in many species with nervous diseases. In rabbits affected by encephalitozoonosis a 'corkscrew appearance' is seen. (See ENCEPHALITOZOONOSIS; PASTEURELLOSIS IN RABBITS; see also WRY-NECK.)

Tortoises

In Britain an amendment to the Endangered Species Act, in 1982, required that every buyer of tortoises must sign an undertaking to provide them with appropriate care, attention, and living quarters necessary for their survival. Failure to comply can result in a fine of up to £400 for an offending supplier, pet trader, or private individual. This little piece of legislation may help to mitigate the extremely high mortality of tortoises imported into the UK, often due to their being crammed into unsuitable containers for their journey here and badly looked after subsequently.

It has been suggested that outbreaks of viral disease are present among tortoises (*Testudo* species) in the Mediterranean region.

Imported tortoises should be carefully examined for the presence of exotic ticks.

Tortoises and turtles have been known to infect dogs, cats, and people with SALMONELLOSIS. Excess feeding of BRASSICAE SPECIES can lead to GOITRE. (See also AMERICAN BOX TORTOISES;CHELONIANS; PETS, CHILDREN'S AND EXOTIC.)

For euthanasia, an injection into the abdomen of pentobarbitone sodium is recommended.

Tortoiseshell Cats, Male

Although nearly all tortoiseshell cats are female, males do occasionally occur. It appears that the most common chromosome complements are 39XXY, 38XY/38XX, 38XY/39XXY and 38XY/38XY. A 38XY is needed for the cat to be fertile.

Total Performance Index (TPI)

In the USA, a value for the genetic merit of a dairy bull and the improvement that will be provided to his daughters. It is the equivalent of PERFORMANCE LIFETIME INDEX used in Britain.

Touch

This sense depends upon receptors at the end of nerves, or upon the nerve endings themselves:

Touch sense proper, by which touches or strokes are perceived, such as the lightest sensation caused by a fly settling on the skin. The size and shapes of bodies in contact with the skin which are not seen is also appreciated by this sense.

Pressure sense, by which the weight of heavy objects and their hardness can be determined.

Heat sense, by which the heat of the surrounding atmosphere, or of bodies in contact with the skin, is appreciated as being above that of body temperature. (Receptors for warmth in the human body number about 16,000 as compared with 150,000 for detecting cold.)

Cold sense.

Pain sense.

Muscle sense, by which the weight of an object can be tested, and the amount of energy necessary for an effort can be gauged.

Sense of position, by which, without using the powers of vision, the attitude and position of any part of the body is known.

The distribution of the sense organs which are concerned with the reception of these sensations is very widespread. There is no part of the surface of the body, except the horns, hoofs and claws, which can be cut without giving evidence of pain, and there is no part, including horny structures, which is insensible to touch.

Pain is detected, it seems, by free nerve endings in the layers of the skin, connective tissue, and cornea. The sense of touch is apparently dependent upon Meissner's corpuscles, situated under the epidermis; upon Merkel's discs in tongue, lips, muzzle. Tactile hairs on muzzle, etc., function through free nerve endings surrounding the hair follicle. Pacinian corpuscles in connective tissue, penis, clitoris, etc., react to pressure and contact. Receptors for heat and cold are named Ruffini's corpuscles and Krause endbulbs, respectively. (See also SKIN; HYPERAESTHESIA; PARALYSIS.)

Tourniquet

A tourniquet is an appliance for the temporary stoppage of the circulation in a limb or appendage of the body, for use only in very severe haemorrhage. Application of a tourniquet is a risky procedure, best not undertaken by the animal-owner unless raising the limb and application of a pressure pad has failed to control the haemorrhage, which appears to be endangering the animal's life. It is to be avoided on cats.

In emergencies, a handkerchief may be tied round the part, the knot being arranged above the principal artery, and a rigid object, piece of wood, pencil, etc., used to twist the loose part up tightly.

A tourniquet must not be left in position around a limb for longer than 20 minutes, or gangrene of the lower part will result. Occasionally, a circular bruise may occur under a tourniquet, especially in the limbs of horses; this, after healing, leaving a ring of white hair marking the place where the tourniquet was applied. Such a circular mark is due to a destruction of the pigmentary apparatus of the hair follicles. (See also BLEEDING.)

Toxaemia

The presence of toxins in the bloodstream.

Toxaphene

A chlorinated hydrocarbon insecticide which remains active for a long time on the hair of cattle, and of value against ticks also.

Toxascaris

(See under *Toxocara*.)

Toxic

Relating to poison. A toxic organism or agent damages an organ or the whole animal. The toxic effect can result in a variety of signs but commonly when signs are SYSTEMIC there are signs of SHOCK.

'Toxic Fat Syndrome'

'Toxic fat syndrome' of broiler chickens, mainly between 3 and 10 weeks old, has occurred in the USA and Britain. It is associated with oedema of the pericardium and abdomen, a waddling gait, squawking, laboured breathing, and sudden death. Mortality may reach 95 per cent. It has been seen in chicks only a few days old.

This condition has to be differentiated from round heart disease, which usually occurs sporadically among older birds and is not associated with the feeding of fat-supplemented rations.

Toxicology

The study of POISONING.

VetBooks.ir

Toxins

Toxins are poisons produced in animal tissues, by some bacteria, ticks and fungi. Waste products, not removed from the body during liver or kidney failure, are also sometimes referred to as toxins. (See TETANUS; BOTULISM; TICKS; MYCOTOXICOSIS; POISONING; VENOM; TOXOID; MOULDY FOOD.)

Toxocara

A genus of roundworm which includes *Toxocara canis*, a parasite of dog and fox, *T. cati*, and *T. vitulorum* of cattle (the last-named not present in the UK). Infection with these worms is known as toxocariosis (formerly toxocariasis). This is important not only from the veterinary aspect but also as regards public health, since toxocara worm larvae cause visceral larva migrans in man.

In dogs, *T. canis* is primarily a parasite of the young puppy, which commonly becomes infected before birth by larvae crossing the bitch's placenta. Post-natal infection may occur through the milk. During the first few weeks of the puppy's life, the life-cycle of toxocara is completed, adult worms being found in the intestine. (In severe infestations, complete impaction of the bowel has been known to occur in puppies as young as 7 weeks.)

Larvae acquired prenatally from the bitch arrive in the puppy's intestine within 3 days of birth, and mature at about the 9th day. Egg production begins when the puppy is about 2 months old. The number of worm eggs excreted by the puppy may be as many as 15,000 per g of faeces.

As the puppy becomes older, the degree of infestation diminishes. It seems that larvae from ingested eggs migrate within the tissues but are unable to complete the life-cycle. Some of these larvae must remain viable, or prenatal infection could not occur in succeeding generations. Mature male dogs are more likely to carry patent infection than adult bitches, but the lactating bitch apparently experiences a hormonal suppression of immunity, resulting in a brief patent infection of *T. canis* from larvae present in the body. One survey found that of 740 unwanted Glasgow dogs examined after euthanasia, just under 21 per cent carried *T. canis*.

Control This is dependent upon what action dog-owners take or fail to take. Several anthelmintics are effective against the adult worm, including piperazine. Pups should be treated at 2 weeks old, before eggs are passed in the faeces, and at 3, 6 and 8 weeks.

Nursing bitches should be dosed when the puppies are 2, 4, 6 and 8 weeks old. Febendazole is a suitable medication; it prevents migration of larvae into the milk. Adult dogs should be wormed every 2 to 3 months.

In kittens, damage, sometimes severe, may affect the glomeruli of the kidneys as a result of larvae of *T. cati*.

Public health *Toxocara* eggs are sticky and readily adhere to children's hands, blankets, dog baskets, etc. Fortunately the eggs are not immediately infective when excreted in canine faeces, but require a period of weeks to become so. Two larval moults occur before hatching of the egg, so the infective stage is the third stage larva.

The danger of transmission lies in the fact that the eggs are very resistant and can survive for long periods in the soil. Garden soil, and that of parks, playing fields, and grass verges, is an important source of eggs and larvae. About 7 per cent of soil samples from public parks have been found to contain viable *toxocara* eggs, although in one survey the figure was as high as 24 per cent.

Children can easily become infected through not washing their hands after contamination by such eggs – many of which will have undergone development, rendering them infective. The World Health Organisation (WHO) has stated: 'Many patients with proven toxocariasis have not owned or had close contact with a dog or cat,' but have become infected from eggs in soil. Moreover: 'even though toxocara eggs are unlikely to mature on an animal's coat, infective eggs from the soil may adhere to the hair so that contact with it can lead to infection.'

Prevalence in man Human toxocariosis is encountered throughout the world. Surveys have demonstrated that about 2 per cent of people over 10 years old in London, and over 30 per cent in various African cities, showed a positive reaction to a toxocara skin test.

In a veterinary medical study, antibodies to *T. canis* were found in over 15 per cent of the dog-breeders' samples, as compared with only 2.6 per cent of the controls.

Visceral larva migrans affects, states WHO, mainly children between 18 months and 3 years of age. Tumours – eosinophilic granulomata – are formed in organs such as the liver, lungs, eye and, occasionally, the brain. In some patients blindness is caused; in others the symptoms may resemble those of asthma or epilepsy. Debility and occasionally partial paralysis may occur. Eosinophilia is usually present.

About 50 cases of ocular toxocariosis are reported each year in England and Wales.

A young woman, who had kept dogs and rabbits for many years, presented with blurred vision in one eye. This condition was treated with corticosteroids. She developed a transient swelling and stiffness of the right elbow and the left ankle and wrist. In the subsequent 18 months she

suffered repeated episodes of choroiditis in the left eye and arthralgia. A toxocaral fluorescent antibody test was positive and after treatment with diethylcarbamazine citrate her symptoms subsided.

Diagnosis An immunofluorescent test or the ELISA test may be used in human medicine. Diagnosis of toxocara affecting the eye may be difficult. In one case, fragments of a larva were not found until the 186th section of an eye had been made.

Toxoid

A toxin which has been rendered non-toxic by physical or chemical means, while retaining its antigenic properties. An example is TETANUS toxoid for immunisation.

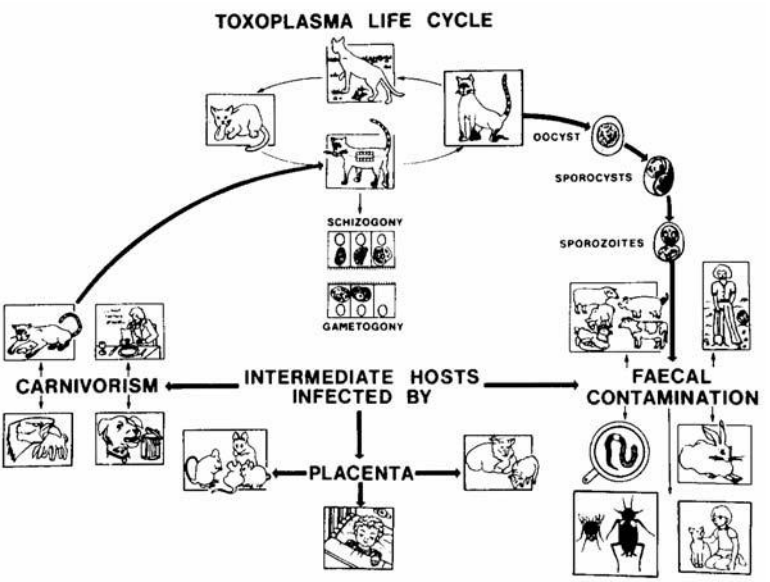
Toxoplasma Eye Infection in Horses

The first UK case was reported in 1991.

Signs Inflammation and degeneration of the retina and of the sclera (white of the eyeball).

Toxoplasmosis

This is a disease of man and of most warm-blooded animals. It is a major cause of abortion in ewes but the signs of disease in other species can vary widely.



Cause A coccidian (see COCCIDIOSIS) parasite, *Toxoplasma gondii*, closely related to the genus Isospora. The reproductive cells (gametes) form in the intestine of cats (and probably of other members of the cat family).

The cat is the definite host. Cats (and other carnivores) can become infected through the ingestion of the cystozoites within cysts in the muscles of their prey; or they can – like other animals and man – become infected by oocysts present in feline faeces. (The oocysts can survive outside the body for 17 months.) The ingestion of oocysts is probably the major source of human urban toxoplasmosis in the UK. According to the FAO, it is one of the 10 food-borne parasites with the greatest global impact.

T. gondii has been isolated from the milk of bitches, cows, ewes, and sows, and it has been shown that the young of these may be born already infected. The parasite has been found in the brain and has given rise to a change in behaviour. Thus mice become less afraid of cats and become easy prey to cats, thereby continuing the parasite's life cycle and ensuring continuing infection in a locality. The parasite can live in ticks and lice, so that the spread of toxoplasmosis by these is not unlikely. The parasite has been recovered from the semen of rams.

For diagnosis, laboratory techniques are essential, e.g. using Sabin-Feldman dye, latex agglutination tests.

Sheep and goats After ingestion of feed or water contaminated by cat faeces with toxoplasma oocysts, susceptible (seronegative) sheep/goats become, and remain, infected for life. Infection of the ovine/caprine placenta and conceptus occurs only when the initial infection establishes in susceptible pregnant sheep, following ingestion of oocysts. The oocysts encyst in the digestive tract and the released sporozoites penetrate the cells lining the gut so that tachyzoites eventually reach and infect the placenta and fetus.

VetBooks.ir

Infection in very early pregnancy causes fetal resorption and the ewes/does subsequently appear to be barren, while infection between about 50 and 120 days' gestation presents the clinical picture typical of the disease, with the premature birth of stillborn and weakly lambs/kids, outwardly of quite normal appearance, often accompanied by a mummified fetus.

Treatment Decoquinate (Deccox; Merial) may be administered in the feed for prophylaxis and treatment.

Control A live vaccine containing tachyzoites of *T. gondii* (Toxovax; Intervet) is available. It may be used in ewe lambs over five months old and older ewes not less than six weeks before mating; repeat dosing may be needed after two years. **Warning:** Accidental exposure to the vaccine can cause infection in man – in particular, abortion. The vaccine must not be handled by women of child-bearing age.

Goats Toxoplasmosis causes abortion and perinatal mortality similar to that seen in sheep. Goats also appear to stay infected for life, but experiments carried out in the USA suggest that, unlike sheep, they may, in subsequent pregnancies, pass infection on to their kids in utero and may even abort with overt toxoplasmosis more than once. Infection can spread also via semen and milk, but the relative importance of these two routes within a herd is uncertain, as is the risk to humans ingesting milk from infected goats.

Signs Toxoplasmosis may be subclinical – no signs being shown, but a degree of immunity being acquired; or the infection may give rise to very varied signs which, in different cases, have included coughing, distressed breathing, mastitis, abortion, fetal degeneration, stillbirths, diarrhoea, and encephalitis.

An Australian report noted that 7 out of 48 penned ewes aborted because of infection with *T. gondii*. They had been eating grain contaminated by faeces from cats which lived in the feed shed.

In a Canadian farm outbreak only 12 out of 50 chicken, reared indoors, survived 3 months after being turned out into the farmyard for the summer. Antibodies to toxoplasma were found in the chickens, in 23 out of 24 of the cows, in all the farm cats, a mare, the farmer, his wife and daughter, but not their son. The source of infection in this outbreak was considered to be wild birds, many of which had been found dead around the farmyard.

Cats The infection is often subclinical. Acute feline toxoplasmosis may prove fatal, a few days after signs such as a high fever, lethargy, loss of appetite and dyspnoea. Chronic toxoplasmosis is often a relapsing disease, with loss of appetite, ANAEMIA, nervous signs, abortion or sterility. Heart disease and liver disease may be found. The fever does not respond to antibiotics. Dyspnoea may be seen in the terminal stages.

Public health Probably all practising veterinary surgeons, and many cat-owners, have had antibodies to toxoplasma in their blood serum; yet of these people only a small percentage were ever ill as a result of the infection (though a proportion may have suffered malaise).

The World Health Organisation (WHO) has stated that the only real danger to human health appears to be: (1) acute, generalised toxoplasmosis, especially in patients undergoing immunosuppressive therapy; and (2) congenital infection which can lead to miscarriage, stillbirth, or abnormality in the baby.

According to the FAO, it is one of the 10 food-borne parasites with the greatest global impact. In the USA 3,000 of the three million babies born each year are reckoned to have congenital toxoplasmosis, but many of the babies are well or only mildly affected.

Medical opinion is that pregnant women should be advised against eating or handling raw or undercooked meat, and should not themselves empty cat litter trays.

There is danger for the baby only if the mother becomes infected during pregnancy; if infected previously, there is no such danger.

The immunosuppression occurring in AIDS has resulted in some deaths from toxoplasmosis.

(See also CANARY.)

Toy Dogs

The term 'toy' is used to identify dogs such as CHIHUAHUAS and YORKSHIRE TERRIERS. It can also refer to a size of dog which is smaller than a MINIATURE or a STANDARD size of the same breed-type. Small breeds of other animals, such as ponies, horses, may also be called 'toy'.

TPI

The abbreviation for TOTAL PERFORMANCE INDEX which is used in the USA to evaluate for farmers the potential genetic merit of specific bulls for breeding with dairy cows and heifer.

Trabecula

A band of fibrous tissue.

Traceability

'Traceability' ensures that food bought by the consumer can be traced back, via the vendor, processor and producer, to the original source of production, often called 'from fork to farm' or

'stable to table'. It involves first the identification of individual animals, and then tracing them through to the end product. FARM ASSURANCE SCHEMES assist in this and traceability is now required by most food retailers. The aim is to give confidence to consumers about the food they buy. If any food-borne disease is found it assists in allowing rapid removal of the product and identifying the source of the infection.

Trace Elements

Trace elements are those of which minute quantities are essential for the maintenance of health in animals (or plants). They include iron, manganese, iodine, cobalt, copper, magnesium, zinc and selenium. (See under HYPOMAGNESAEMIA; PIGLET ANAEMIA; 'PINING'; IODINE; HYPOCUPRAEMIA; perosis (See under 'SLIPPED TENDON'; LEISHMANIASIS; SALT licks.) Calcium and phosphorus are also needed, but in much larger quantities than is the case with trace elements. (See also VITAMINS - VITAMIN E.)

Trachea

Trachea is another name for the windpipe, the tube made up of cartilaginous rings connecting the larynx with the BRONCHIAL TUBES in mammals. In birds it connects the pharynx with the SYRINX. (See NOSE AND NASAL PASSAGES.)

Foreign bodies have included a spanner in a dog's trachea; a chip of stone in a cat; a snail; and – not strictly 'foreign' – a cat's own tooth. An incision into the trachea, to admit an endoscope from the outside, was necessary in this last case.

Trachea, Diseases of

These include hypoplasia, with a narrow lumen – a congenital defect in several breeds of dogs.

Signs A chronic moist cough, wheezing, dyspnoea, aversion to exercise.

Tracheal Collapse

A condition in which there is a disorder of the tracheal membrane, muscle (trachealis muscle) or tracheal rings and results in functional tracheal stenosis. It is many seen in dogs of the miniature and toy breeds such as YORKSHIRE TERRIERS and AFFENPINSCHERS. There is a cough and a reduced exercise tolerance.

Tracheal Worms

In the dog, infestation with the worm *Filaroides osleri* gives rise to a persistent cough, and sometimes to retching. The cough may be like that in kennel cough, and hoarse. This disease occurs in Britain. Diagnosis depends on use of an endoscope (which can reveal the characteristic pink nodules), or of X-rays. Treatment can be successful, using an appropriate anthelmintic, e.g. oxfendazole.

Another tracheal worm, which seldom gives rise to clinical signs, is *Capillaria aerophilia*. (See also under COUGHING.)

Tracheitis

Inflammation of the TRACHEA. The trachea may be severely damaged as the result of a dog fight, involving bites of the neck.

Tracheostomy

Tracheostomy refers to an artificial opening into the trachea, and is usually taken to include the insertion of a tracheostomy tube to overcome nerve dysfunction. Tracheotomy is the surgical procedure of creating a tracheostomy, although some authors use these words interchangeably.

Severe upper respiratory obstruction presents as an anxious, sweating horse with possibly stridulous breathing noises at rest, flared nostrils, extended neck, increased costo-abdominal respiratory effort, cyanosis and functioning accessory muscles of respiration. Particularly if the last two signs are present, a temporary tracheostomy is imperative.

Permanent tracheostomy A tracheostomy tube is used to bypass a permanent upper-airway obstruction. A permanent tracheostomy is most commonly used in performance animals to bypass performance-limiting, less severe respiratory obstruction, e.g. cases of laryngeal paralysis non-responsive to conventional surgery. The term 'permanent tracheostomy' is not absolute because for ease of management many owners request the removal of 'permanent' tracheostomy tubes at the end of each working season, with replacement at the beginning of the following season.

In one survey, of 34 cases of permanent tracheostomy involving 11 dogs and 23 cats, the pet-owners assessed the results as good in 16, and fair in six, cases. The most common post-operative problem was occlusion of the trachea by a fold of skin.

A surgical accident Abscesses due to *Streptococcus equi* caused upper-airway obstruction in a two-month-old Standardbred foal. Unfortunately, while attempting surgical relief, four mid-cervical tracheal rings were completely severed. This led to dyspnoea and a loud respiratory noise even with mild exercise; an endoscopic examination showed that the lumen of the trachea was now key-shaped for a distance of 6 cm.

When six months old, the foal was referred to the Ohio State University veterinary hospital, where it was found that the severed ends of the four tracheal rings had not healed but were connected solely by fibrous tissue.

VetBooks.ir

VetBooks.ir

In order to effect repair, a prosthesis was made by cutting in half longitudinally a 60 ml plastic syringe, and then cutting segments 2 cm to 5 cm (1 in to 2 in) in length, with 2 mm holes drilled to take sutures.

Two ¾-thickness incisions were made transversely at 1 cm intervals in each ring on both sides of the defect, and sutures placed, avoiding penetration of the tracheal mucosa.

Nine days after surgery, endoscopy showed the tracheal lumen to be nearly normal and the mucous membrane free from inflammation. Ten months later the surgical site was normal. As a two-year-old, the colt was raced successfully.

Tracheotomy

Tracheotomy is indicated when some foreign body has gained entrance into the trachea or larynx and hinders the flow of air; it relieves breathing when an abscess develops at the back of the throat in strangles in horses, and threatens to occlude the passages; it is also undertaken in oedema of the glottis, in roaring, and in other conditions.

An incision is made into the trachea, through the skin and muscles, usually in the middle line (in cattle sometimes at the side), and a tracheotomy tube is inserted and fixed in place.

The air in the stable must be kept as clean and free from dust as possible, and during foddering or bedding operations a plug should be put into the tube to prevent pieces of chaff, hay seeds, etc., from getting drawn in by the inspired air.

Trachoma

(See EYE, DISEASES AND INJURIES OF.)

Track Leg

A condition seen in the racing greyhound. There is a swelling of the triceps muscle or the semitendinosus muscle – due to sprain. Prolonged rest is necessary.

Tragelaphus strepsiceros

(See KUDU, GREATER.)

Training

(See MUSCLES; EXERCISE.)

Tramadol

An opioid analgesic for the relief of moderate and severe pain; particularly used for ARTHRITIS in dogs.

'Trancing Syndrome'

Episodes from a few seconds to longer than half an hour where a dog exhibits a slow motion walk with compulsive pacing. The dog remains conscious of its surroundings. It has been seen in BULL TERRIERS.

Tranquillisers

This term usually implies drugs which reduce anxiety without inducing sleep or drowsiness. They include benzodiazepines such as diazepam and azapirones such as buspirone. They are used in veterinary practice to calm or restrain vicious or nervous animals; to obviate travel sickness; and to facilitate the induction of anaesthesia. Their use is not permitted at Kennel Club shows.

(For horses, see DETOMIDINE.)

Tranquillisers have been administered to cattle, zoo and wild animals, by firing a hypodermic syringe from a cross-bow, gun, or blow-pipe. (See DART GUNS OR SYRINGES; also PIGS, SEDATION OF; ROMPUN.)

Natural Several steroids have been found in extracts of ovarian tissue which exert a strong sedative effect on the central nervous system. Variations in secretion rates of these steroids during the reproductive cycle may be partly responsible for cyclic variations in behaviour. Slight tranquillity could occur when the blood concentration of the steroids is relatively high; restlessness or even aggressiveness might result from a low concentration. (AFRC)

Transcription

A process of producing a complementary RNA from a DNA sequence. DNA and RNA can be converted from one to the other by the use of specific enzymes.

Transferable Resistance

(See under ANTIBIOTIC RESISTANCE; PLASMIDS.)

Transferrin

A beta-globulin present in blood plasma and acting as a carrier of iron. (See also IRON.)

Transfusion of Blood

(See under BLOOD TRANSFUSIONS.)

Transgenic Animals

Those bred by genetic engineering methods involving the isolation of genes from one animal, modification of them in the laboratory, and introduction of them into animals of the same or different species. (See also RETROVIRUS.)

Transitional Cell Carcinoma

A malignant cancer of the mammalian urinary bladder.

Transition Cow, Transition Period

A cow during the period of about two to three weeks before calving when she is a DRY COW and for the two to three weeks after calving. The aim is

VetBooks.ir

to provide diets to adapt the cow to her next lactation, without resulting in metabolic diseases such as MILK FEVER, HYPOMAGNESAEMIA, HYPOPHOSPHATAEMIA and FATTY LIVER SYNDROME, improve milk production, fertility and reduce susceptibility to infection.

Transit Tetany

Transit tetany is the result mainly of HYPOCALCAEMIA, which is precipitated by the stress of long travel. It is seen in ruminants and, more rarely, in horses.

In lactating mares (also known as lactation tetany), it may occur about 10 days after foaling or a day or two after weaning. It can also occur, it has been said, in fillies and colts.

In ruminants, prolonged travel may induce HYPOCALCAEMIA or HYPOPHOSPHATAEMIA in cattle, with HYPOCALCAEMIA, HYPOMAGNESAEMIA and HYPOGLYCAEMIA in ewes.

Signs These vary according to the extent to which the blood calcium level is reduced. A slight reduction causes the mare to be excitable, but a further fall produces muscular incoordination and staggering, and the animal appears obviously distressed. Sweating may occur; rapid and noisy breathing and, in the mare, flared nostrils are other signs. A stiff gait, raised tail, and spasms similar to those of tetanus occur.

Another similarity is that eating and drinking may become impossible. RECUMBENCY, coma, and death follow within a couple of days.

While mild cases recover, the mortality is high in untreated animals showing the more severe signs.

Treatment The animal should be kept quiet and the appropriate dose of a mineral replacement solution, e.g. CALCIUM BOROGLUCONATE 20 per cent, given subcutaneously or by slow intravenous injection.

Translocation

In CYTOGENETICS, this means transfer of a broken-off fragment of one chromosome to another. A cause of some congenital diseases. The frequency of occurrence increases with age.

Transmissible Gastroenteritis of Pigs (TGE)

Transmissible gastroenteritis of pigs (TGE) is a rapidly fatal disease in young piglets. The cause is a coronavirus; mortality decreases with age of the piglet. For example, mortality may be 90 per cent in the first week of life, 50 per cent in the second, 25 per cent in the third, and zero in older pigs.

Foul-smelling watery diarrhoea, vomiting and loss of appetite are the main signs in piglets. Adult pigs are usually little affected, although fattening pigs require extra water during an outbreak.

TGE is typically but not exclusively a disease of the winter months. Epidemics occurred in winter every five to seven years between 1956 and 1983. Apart from two incidents in 1996, the UK was free from TGE until a single incident in 1999. The absence of disease from Britain and continental Europe since the mid-1980s has been attributed to the emergence in 1986 of porcine respiratory coronavirus. This is an apparent mutant of TGE virus and is believed to have effectively immunised the pig population against TGE. The reservoir of virus may be as a subclinical infection in large herds.

There is no specific treatment, but losses may be reduced by extra care and management: warmth and extra fluids; good-quality milk replacer/creep pellets; early weaning into warm accommodation; cross-suckling affected piglets onto recovered sows; using antibiotics to control secondary infection.

Control TGE is spread by direct or indirect contact with infected faeces; strict attention to disinfection and hygiene is essential. Sows due to farrow, and sucking piglets under seven days old should be isolated. Exposure of uninfected pigs to recently infected stock may help to develop herd immunity.

Transmissible Mink Encephalopathy

A spongiform encephalopathy which has been reported in mink in the USA. The affected mink were fed bovine offal.

Transmissible Viral Proventriculitis (TVP)

A disease of broiler chickens caused by a BIRNAVIRUS. referred to as chicken proventricular necrosis virus. It is known in the USA and in Europe. It is characterised by poor growth ('runting'), poor feed conversion but low mortality. At post mortem there is an enlarged whitish proventriculus.

Transplants

(See EMBRYO TRANSFER and SKIN GRAFTING TRANSPLANTATION).

Transponder

An electronic device which stores information that can be read by a suitable scanner. In miniaturised form, transponders are the basis of identity MICROCHIPS.

Transport Stress

Stress caused by transportation can adversely affect the welfare and health of farm animals and the

VetBooks.ir

meat quality of the carcase. A method has been developed for measuring the adverse nature of the noise and vibration components of transport, using operant conditioning. The equipment is a modification of a machine originally developed for testing tractors, and consists of a pen which is tilted up and down in all directions, generating a noise of 80 decibels. It was found that pigs soon learn to press a panel with their snouts in order to obtain a 30-seconds respite from vibration and keep the machine immobile for 70 per cent to 80 per cent of the time. The animals switch the machine off more frequently when the speed of vibration is increased and also when they have eaten a large meal just before the test. During an hour-long session the frequency with which the machine was switched off tended to increase, showing that aversion to the conditions does not diminish with time. Pigs which have experienced the machine will press the switch when exposed to a recording of the noise even when there is no movement. In contrast, naive animals do not learn to operate the switch when exposed to the noise alone. The advantage of this technique is that specifications for improved methods of transport can be based on the animal's own preferences. Pigs may vomit when being transported. Animals transported over rough ground, stormy seas or buffeted in aircraft usually lie down to minimise the effect on their bodies. In horses, air transport increased heart rate during loading, taxiing and turbulence, but it was less stressful than road transport. Resting values were achieved during the flight, which did not occur in road transport.

Transudate

A fluid which has passed through a membrane such as the peritoneum, or exuded from a tissue. Unlike an EXUDATE it is very liquid and does not contain much protein, cells or cellular debris.

Transverse Facial Cleft

A congenital fissure that extends laterally from the angle of the mouth.

Trapped Neutrophil Syndrome (TNS)

An inherited disorder seen in dog breeds such as the BORDER COLLIES. It is an immune deficiency due to altered neutrophil production in that these white cells are not released from the bone marrow into the blood. Some animals show bone alterations of size or shape, but often is not seen until vaccination or a poor response to fever. It can be detected by blood tests and confirmed by bone marrow biopsy.

Traumatic Pericarditis

(See HEART DISEASES.)

Traumatic Peritonitis

Seen in ruminants (particularly cattle) where a sharp object penetrates the wall of the RETICULUM, usually causing a localised area of peritonitis. It used to be called 'HARDWARE DISEASE' because most cases resulted from nails and other metal objects dropped when building or fencing. It often occurs due to parts of rotting tyres entering silage; or occasionally from CHINESE LANTERNS. (See PERITONITIS; STOMACH, DISEASES OF – Foreign bodies in the reticulum.)

Traumatic Reticulitis

Inflammation of the wall of the RETICULUM, caused by its penetration, partial or complete, by sharp objects. (See PERITONITIS; STOMACH, DISEASES OF – Foreign bodies in the reticulum.)

Traumatic Reticulopericarditis

This results when a foreign body penetrates the reticulum, the peritoneum and diaphragm and then enters the pericardial sac resulting in a pericarditis. (See TRAUMATIC PERICARDITIS.)

Traumatic Reticuloperitonitis

Also known as 'WIRE' or 'HARDWARE DISEASE', the term is used where a sharp hard material, usually metal, penetrates the wall of the reticulum, and the peritoneum. Cases have increased due to breakdown of tyres used to weigh down silage clamps. It results in a painful ruminal cycle, arched back with reduced milk yield, fluctuating temperature and appetite. There is LEUKOCYTOSIS and lesions may be seen on ultrasonography. Control can involve MAGNETS.

Travel Problems in Pets

About one in four dogs (23.8 per cent) display behavioural problems when travelling by car. Dogs not previously transported by car when puppies are more prone to show signs as adults.

Travel Sickness

Travel sickness is observed in dogs and cats – some individuals being particularly susceptible – and may be relieved by the administration of a suitable tranquilliser prior to the journey. Fitting a chain to a car so as to act as an earth has been recommended, but may be less effective than periodic stops and adequate ventilation. It may also occur in horses on long sea voyages. (See also TRANSIT TETANY.)

Treads

Treads are injuries inflicted at the coronet of the horse's foot, either by the shoe of the opposite foot, or, when horses are worked in pairs, by the adjacent horse. When situated in the posterior half of the foot, the upper free edge of the lateral cartilage may be damaged and a QUITTOR result.

Trefoil
Consumption of the plant is a cause of LIGHT SENSITISATION in Australia.

Trematode
An unsegmented flat worm or fluke. (See LIVER-FLUKES; LUNG-FLUKES; RUMEN FLUKES; SCHISTOSOMIASIS.)

Trembling in Dogs
(See under 'SHIVERING'.)

Tremors
Very fine jerky contractions of a muscle or of some of the fibres of a muscle. They are often seen in nervous animals when frightened, and they are one of the signs of viciousness in a horse when seen on the quarters, especially when the horse is watching out of the corner of its eye. Tremors are, however, encountered in certain nervous disorders, such as shivering in horses and chorea in dogs. (See also 'CRAZY CHICK' DISEASE.HYPOMAGNESAEMIA in cattle, and RABIES in many species, also give rise to tremors. (For tremors in pigs, see SWINE FEVER.)

Trephining
Trephining is an operation in which a small disc of bone is removed from the cranium to permit the elevation of a depressed portion, or to allow access into the brain cavity or elsewhere in the skull to gain access to a sinus. In certain purulent conditions of the air sinuses of the horse's head, trephining may be required to give drainage for the pus.

Treponema
A genus of spiral organisms of the family Treponemaceae, which includes also *Borrelia* and *Leptospira*. (See also SWINE DYSENTERY.)

Triamcinolone Acetonide
A steroid which has anti-inflammatory, anti-pruritic and anti-allergic activity. It is used in topical preparations and in horses as an intra-articular injection for OSTEOARTHRITIS.

Triamilides
Macrolide antimicrobial agents, with a 15-membered ring, which include TULATHROMYCIN.

Triatomid Bugs
Triatomid bugs are the most important vectors of human trypanosomiasis in South and Central America.

Tricaine Methane Sulphonate
This is licensed for use as an immersion bath for fish to achieve sedation, immobilisation or anaesthesia. It may be used during transportation, weighing, tagging, stripping of brood stock, blood sampling and surgery. Fish should be fasted for 24 hours prior to prolonged use or surgery. It can be used on ornamental fish (but it is toxic in some species) and those for human consumption, but the withdrawal period is 70 days.

Tricarboxylic Acid Cycle
Also called the KREB'S CYCLE and CITRIC ACID CYCLE. It is the conversion of glucose into energy within the body from carbohydrates (sugars), lipids (fatty acids), proteins (amino acids).

Trichiasis
Ingrowing eyelashes (See EYE, DISEASES AND INJURIES OF).

Trichinosis, Trichinellosis
Trichinosis is an infestation of the muscles of the pig, man, dog, etc., with the larvae of *Trichinella spiralis*, a small roundworm. Pigs become infected by eating infected rats, or raw swill or garbage containing pieces of infected pork. Trichinosis constitutes a serious problem among sledge-dogs in the Arctic and may follow the eating of walrus, bear, seal or fox-meat. A temperature of –15° C (5° F) for 20 days is needed to kill the larvae. According to the FAO, it is one of the 10 food-borne parasites with the greatest global impact.

Infection in man occurs through the eating of raw or undercooked meat. Human symptoms include pain in muscles; myocarditis, meningitis, encephalitis, and rarely death have occurred.

The disease has not been seen in the UK for some years, but outbreaks have occurred in the past. Thus in the UK, human cases of infection are rare and acquired abroad. (See ROUNDWORMS.)

Trichocephalus, Whipworm
Trichocephalus (whipworm) is the name of a worm that infests the caeca of various animals. (See ROUNDWORMS.)

Trichodinella and *Trichodinia*
Trichodinella and trichodinia are skin parasites of fish. Their sharp, rasping teeth damage the skin.

Trichoglyphs
(See WHORLS.)

Trichomonas
(See TRITRICHOMONAS.)

Trichomoniasis
(See TRITRICHOMONIASIS.)

Trichomoniasis, Avian
(See AVIAN TRITRICHOMONIASIS.)

Trichophyton
(See RINGWORM.)

Trichosporum mycotoxinvorans
It has ameliorated the toxic effect of ochratoxin by biotransformation. Supplementing the diet of contaminated feed reversed the growth-depressing effect and increased macrophage and heterophil production, offsetting the immunosuppressive effect of the toxin. It also reversed the growth-depressing effect of T-2 toxin.

Trichostrongylosis
Parasitic disease caused by infection with *Trychostrongylus* worms. It can affect most mammals, causing poor growth, lack of condition and diarrhoea.

Trichostrongylus
A large group of parasitic worms which infest both people and their domestic animals, and which cause persistent diarrhoea.

Trichothecenes
Trichothecenes are fungal metabolites which contaminate animal feeds and human foods. Examples are deoxynivalenol and nivalenol. The most potent toxin is T_2 TOXIN.

Throat irritation and digestive disorders are caused in people. Baking does not destroy the toxin.

Trichuris
A genus of roundworms which has a thick posterior part and a long thin anterior part to the body resembling a whip, hence the common name of WHIPWORM. *T. campanula* (cat whipworm), *T. muris* (mouse whipworm), *T suis* (pig whipworm) and *T. vulpis* (dog whipworm). The adults are mainly found in the large intestines.

Triclabendazole
A flukicide licensed for use in cattle and sheep; it is effective against adult, immature and early stages of the parasite. Some fluke in sheep have become resistant to this treatment. In heifers, it can be used orally but not during the last trimester of pregnancy, and if used as a pour-on, it must not be used in cattle at any age intended to produce milk for human consumption. In sheep and goats, it is administered orally and must not be used within one year prior to the first lambing or kidding.

Tricuspid Valve
The tricuspid valve is the valve lying in the heart between the right atrium and the right ventricle, which possesses three cusps or flaps. (See HEART.)

Trigeminal Nerve
Trigeminal nerve is the fifth of the cranial nerves. (See NERVES.)

Triiodothyronine (T3)
An iodine-containing hormone produced in the THYROID GLAND. It affects almost all physiological processes, including development, growth, metabolism, body temperature and heart rate. It is more active than THYROXINE.

Trilostane
It is licensed for use in the treatment of Cushing's Disease in dogs. It is useful in both pituitary-dependent and adrenal-dependent HYPERADRENOCORTICISM.

Trimester
A term adopted from human pregnancy and meaning a period of three months. However in pregnancy it usually refers to a third of the normal pregnant period.

Trimethoprim
A drug which inhibits the growth of many bacteria and some protozoa through reducing their synthesis of folinic acid (necessary for synthesis of nucleic acids). Effective against many Gram-positive and Gram-negative bacteria. One part of trimethoprim is combined with five parts of sulfadiazine, with which it is synergistic, in co-trimazine. Several other preparations of trimethoprim with one or other of the sulfa drugs also exist.

Triorchidism
A condition in which three testicles are present. This was found in a cock – all three being functional, and structurally independent. A case in which there was duplication of the right testicle was seen in a calf. (In man, triorchidism is not extremely rare, and even five testes in a scrotum have been recorded.)

Triphalangia
A congenital problem where there are three phalanges present in a thumb or big toe or its equivalent.

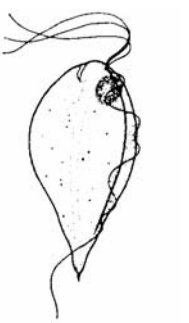
Triplet Calves
In the UK in 1985 a Friesian cow had triplets. After initial breathing difficulties, all three survived and were described as 'fine, strong calves'. Quintuplets have been recorded.

Triploid
An animal having one-and-a-half times as many chromosomes in its cells as a normal (i.e. diploid) animal. (See COLCHICINE.)

Triploidy accounts for up to 13 per cent of embryonic loss in animals, and for 20 per cent of all chromosomally-caused spontaneous human abortion (ARC). (See CHROMOSOMES; CYTOGENETICS.)

Trisaccharides
A sugar which breaks down on hydrolysis to three MONOSACCHARIDES.

Trismus
The clenching and thus locking of the jaws, which is characteristic of TETANUS.



Trisomy
The presence in triplicate of a particular chromosome. In the cow, such a condition would be denoted as 61,XXX.

X-trisomy is associated with nymphomania and infertility in cows.

Triticum species
(See WHEAT.)

Tritrichomonas
The flagellates of the genus *Tritrichomonas* are usually pear-shaped, with three to five anterior flagella, an undulating membrane and, in some species, one free flagellum directed backwards. Species of this genus very commonly occur in the intestinal canal of many different species of mammals and birds.

Tritrichomoniasis
Tritrichomonas fetus causes abortions, pyometra and, sometimes, sterility in cattle. The cow becomes infected by the bull at coitus, or vice versa.

Trichomonas fetus.

Signs A transient vaginitis, which is often overlooked. It can appear when conception has occurred, a cow is pregnant, the fetus dies and is either aborted one to four months later or retained in the uterus, where it becomes macerated and a PYOMETRA develops.

Control of the disease includes the disposal of infected bulls, withholding all breeding operations on infected cows for at least three months, and the serving of non-infected cows and virgin heifers by a 'clean' bull. Freezing bull semen to –79° C (-110° F), in the presence of 10 per cent glycerol, kills *T. fetus* but allows the spermatozoa to survive. This method of deep-freeze, commonly practised at AI centres, is one way of getting rid of the infection from semen.

Avian tritrichomoniasis, caused by *T. gallinae*, affects the oesophagus of budgerigars, pigeons, etc. causing necrotic lesions with retching and vomiting. Also known as canker or roup. In pigeons, which feed their young on 'crop milk', squabs are easily infected which led to the belief among pigeon-fanciers that the disease was inherited. It can be treated by lowering stocking densities and oxytetracyclines to reduce losses.

Trixacarus caviae
The mange mite which is a parasite of guinea-pigs.

Trixylphosphate
A substance used in the manufacture of plastics. Poisoning of cattle has occurred through contamination of molasses with this substance. Signs included diarrhoea, coughing, unsteady gait, partial paralysis.

Trocar
A sharp-pointed, rod-like instrument used with a cannula to puncture the wall of a body cavity. It is often used to release gas in cases of bloat in ruminants.

Trochanter
One of the protuberances on the femur which serve as attachment sites for hindquarter muscles.

Trochlear Nerve
The fourth cranial nerve (see NERVES), also known as the pathetic nerve. It controls the superior oblique muscle of the eye.

Trombicula autumnalis
A harvest mite, now often referred to as *Neotrombicula autumnalis.* (See MITES, PARASITIC - OTHER MITES - HARVEST MITES.)

Trombiculosis
Infestation with *Trombicula autumnalis*, the harvest mite.

Trophic
Relating to nutrition; neurotrophic means the influence that nerves exert upon the tissues to which they are distributed, for health and nourishment.

Trophins
Gland-regulating hormones.

VetBooks.ir

VetBooks.ir

Trophoblast

The outer layer of BLASTOCYSTS which make contact with the wall of the uterus, and through which nutrients and waste products are exchanged between fetal and maternal circulations. (See also SYNCYTIUM.)

Tropics, Livestock Production in the

Livestock farming in the tropics, and even in some subtropical developing countries, is beset with difficulties not experienced to anything like the same degree in developed countries having a temperate climate.

In developing countries there is often the additional problem of limited financial resources. Money may not be available for measures to counter or ameliorate adverse conditions for animals; to provide adequate supplies of safe drinking water, good-quality feeds, vaccines, prophylactic drugs; or to support disease eradication programmes on a large scale. Veterinarians are usually few in number in relation to the large areas in which they are needed (see VETERINARY PROFESSION), and faced with great distances to cover and an absence of local laboratory services.

Heat Animals can survive in temperatures of up to 60° C (140° F). Temperatures above that are lethal. Cattle in Death Valley, California, and in Queensland, Australia, for example, exist at temperatures of 52° C to 58° C (125° F to 136° F). Such heat, however, is far above the comfort zone – estimated as air temperature at between 21° C and 26° C (70° F to 79° F); or 13° C to 18° C (55° F to 64° F) for adult cattle.

High temperatures impose stress upon the animal's physiological processes and productive capacity.

Records for more than 12,000 inseminations over a two-year period in a Florida herd indicated a sharp decline in conception rates of cows when a maximum air temperature the day after artificial insemination exceeded 30° C (86° F) (35° C (95° F) for heifers).

Besides air temperature, radiation, air movement, and humidity all influence the animal's immediate environment. Body temperature is controlled by the heat-regulating mechanism (see HYPOTHALAMUS), and affected not only by environmental heat but also by the heat generated in the tissues (see METABOLISM). The more the animal eats, the more heat its body will produce. Water intake also plays a part in the physiological reactions; as does sweating, but in this respect cattle are less efficient than people. In great environmental heat, the point may be reached where normal body temperature cannot be maintained, and it rises – a state of HYPERTHERMIA. Death may result.

Even at non-lethal levels, tropical heat is a limiting factor so far as fertility and yields of milk, meat and eggs are concerned. Poor feed, and water deprivation, can further depress growth rates, fertility and yields. Humidity can increase heat stress.

Signs Heat stress may cause the body temperature to rise to 42° C to 43° C (107° F to 110° F) in cattle. The earlier sign of rapid breathing progresses to panting. The mouth may be kept open, tongue lolling out, and frothy saliva may be in evidence. Appetite is lost. Cattle may remain standing, huddling together.

Preventive Measures If heat stress is to be avoided or minimised, livestock must have shade (from trees or shelters) to protect them from the sun's rays. Cooled drinking water is beneficial to all livestock in tropical heat. Pigs need to be able to wallow – their normal, instinctive method of cooling themselves. Cool water sprays can help dairy cattle to withstand high temperatures. Grazing should take place at night rather than during the day.

Zero-grazing may be practicable in some places, and beneficial too.

Poultry in the tropics grow larger combs and wattles than do similar birds in temperate climates, as a physiological means of body cooling. At very high temperatures they dip combs and wattles into water, for an extra cooling effect. It has been suggested that the design of drinkers in intensive poultry units should be such as to make possible this beneficial practice.

Antibiotics and poultry In developing countries in the tropics, the widespread use of antibiotics – especially the tetracyclines – in modern battery poultry units has been blamed for encouraging the proliferation of drug-resistant bacteria. Where indiscriminate use is coupled with poor sanitation and low personal hygiene, the situation may constitute a danger to public health.

In a study in Nigeria of *E. Coli*, 1248 strains isolated from battery hens at the University of Ibadan, and 2196 strains from a commercial poultry farm, were resistant to tetracycline, streptomycin, and also sulfonamides. By contrast, all strains isolated from free-range town and village poultry were sensitive to these drugs.

Altitude In some regions, altitude mitigates the effect of heat. The uplands of Jordan are regarded as suitable for intensive poultry production; and Iran's uplands, with their dry climate, make dairy farming practicable despite very high summer temperatures of 43° C (109° F) upwards, and very cold ones in winter.

VetBooks.ir

When temperature falls during night-time hours, cattle may withstand a higher day-time temperature than they otherwise could.

Very high altitudes, e.g. in the mountains of Peru, can themselves be an obstacle to livestock production. (See ALTITUDE; 'MOUNTAIN SICKNESS'.)

Stock improvement When high-yield stock are imported into tropical regions from countries having a temperate climate, disappointment often follows. At first, yields – whether of beef, milk, pork or eggs – are better than those of the indigenous stock, as expected; but before long, in many instances, the initial gains are offset by a high mortality rate. The exotic animals may not be able to tolerate the heat, may not produce so well when fed on local feeds of lower quality, and will have no resistance to many local diseases and parasites, especially ticks. (For cattle resistant to heat and ticks, see DROUGHTMASTER; ZEBU; SANTA GERTRUDI; AFRICANDER)

In many situations it is often preferable to improve indigenous stock first, before introducing new blood from overseas, by selective breeding and better management; ensuring that they are better fed and not deprived of adequate quantities of drinking water. After improvement has been obtained by these means (but not before), cross-breeding with exotic high-performance stock may be begun, preferably on a small-scale trial basis to start with. Use may be made of AI.

Animal power In India it is estimated that work animals provide as much energy as the entire electrical system of the country. The number of work animals is estimated to be 70 million bullocks, 8 million buffaloes, 1million horses and 1 million camels. Throughout the Far East animal power remains the major factor in agriculture. Small farms, difficult terrain, lack of roads and the structure of the rural economy in many countries mean that situation is unlikely to change in the foreseeable future. (See WATER BUFFALOES.)

Animal feeds In poorer countries the cost of importing cereal grains or high-quality protein feeds may be prohibitive, and local stock will then be dependent on feeds which may restrict their yields – though obviously this is not always the case.

Imported feeds sometimes deteriorate to some extent during long sea voyages and subsequent storage in a hot and often humid climate. There may, for example, be a serious loss of vitamin E, so that a supplement is required if ENCEPHALOMALACIA is to be avoided. (See also VITAMINS.)

Local crops such as groundnuts, cotton seed, sorghum and sunflower seed may be contaminated by AFLATOXINS, so that precautions are needed. Groundnuts may be affected in this way through being left too long in the ground before harvesting, or during subsequent storage.

Minerals In many parts of the tropics, milling and processing facilities are lacking – at any rate in the more remote areas; this fact makes feed supplementation more difficult. Mineral and trace element supplements are necessary for avoidance of deficiencies. In South Africa many years ago, Sir Arnold Theiler showed that the need of cattle for phosphorus drove them to eat the bones of dead animals, and many cattle became infected with botulism in that way and died. (See LAMZIEKTE.) In several parts of the world a deficiency of copper in the herbage has impeded livestock production, and appropriate dressings of the land have brought great benefit. (See TRACE ELEMENTS.)

Some tropical crops Apart from the crops mentioned above, many others – or their by-products – are used. For example, cattle may have the leaves of shade trees, or sugar-cane; pigs may be given dried leaf meal, banana waste, coca pod husks, or sweet potatoes; poultry may receive millet (if any can be spared from human food requirements) or sago.

(See GOSSYPOL - GOSSYPOL POISONING; CASTOR SEED POISONING; COCOA POISONING.)

Tropical diseases In some tropical regions the presence of animal parasites and their vectors makes livestock production difficult, costly, or even impracticable. This is true of the African tsetse-fly belt, extending roughly from latitude 15°N to 30°S. Here control of trypanosomiasis (see TRYPANOSOMES) is dependent on drugs for prevention, drugs for treatment, and use of insecticides against flies. Aerial spraying, bush clearance, and attempts to eradicate reservoirs of infection among wild animals will, if undertaken, obviously add to the cost, which in some territories may be beyond local resources. For many years control of trypanosomiasis had been successfully achieved by aerial spraying with insecticides, but the ever-rising cost of these, and of aviation fuel, has led to the abandonment of many such government schemes. Fly traps have had to be used instead. The Manitoba trap designed specially for tabanids is reported to be very successful; another widely used trap is the Laveissire. In other territories long-term, government-controlled campaigns have proved successful in maintaining and extending production.

Humpless cattle, such as the N'Dama, in West Africa had long been regarded as historic relics, and their reduced susceptibility to trypanosomiasis as a biological oddity. It has been shown, however,

VetBooks.ir

that despite their relatively small size, N'Dama cattle could survive and be productive in endemic trypanosomiasis areas where Zebu cattle died.

Comparative studies on two types of large East African zebu (*Bos indicus*) Boran cattle, on a beef ranch in Kenya, indicated that a Boran type bred by the Orma tribe has a superior response to tsetse fly challenge. The Orma Boran when compared with an improved Boran was found to have lower trypanosome infection rates and, when untreated, better control of anaemia as well as decreased mortality.

In areas where trypanosomiasis is endemic in susceptible cattle, sequential use of such drugs as diminazine and suramin has been effective in controlling the disease without causing drug resistance to develop.

Trypanosomes cause disease also in Asia and Central and South America.

Ticks are of great importance in the tropics, transmitting numerous protozoal parasites, viruses, and rickettsias. (See under TICKS.)

Among the major diseases caused by viruses are cattle plague (RINDERPEST), African swine fever, foot-and-mouth disease, and various types of encephalitis. Bacterial diseases include ANTHRAX, BOTULISM, HAEMORRHAGIC SEPTICAEMIA (PASTEURELLOSIS IN CATTLE) and SALMONELLOSIS. A notable mycoplasmal disease is CONTAGIOUS BOVINE PLEURO-PNEUMONIA; another is CONTAGIOUS AGALACTIA OF SHEEP AND GOATS.

Vaccine storage/transport One of the problems of veterinary medicine in the tropics is the storage of vaccines at a sufficiently low temperature (below 8° C [46° F]). With the high cost and scarcity of kerosene or liquid propane gas in many rural areas, and the fact that electricity supply is often unreliable or non-existent, there is scope for solar refrigerators. Under a WHO scheme these have been tried in 13 countries. Photo-voltaic panels exposed to the sun supply electricity direct to an ordinary commercial refrigerator.

Sterilisation In the tropics the sun's rays can be used for sterilisation purposes. Research at the American University of Beirut showed that oral rehydration solution, for treating dehydration, can be sterilised in plastic bags or transparent plastic or glass vessels by exposure to sunlight. In an experiment, such a solution contaminated with fresh sewage, proved to have a zero coliform count after one hour. It appears that the sterilising effect is not heat, since the temperature of the solution rises by less than 5° C (41° F) after two hours, but is rather solar radiation in the near ultra-violet range.

Another application is the Solomon solar steriliser which uses only solar energy to boil water and sterilise needles and syringes. The prototype consisted of a metal-lined plywood box topped with a truncated pyramid of glass. The steriliser, in use in the Solomon Islands, is easily constructed, has no moving parts, and requires no fuel; but it does need orienting to the sun every half-hour (World Health Organisation)

Carcase disposal, following post-mortem examinations, may present problems in undeveloped areas. An Australian veterinarian working at an Indian sheep project found the answer. If unsuitable for boiling as dog food, and yet not likely to spread infection, the carcase is dragged out into the open. He timed events on one occasion. 'At 2.46 p.m., post-mortem examination completed; no vultures to be seen in a clear sky. At 2.50 the first arrived; at 2.53 there were approximately 40 vultures around the carcase; at 2.58 carcase stripped to bones and sinew – vultures leaving.'

Trp

(See TRYPTOPHAN.)

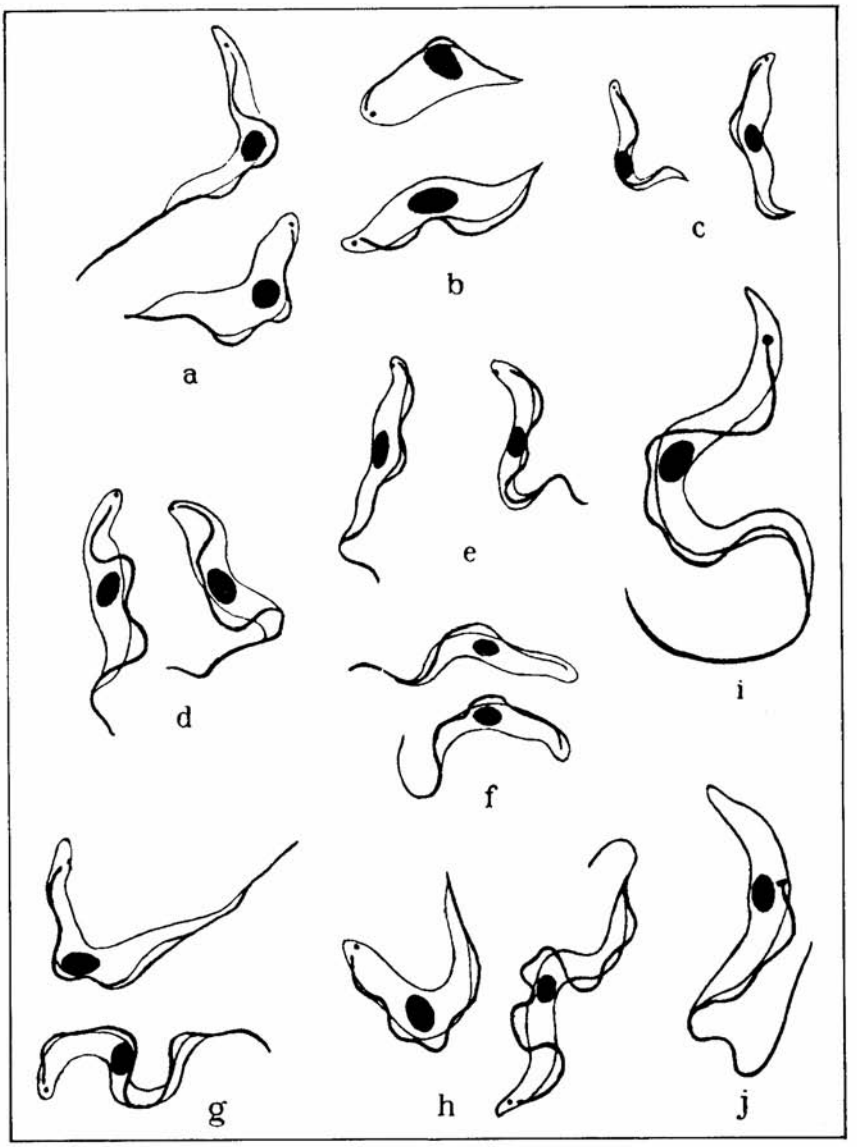
Trueperella pyogenes

The current name for *Arcanobacterium pyogenes*.

Trypanocide

A drug which will kill TRYPANOSOMES within the host's body.

Trypanosomes



Trypanosomes are small single-celled parasites found in the bloodstream in certain diseases that are classed together as the trypanosomiases.

The trypanosome is of an elongated shape with a single flagellum and an undulating membrane. There are two nuclei – a large nucleus (macronucleus or trophonucleus) near the centre of the body; and a small kinetoplast (micronucleus) at the posterior end remote from the flagellum. In some forms there is no free flagellum.

Transmission is generally by the bite of an insect (except in the case of dourine). The transmission may be mechanical, i.e. carried directly from an infected animal to an uninfected one by the bite of a blood-sucking fly; or cyclical, when the insect host is not infective for a definite time after ingestion of the parasite. In this case the parasite passes a definite part of its life-cycle in the fly. In many cases transmission may be both mechanical and cyclical. Thus the tsetse fly may have two infective periods, one immediately after biting a sick animal and the second some time later (about 20 days) after the trypanosome has progressed to its infective stage along normal lines.

Life histories of trypanosomes In the blood of the mammalian host, the trypanosomes

VetBooks.ir

Some typical trypanosomes (drawn to the same scale and magnified 2000 times): (a) *Trypanosoma brucei*; (b) *T. montgomery*; (c) *T. congolense*; (d) *T. vivax*; (e) *T. simiae*; (f) *T. equinum*; (g) *T. equiperdum*; (h) *T. evanis*; (i) and (j) *T. theileri*.

reproduce by splitting lengthwise (longitudinal fission). A quantity of blood is sucked up by the tsetse fly, a species of *Glossina*, and in that host the flagellates undergo a developmental cycle. The location chosen by the parasite for its development varies with the species. Thus some will develop only in the salivary glands, others in the gut, and still others in the proboscis. After some time they assume the infective form, and are ready to be passed with the salivary fluids into the bloodstream of a suitable vertebrate host.

African trypanosomiasis Tsetse-borne trypanosomiasis renders approximately 10 million square km of prime African land unsuitable for cattle production. It has been estimated that if this disease could be controlled, the infested area would increase its cattle holding capacity from 20 million head to 140 million head.

The disease is of greatest importance in cattle, which are hosts of the following trypanosomes: *Trypanosoma congolense*, *T. vivax*, *T brucei, T. uniforme*, and *T. evansi*.

VetBooks.ir

Usually a chronic disease, acute cases also occur, and the mortality may be high. (See also PREMUNITION; and, for resistant breeds, TROPICS, LIVESTOCK PRODUCTION IN THE.)

Signs These include intermittent fever, anaemia, anorexia or pica, a progressive loss of condition, and increasing weakness. (See under CHANCRE for the hard swelling which is often the first pointer to trypanosomiasis.) Lymph nodes are enlarged in many cases, the coat harsh, and abortion may occur.

Some cattle recover, but in others apparent recovery is followed later by a relapse and death. In acute cases, death may occur within a fortnight.

Horses Additional signs include oedema of the limbs and abdomen, and corneal opacity. Species of trypanosome infecting horses are *T. brucei*, *T. vivax*, and *T. evansi*. (See also DOURINE, caused by *T. equiperdum*, transmitted at coitus, and occurring also in Asia.)

Dogs The eyes may be affected, as in horses. Canine trypanosomiasis is caused by *T. brucei*, *T. congolense*, and *T. evansi*.

Pigs often suffer from acute and fatal trypanosomiasis caused by either *T. simiae* or *T. evansi*.

Control This is difficult, on account of trypanosomiasis existing in wild animals in the vicinity of cattle herds, and the fact that vaccination has not been practicable.

In well-managed herds in areas where tsetse-fly numbers are relatively low, drugs are used for preventive purposes against the trypanosomes; but as the latter develop drug resistance, it is usually necessary to change drugs.

In other areas, reliance is placed on drugs for treatment rather than prophylaxis; these can achieve survival of cattle where untreated animals die.

(See also under TSETSE FLY for another aid to control of the disease, and under TROPICS, LIVESTOCK PRODUCTION IN THE for breeds resistant to trypanosomiasis, and for drugs in current use.)

Diseases caused by trypanosomes are separately described under NAGANA, DOURINE, SURRA and (for human trypanosomiasis) SLEEPING SICKNESS and CHAGAS DISEASE. The latter also affects domestic animals and is described immediately below.

American trypanosomiasis (Chagas disease) Caused by *Trypanosoma cruzi*, this occurs in South and Central America, and also in the southern states of the USA. WHO estimates that at least seven million people are infected with *T. cruzi*. According to the FAO, it is one of the 10 food-borne parasites with the greatest global impact.

The infection can be carried from both wild and domestic animals to people by blood-sucking triatomid bugs; and the latter also cause people-to-people infections. Blood transfusions, and infection of the human fetus in utero, have also to be borne in mind.

Dogs, cats, and guinea-pigs are among domestic animals which are hosts; pigs and rabbits also have the disease. Rats, mice, foxes, ferrets, and vampire bats are other vectors.

Signs Fever, anaemia, emaciation, ascites, with death from heart failure following myocarditis in children.

Trypanosomiasis

Infection with one of a number of TRYPANOSOMES, which are small single-celled parasites found in the bloodstream in certain diseases.

Trypsin

Trypsin is a proteolytic enzyme of the pancreatic secretion. It changes proteins into peptones. It is said to be helpful in cases of non-specific diarrhoea in dogs.

Tryptophan (Trp; W)

One of the essential AMINO ACIDS necessary in brain metabolism to produce SEROTONIN, which has a calming effect. Serotonin can in turn be converted to MELATONIN. Tryptophan is also involved in the stimulation of growth hormone stimulation and is also a biochemical precursor for NIACIN and the plant hormone auxin. Diets deficient in tryptophan are associated with increased dominance aggression in dogs. Excessively high levels of L-tryptophan can result in fog fever (atypical interstitial pneumonia).

Tsetse Fly

Tsetse fly is the insect vector which is of such importance in the transmission of African TRYPANOSOMES. (See also FLIES – Glossina; TROPICS, LIVESTOCK PRODUCTION IN THE)

Destruction of tsetse flies in the fly-belts – tracts of bush country in which only cattle which have acquired some degree of immunity to trypanosomiasis can survive – has proved an almost insuperable problem. One method is the sterilisation of tsetse flies by the chemicals tepa or metepa, or by gamma radiation, and the release of sterile males. This can be complementary to the use of insecticides. A difficulty at present is the rearing of tsetse flies in sufficient quantities.

Wide use is also made of fly traps, to which tsetse flies may be attracted by means of PHEROMONES

or other chemical compounds such as CO_2, acetone, or octenol.

TS Viruses

(See VACCINE.)

Tubercle

Tubercle is a term used in two quite distinct senses. As a descriptive term in anatomy, a tubercle means a small elevation or roughness upon the surface of a bone, such as the tubercles of the ribs. In a pathological sense a tubercle is a small mass, barely visible to the naked eye, formed in some organ as the starting-point of the disease which has been called after the tubercle, viz. tuberculosis.

Tuberculin Test

The tuberculin test, in its original form, came into use in 1890. It was developed by Koch, who grew his tubercle bacilli on broth. Today, Purified Protein Derivatives (PPD) extracted from bovine and from avian tubercle bacilli are used. These greatly improve the reliability of the test, although false positives still occur. Tuberculin (PPD) is prepared from killed bacteria by adding trichloracetic acid; the precipitated tuberculo-protein is allowed to sediment, collected by centrifugation and adjusted to a standard strength.

Tuberculin has in the past been used by instillation beneath the lower eyelid of one eye (the ophthalmic test); or by subcutaneous injection (the subcutaneous tuberculin test). Today, in the UK, the test used is the double intradermal comparative test. Skin is clipped free from hair over an area the size of a 50p piece in two places on the neck.

A fold of the clipped skin is gathered up and measured with special callipers. Using a standard tuberculin syringe, 0.1 ml of tuberculin is injected into the skin (not subcutaneously). Avian tuberculin is used for one injection, bovine for the other – the avian tuberculin being given above the bovine. After 72 hours, the test is read by again measuring the thickness of the skin and the nature of the swelling produced by the injection.

A reaction to the avian tuberculin can mean exposure to *Mycobacterium avium* (especially if cattle are close to woods – pigeons are often infected), the presence of non-specific myco-bacterial infection, of Johne's disease or so-called skin tuberculosis. The swelling caused by the avian tuberculin is compared to that caused by the bovine tuberculin, using the same callipers. Where the increase in skin thickness reaction to the bovine is 4 mm or more greater than the avian PPD injection site, then the animal is considered a positive reactor and it will be slaughtered; a swelling at the bovine site is more than at the avian site of 1 mm to 3 mm indicates an inconclusive reaction and such an animal will be retested in 60 days. All other readings at an initial test are classified as a pass. Reactors are normally slaughtered at a licensed abattoir and certain organs removed for examination, if lesions are present they are cultured, even if there are no visible lesions, the retropharyngeal lymph nodes are swabbed and cultured. In the event of the culture being positive the skin test will be reinterpreted (the so-called severe interpretation) so that any animal with an increased thickness of 3 mm or more will be reclassified as a reactor and will be slaughtered. If several animals are found to have lesions likely to be TB, the original skin test may be reinterpreted at the discretion of a Veterinary Officer using the severe interpretation without waiting for the culture results.

Herds with reactors are retested with the severe interpretation not less than 60 days after the previous test. The interpretation also reclassifies animals with a bovine injection site increase in thickness of less than the increase in thickness of any reaction as inconclusive, unless the increase in skin thickness at the bovine site is 2 mm of less, at which level the animal will pass the test. Any animal which is inconclusive at two consecutive tests will be considered to be a reactor, and will be slaughtered accordingly.

Due to the cyclical nature of antibody production to TB which is affected by age, period around calving, etc. about 12 per cent of infected cattle will not react to the test. In herds with a heavy or persistent level of infection, a gamma-interferon blood test is used following a tuberculin test to help remove early infected animals. It detects a different fraction of the TB antibody to the skin test, resulting in fewer false negative results. However it can produce a few false positive animals due to cross-reaction with other bacteria including *Yersinia enterocolitica* and so it is not considered to be suitable as a screening test for cattle, goats and pigs. In camelids it may become the first test of choice as it appears more accurate than the skin test.

If a herd being tested has previously been vaccinated against JOHNE'S DISEASE, the State Veterinary Service will normally carry out the test as this vaccination produces a severe reaction to tuberculin. Some infected animals do not give a positive reaction particularly if newly infected, chronically infected or immuno-suppressed.

Testing other animals Tuberculin testing of deer requires special training, as a swelling of as little as 0.5 mm difference, can be considered significant. Poultry can be tuberculin-tested using only the avian tuberculin injected intradermally into the left wattle. Any resulting swelling of that wattle is regarded as significant. Sheep, goats and

VetBooks.ir

pigs can be subjected to the double intradermal comparative test, with the avian tuberculin being given on the left side of the neck and the bovine on the right. As pigs are not clipped, a ring made by indelible marker is drawn round the site of the injection. Primates in zoos or research facilities may be tested; only mammalin tuberculin is used and the test carried out under sedation, using the left eyelid. Any swelling is regarded as significant. LIVER-FLUKE infection can also reduce the reaction.

Tuberculosis (TB)

An infectious disease of man, all the domesticated animals, many wild animals in captivity, birds, fishes, and reptiles. It is caused by *Mycobacterium tuberculosis* (bovine, human, or avian strains). It is a NOTIFIABLE DISEASE in cattle and deer.

The disease is usually a chronic one, though the miliary form is acute. It is characterised by the formation of nodules or tubercles in almost any or all of the organs or tissues of the body. (See also 'SKIN TUBERCULOSIS'.)

Occurrence The prevalence of tuberculosis in animals bears a direct ratio to the intensity of the methods of agriculture in an area. Cattle closely confined, and housed to a great extent in buildings, are much more often affected than are those living a free open-air life. The cattle in the prairies of North America, on the tablelands of Central Africa, and in the steppes of Eastern Europe, are almost entirely free from its ravages, while it is unknown in many islands (Iceland, Sicily, etc.).

Bovine tuberculosis eradication campaigns have succeeded in several countries where there is no reservoir of infection in local wildlife.

Animals affected Among the ordinary domesticated animals, cattle and pigs are more commonly affected than are other species. Goats are also susceptible. Dogs and cats are rarely infected but have been known to contract TB where there are high infection levels in both cattle and wildlife. Horses and sheep appear to be more resistant, though cases of progressive avian TB have been recorded in both species. Donkeys and mules are only very seldom attacked. South American camelids are susceptible to the infection and are widely infected in areas where tuberculosis levels are high.

Methods of infection Cattle are infected in two chief ways: (1) by the respiratory system (most common); and (2) by the digestive tract. They are susceptible to infection from humans suffering from bovine tuberculosis, and serious breakdowns in attested herds have been traced to farm workers suffering from the disease. Cattle are also susceptible, to a lesser degree, to infection of the human type. (See also under TUBERCULIN TEST *re* avian tuberculosis) From about a week after infection in cattle until the bacteria become 'walled off' in a tubercle, cattle are highly infectious and in a period (on average of about three weeks), they can spread infection but do not have any detectable immunity and so they will pass any TUBERCULIN TEST undertaken at this time.

Badgers have been implicated in the spread of bovine TB and long-running tests were undertaken in the UK to establish whether this is the case (*See below*, Tuberculosis in wildlife).

Sometimes tuberculosis may be contracted through a wound (e.g. after dehorning) or by direct introduction into the tissues of a penetrating instrument, and an infection of the udder may easily occur through the teat canal. An aerosol infection commonly results from coughing cows, and infected sputum may contaminate feed or be swallowed, thereby spreading infection to the intestines.

Within the body, infection may spread via the lymphatic system or the bloodstream.

Tuberculosis of the vagina occurs in cows, and the disease may be spread from them to healthy cows through the medium of the bull. Infected dung can be a source of infection.

When *M. bovis* is first found in a herd or animal, it is now possible to use SPOLIGOTYPING to determine the strain, its most likely origin geographically and often the most likely species involved in introducing the infection to that herd or animal.

Nature of the lesions A typical lesion is a tubercle – a small nodular swelling whose centre contains either pus or dry yellowish cheesy material. The peritoneum, liver, lymph nodes, lungs, etc., may be affected. Sometimes the disease remains localised to the area of its first infection and does not spread. In other cases the defensive forces of the body overcome and destroy the focus of infection.

Tuberculosis may affect bones and one or more joints, causing arthritis.

Superficial, as well as deep, lymph nodes may become enlarged.

A subclinical infection may occur, and result in overt illness only when stress, under-feeding, exposure or some other infection lowers the animal's resistance.

Cattle As a rule a considerable period of time elapses between infection and the appearance of the first signs.

Tuberculosis of the lungs – the commonest type – gives rise to a hard, dry, short cough in the early stages. Later, coughing becomes more frequent and DYSPNOEA is evident.

VetBooks.ir

Appetite is variable. Sometimes a difficulty in swallowing is noticed. Loss of condition follows, with pale mucous membranes, and a staring coat. There may be diarrhoea.

Superficial lymph nodes may become enlarged. Those at the back of the throat or at the corner of the lower jaw, or the glands of the neck, shoulder, or stifle, may be swollen.

Tuberculosis of the udder – which is all-important from the milk standpoint – begins insidiously. The gland slowly becomes diffusely thickened, and more solid to the touch than normally. After milking, it does not feel quite so elastic as it should, and in some cases distinct hard nodules can be felt.

(Tuberculoid mastitis. Over 700 cases of this, due to rapidly growing acid-fast organisms other than *Mycobacterium tuberculosis*, occur in the UK annually – mainly due to not cleaning the teats before introducing antibiotics.)

Tuberculosis sometimes involves the brain or spinal cord, giving rise to signs described under MENINGITIS.

Tuberculosis of the bones and joints is not uncommon.

In the skin there occasionally develop hard tumours, about the size of a hazelnut (See also 'SKIN TUBERCULOSIS'), which, if they are opened, are found to contain cheesy or mortar-like masses in their centres. Later, ulcers may develop with the formation of multiple small abscesses in any or all of the organs. The abscesses are millet-seed sized (hence 'miliary'). This form of tuberculosis is rapidly fatal.

Sheep and goats A distressing persistent painful cough, always present, but most noticeable upon exertion and unresponsive to antibiotics; and a gradual, but quite definite, loss of condition, with progressing weakness, are the main signs observed in these animals. Sheep are very rarely affected, with about one outbreak each year in GB between 2005 and 2010, all in areas where cattle infection is common. Milking goats kept in the vicinity of infected cattle can develop tuberculosis but since 1960 it has been very uncommon other than an outbreak in 2008 involving mainly GOLDEN GUERNSEY GOATS. There is nearly always a marked anaemia, pneumonia, sometimes diarrhoea, and occasionally an infection of the udder corresponding to that found in cattle.

Horses Tuberculosis in the horse is not very common, but there are certain signs which should always lead one to suspect its presence: a gradual emaciation in spite of good food and without any other established possible cause; a slight fluctuating increase in the temperature, an occasional moist weak cough; a tucked-up appearance of the abdomen, or in some cases (where ascites exists) a heavy pendulous condition, 'pot-bellied'.

Cases in which the abdominal organs are affected sometimes terminate by lung complications – i.e. miliary tuberculosis sets in – the animal becomes feverish, distressed in its breathing, refuses all food, and generally dies within a few days. Tuberculosis may also become localised in the skin, lymph nodes, brain, or udder, but these are not common. It is comparatively often found that sooner or later some part of the skeleton (the bones of the neck being a very usual situation) becomes infected.

Occasionally, tuberculosis in the horse may be caused by the human or avian type of the tubercle bacillus.

Pigs Tubercular poultry, or wild birds such as wood-pigeons, are a not uncommon source of infection. A diagnosis may be established by means of the tuberculin test.

Signs are as in the horse. Scouring and emaciation may occur. Anaemia is common. As in horses, the bones are especially vulnerable to attack.

Lesions, which, to the naked eye, appear identical with tuberculosis, may be caused by infection with *Corynebacterium equi*. Even the use of a microscope sometimes fails to differentiate between the two infections.

Deer Disease caused by bovine or avian tubercle bacilli can be found. The clinical signs, which may not be noticeable until the disease is advanced, include respiratory signs. Caseous lesions are rarely seen as tuberculous lesions are usually filled with pus.

Dogs and cats Where tuberculosis is common in the human population, these domestic animals are liable to become infected – either as the result of receiving tubercle-containing milk, or as the result of infection from sputum or discharges from a human case. Not only may dogs and cats contract the disease from man, but they may occasionally be sources of infection to healthy human beings, and especially to children. Cats may also be infected by association with feral cats, especially those living on farms where cattle are infected by bovine tuberculosis, although *M. microti* is the most common infection type seen. (See MYCOBACTERIUM.)

As in other animals, the signs are somewhat vague until the disease is well established. The first signs may be no more than a capricious appetite, slight loss of condition, general weakness, and exhaustion when at exercise. Pulmonary tuberculosis usually begins with a short dry cough. It is less common in these animals than the abdominal form (but see PLEURISY).

VetBooks.ir

Tuberculosis of the abdominal organs is indicated by impaired nutrition and anaemia, attacks of diarrhoea and constipation alternating with each other. There may be vomiting, also ascites. Body temperature is very variable.

Joints and sinuses may be sites of infection in the cat. Occasionally skin tuberculosis is seen in dogs and cats, and may take the form of raised plaques with a tendency to ulcerate.

Amphibians It is due to *T. xenopi* and is seen as loss of body condition and a loss of colour. The animals are usually lethargic and show loss of appetite. Treatment is impractical.

Fish This is caused by *M. marinum* and is not uncommon in wild fish and thereby poses as a threat to farmed fish, especially salmon. The disease is characterised by loss of scales, pallor and unthriftiness. Badly processed fish-meal fed to farmed fish is also a possible source of infection. In the USA, the collection of dying Pacific Salmon for processing into feed for farmed salmon led to very severe outbreaks.

Reptiles This may be due to infection with *M. tuberculosis*, *M. avium* and *M. marinum* to which they are susceptible. The disease is seen as unthriftiness with few respiratory signs. It is very difficult to diagnose and the findings on post-mortem examination are usually of the military type. Treatment, if diagnosed, is possible but expensive and lasts at least six months.

Treatment The treatment of tuberculosis in the domesticated animals is not attempted, for four reasons: (1) because of the nature of the disease; (2) because of the ever-increasing danger to human beings who have to attend affected animals; (3) for economic reasons; and (4) for humanitarian ones. However, in zoological gardens, animals are sometimes treated. (See PAS.)

Prevention Good hygiene, good feeding and good ventilation all help. Animals brought in from areas known to be infected should be quarantined on the premises and a tuberculin test carried out by the veterinarian before they are allowed to mix with other stock.

History of control in Britain It was not until 1928 that measures to control bovine tuberculosis were introduced by the government. In that year, the Tuberculosis Order, enacted in 1915, came into force, and the attempt to control the disease by the detection and elimination of 'open' cases began. In 1935 the Attested Herds Scheme carried control measures a stage further.

Area Eradication, which began in 1950, and meant, at first, an extension of the Attested Herds Scheme on a voluntary basis, and then the compulsory slaughter of reactors within the prescribed areas, followed.

In October 1960, the whole of the UK was declared one Attested Area – bovine tuberculosis being virtually eradicated from all herds of cattle.

In 1962, the incidence of bovine tuberculosis in herds in England and Wales was 0.14 per cent. The number of reactors slaughtered was 8846.

During 1968, 5,854,915 cattle were tested in 108,452 herds and as a result 2,170 reactors (including two 'affected' animals) and 202 contacts in 1040 herds were slaughtered.

The Tuberculosis Orders 1964 provide for the notification and slaughter of cattle found to be affected with certain forms of tuberculosis – i.e. tuberculosis of the udder; giving tuberculous milk; tuberculous emaciation; chronic cough accompanied by clinical signs of tuberculosis; or found to be excreting or discharging tuberculous material. In 1975 the mammalian tuberculin was changed to that derived from M. *bovis*, the cause of bovine tuberculosis. Since the discovery of *M. bovis* in badgers, bovine cases have been increasingly detected and the original area where infection occurred has spread.

Since 1990, TB outbreaks in cattle have been increasing by 20 per cent a year in certain parts of the UK, including the West Country and Staffordshire. The search is on for a vaccine, which, unlike BCG, does not interfere with the diagnostic skin test. Trials of a promising DNA-based vaccine took, place in 2004. Badger vaccination is occurring and by 2015 it was hoped an oral vaccine would become available. In 2012, badger culling was being trialled in an 'Intensive Action Area' in West Wales.

Tuberculosis in wildlife In many countries, complete eradication of TB has been elusive because of reservoirs of infection in wildlife. In Britain, BADGERS (*Meles meles*) can become infected and die from TB as can other animals, although badgers seem the most affected. In 1970 the badger population was estimated at 300,000. Road accidents are estimated at 30,000 annually which indicates a large national population. The form of the disease in badgers is variable but is often respiratory; it can be spread between badgers by aerosol (in the breath) or by the shedding of bacilli in the urine. The State Veterinary Service (currently part of AHVLA) has carried out a long-term policy of eradicating badger populations in the vicinity of cattle herds. This has not resulted in an overall improvement of the situation as the disease has spread from the original infected area. In 1999, following a report by Professor Krebs, a

VetBooks.ir

long-term study to evaluate how TB may be spread between cattle, badgers and other wildlife was begun but was interrupted by the 2001 foot-and-mouth disease outbreak. The aims are to establish definitively what proportion of TB outbreaks in cattle is caused by badgers; and whether culling badgers is an effective way of controlling the disease. The trial is in three parts: (a) badgers are culled on and around farms following TB outbreaks; (b) those where all badgers are killed; and (c) those where no badgers are culled. Part (a) of the trial was discontinued in late 2003 as interim results showed an increase of 27 per cent in TB breakdowns in that area compared with the other two. However, after three years it was found there was a decrease in the proactively culled areas when compared with the control areas. The average decrease was 30 per cent over several years, with the greatest effect in the centre of the trial areas. Tuberculosis has been found in many wild animals including deer, foxes, weasels and hedgehogs. In New Zealand possums are the main reservoir for cattle tuberculosis and control of them in cattle rearing areas has caused an 85 per cent reduction in tuberculosis in 10 years.

The relationship of tuberculosis in animals and man; bovine tuberculosis

This is not a pedantic way of saying 'tuberculosis in cattle', but indicates that one is referring to disease set up by the bovine strain of tubercle bacillus as opposed to the human strain or the avian strain. Man may become infected by any one of the three strains. The bovine strain of the tubercle bacillus is particularly pathogenic for children under 16.

In considering statistics dealing with incidence of bovine tuberculosis in humans, it must be borne in mind that bovine tuberculosis can be spread from one person to another, just as it can be from animal to man.

Human infection with tuberculosis may also arise from eating infected meat, but this risk, is, in civilised countries, not great owing to meat inspection services, and cooking of the meat. The protection of the human population from TB involves the tuberculin test, meat inspection and pasteurisation of milk.

Tuberculosis, Avian

(See AVIAN TUBERCULOSIS.)

Tuberculosis (Amendment) Order 1973

The Tuberculosis (Amendment) Order 1973, made under the Diseases of Animals Act 1950, requires anyone who suspects a carcase to be affected with tuberculosis to notify a veterinary inspector and to retain the carcase (or parts of it) for examination. The purpose of the Order is to enable the herd of origin to be traced. Isolation of suspected tubercular cattle is also empowered. It is continued on in the Tuberculosis Order 2007.

Tuber Ischii

(See PIN BONE.)

Tularaemia

Tularaemia is a disease of HARES, ground squirrels, rabbits and rats, caused by the *Pasteurella (Francisella) tularensis*, and spread mechanically either by flies or ticks, or by direct inoculation – for example, into the hands of a person engaged in skinning rabbits. In man, the disease takes the form of a slow fever, lasting several weeks, with much malaise and depression, followed by considerable emaciation. It was first described in the district of Tulare in California, but is found widely spread in North America, also in parts of Europe and Japan. Sheep and pigs are attacked and many die. AMINOGLYCOSIDES including STREPTOMYCIN may prove effective in treatment.

Dogs are susceptible, too.

Tulathromycin

One of a new class of antibacterial agents called TRIAMILIDES. It is rapidly absorbed after intramuscular injection and reaches peak plasma levels in 30 minutes. The antibiotic is concentrated in the lungs where the levels may be 60 times that in plasma. It is used for respiratory diseases in cattle and pigs. Levels remain above the minimum inhibitory concentration for *Pasteurella multocida* for five days and *Mycoplasma hyopneumoniae* for 15 days. It has been approved for the treatment and prevention of bovine respiratory disease and the treatment of respiratory disease in pigs in the European Union and USA.

Tumbu Fly

(See under SCREW-WORM FLIES.)

Tumour

Malignant tumours are those which tend to grow and spread rapidly, destroying neighbouring tissues and infiltrating the healthy structures nearby. They are liable to ulcerate through the skin when superficial, are non-encapsulated, and may spread to distant parts of the body by the blood- or lymph-stream, giving rise to secondary tumours there. (Further information upon malignant tumours appears under CANCER.)

Benign tumours grow slowly at one place, press neighbouring parts aside, but neither invade nor destroy them, only seldom ulcerate through the skin or mucous membrane, have usually a capsule of fibrous tissue surrounding them, and when once completely removed by surgical excision or other means, do not recur.

VetBooks.ir

While this classification serves in a measure to differentiate typical varieties into two classes, it is by no means absolutely satisfactory. There are certain kinds of normally benign tumours which may remain comparatively small and circumscribed for a number of years, and then suddenly become malignant.

Benign or simple tumours include ANGIOMA, CHONDROMA, FIBROMA, GLIOMA, LIPOMA, MYOMA, MYXOMA, NEUROMA, ODONTOMA and PAPILLOMA. The last-named may be benign in the beginning but become malignant later; also MELANOMA and ADENOMA. (See also CYST; WARTS; CANCER.) While normally all tumours tend to increase in size – either slowly or rapidly – some grow to a certain size, remain stationary, then decrease in size, and a few may even disappear completely.

Two of the most common tumours of the dog are mammary carcinoma and anal adenoma (usually benign). (See also EOSINOPHILIC GRANULOMA.)

Tumour Angiogenesis Factor (TAF)

This has been isolated from human and animal tumours. It stimulates mitosis in endothelial cells and rapid formation of new capillaries for tumour nourishment. (Unlike a skin-graft, which sends out capillary shoots to join the capillaries of the recipient tissue, a tumour has to rely entirely on the host, and makes use of TAF for this purpose.)

Tungiasis

Infestation with *Tunga penetrans*, the jigger flea. (See under FLEAS.)

Tup

A ram (See under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC.).

Turbinate Bones

(See under NOSE AND NASAL PASSAGES and RHINITIS.)

Turkey Coryza

A disease of the upper respiratory tract, with sneezing and nasal discharge, whose probable cause is *Bordetella avium*. It occurs in turkey poults, usually in conditions where ventilation is poor and the birds are stressed.

Turkey Rhinotracheitis

It is caused by metapneumovirus and first became a problem in the 1970s. The European strains A and B are different from the C strain found in USA, where it occurs regionally in Minnesota and the Dakotas. In chickens it is responsible for SWOLLEN HEAD SYNDROME OF CHICKENS (SHS). Often the disease is complicated by the presence of bacteria and/or mycoplasmata. Blood sampling for antibodies shows that the virus can also infect pheasants, guinea fowl, geese, sparrows, pigeons and other wild birds. Affected turkeys show watery discharge from the nostrils and eyes, sneezing, and it can descend into the lungs where there is pneumonia. Morbidity is 100 per cent and in breeding herds there is a severe drop in egg production, and infection of the oviduct results in changes in shell colour and quality. One per cent of birds show nervous signs and mortality may be up to 30 per cent. Control is by vaccination, preferably by spraying to stimulate local antibody production in the upper respiratory tract.

Turkeys

These are native to the Americas and were first domesticated by the Aztecs in Mexico. They came to Europe (Spain) in 1500 and were introduced to Britain in 1524. There are five recognised subspecies in the USA and the one initially introduced to Europe was *Meleagris gallopavo,* a bronze with white in the tail. The BLACK TURKEY is believed to have been the first domesticated variety in Britain and is now known as the NORFOLK BLACK. The BROAD-BREASTED BRONZE is a commercially developed strain for meat. The BRONZE is single breasted and able to breed naturally.

Turkey diseases include AORTIC RUPTURE, ARIZONA INFECTION, AVIAN INFLUENZA, BLACKHEAD, COCCIDIOSIS, ERYSIPELAS, SWINE, HEXAMITIASIS, HAEMORRHAGIC ENTERITIS, MONILIASIS, NEWCASTLE DISEASE, OREGON MUSCLE DISEASE, ORNITHOSIS, MYCOPLASMOSIS, PULLORUM DISEASE OF CHICKS, RETICULOENDOTHELIOSIS, SINUSITIS, and SYNOVITIS (See also GROUNDNUT MEAL; MANIOC).

Turkey meningoencephalitis occurs in Israel. Influenza viruses cause disease in North American domestic turkeys.

Turkey rhinotracheitis has been seen in several countries, and appeared in the UK in 1985, causing severe financial losses due to deaths, carcase rejections, and lowered egg production. The first sign is sneezing.

Turkey Viral Hepatitis

This occurs in Europe, the USA, and Canada; and in 1982 isolation of a picorna-like virus causing hepatitis and disease of the pancreas was isolated from an outbreak in Scotland. The infection, which is highly contagious, is often, if not usually, subclinical, but may take an acute form, and prove fatal.

Turkish Van Cat

A breed of cat originating in the valley of Lake Van in Turkey. The breed is unusual in that the cats like to swim and they should be given the opportunity to do so.

Turning
(See VERSION.)

Turnips
Like kale, these contain a goitre-producing factor, and if fed in large amounts to pregnant ewes are liable to cause abortion – unless iodine licks are provided. (See VAGINA - RUPTURE.)

Turpentine, Medicinal Oil of
Turpentine is the oleo-resin which exudes from various members of the pine family, especially the *Pinus australis*, *P. taeda*, and *P. sylvestris*. The oil distilled from this oleo-resin is known as oil of turpentine. The natural turpentine is not used in medicine, as it is highly irritating and when the word 'turpentine' is employed, the oil of turpentine is indicated.

In collections of gas in the abdominal organs, medicinal turpentine has been used (e.g. tympany in horses and cattle). Large doses are liable to irritate the stomach and kidneys.

Turpentine should never be given when an animal is suffering from nephritis, inflammations of the bladder, stomach, or bowels, as its active irritant action only increases the already existing inflammation. (See under SMELL.)

Externally, oil of turpentine is used as a constituent of liniments.

Turtles
(See AMERICAN BOX TORTOISES; TORTOISES.)

Threat to public health from pet turtles
Serious infection can be transmitted to owners by turtles, including aquatic turtles (terrapins). Six of 28 lots of embryonated eggs of the red-eared turtle (*Pseudemys scripta elegans*) imported into Canada from Louisiana were found to harbour salmonellae. *Salmonella poona* and *S. arizonae* were isolated from the eggs and the packaging moss, and the turtles hatched from the contaminated eggs continued to shed salmonellae into the tank water for up to 11 months. Of the 37 strains of salmonellae isolated, 30 were resistant to gentamicin, probably because of the widespread use of the antibiotic to try to produce salmonella-free eggs for export. Such high levels of antibiotic-resistant salmonellae in turtle eggs could pose a serious risk to human health.

'Twin Lamb' Disease
A colloquial name for PREGNANCY TOXAEMIA IN EWES.

Twinning, Artificial
In the interests of increased beef production, techniques have been developed to encourage the production of twin calves. A suitable dose of pregnant mare's serum (PMS), injected subcutaneously at a suitable time, e.g. four days before oestrus, will on average give twins; but there will be some triplets and singles. The FOLLICLE STIMULATING HORMONE contained in the serum causes an extra follicle to mature and shed an extra egg with resultant twinning. Overdosage, however, leads to undesired quadruplets, etc.; or to numerous eggs which pass quickly down the Fallopian tubes without being fertilised; result – no calf at all. There is a risk of stillbirths and of strain on the dam.

Twins, Monozygous
Identical twins, from the same ovum.

Twins (Calves)
Twins tend to run in families. For example, a cow had three pairs of twins, her daughter four pairs, and a grand-daughter two pairs. That might be called twinning at its best. Of course, there is sometimes trouble. Perhaps the condition of the dam is pulled down; or perhaps the 'cleansing' is retained, becomes infected, and infertility follows. Twinning occurs in about 2 per cent to 5.5 per cent of pregnancies.

Predicting twins The presence of twins can sometimes be detected by manual examination, but ultrasound scanning is more reliable and allows earlier detection.

The concentration of oestrone sulphate, a hormone produced by a cow carrying a viable fetus and present in blood plasma or milk, can be used to confirm pregnancy.

The concentration is higher in cows carrying twins, but the difference does not become significant until about the 220th day of gestation. However, even at this late stage, the prediction of twins could be used as a guide to increase the feed allowance of cows carrying more than one fetus.

In strains not noted for twins, twinning may occur on farms where there is a herd infertility problem.

IDENTICAL TWINS – always of the same sex – result from the division of the fertilised egg into two; whereas ordinary twins are produced as the result of the fertilisation of two eggs.

These two eggs may come from the same ovary, when the two fetuses may develop in the same horn of the uterus. Sometimes they result in a FREEMARTIN.

There is apparently, with cattle, a close affinity between identical twins – as there undoubtedly is with human beings. In a Swedish study, six pairs of twins were split at birth and reared separately for 15 months. At this age they were all put into a field together. Within a few days each twin had found and paired off with its sister. (See ERYTHROCYTE MOSAICISM; also GENETICS,

VetBooks.ir

HEREDITY AND BREEDING; SUPERFETATION; TWINNING, ARTIFICIAL; TRIPLET CALVES.)

Twins (Foals)
In the mare, the presence of twins in the uterus is a common cause of abortion. About 3 per cent of pregnant mares conceive twin fetuses, but the birth of healthy twins is exceedingly rare – about 0.01 per cent.

Twisting
(See TORSION.)

Twitch
This consists of a loop of soft rope threaded through a hole near the end of a stout piece of wood. The twitch is applied to the horse's upper lip, where it compresses the sensitive nerves. It used to be thought that the twitch merely diverted the horse's attention away from other parts of the body, but this view is now disputed. It is thought that pain perception or awareness are diminished through the activation of ENDORPHINS. Twitching significantly increases plasma levels of beta-endorphin, which returns to normal 30 minutes or so after the twitch is removed. Twitching could therefore be said to be analogous to ACUPUNCTURE.

'Tying-Up Syndrome'
Also known as set-fast, this condition in racehorses appears to be identical with azoturia. Signs include stiffness, a rolling gait, blowing and sweating and, if exercise continues, the adoption of a crouching attitude. Pain is evident. The animal may lie down and be unable to rise. (See azoturia, under EQUINE RHABDOMYOLYSIS.)

Tylan
The proprietary name of a preparation of tylosin.

Tylosin
A macrolide antibiotic effective against Gram-positive organisms; it concentrates in acidic conditions, as in the udder and the lung. It has been used to treat respiratory diseases in cattle, pigs and poultry (some chicken and turkey strains of *Mycoplasma gallisepticum* may be resistant) and MASTITIS in cattle. It was used as a growth promoter in pigs but it is now banned in the EU. The antibiotic can be administered by injection or in the feed. (See ADDITIVES.)

Tylvalosin
An antibiotic licensed for use in pigs and poultry for the treatment of diseases caused by *Mycoplasma* spp., *Lawsonia intracellularis*, *Brachyspira hyodysenteriae*, *Pasteurella multocida* and *Actinobacillus pleuropneumoniae*.

Tympanites
The drum-like condition of the abdomen, which results from distension of the stomach or bowels with gas, as the result of fermentation, constipation, or of simple obstruction. (See under STOMACH, DISEASES OF; INTESTINES, DISEASES OF; BLOAT; TYMPANY; TYMPANITIC RESONANCE IN CATTLE.)

Tympanitic Resonance in Cattle
Right-side tympanitic resonance (ping) caused by gas distention of intra-abdominal structures was diagnosed in 366 adult cattle, in a USA study. The source of the ping was identified as the abomasum in 137 animals, various segments of the intestinal tract in 157 and peritoneal gas in two. The source of the noise was not identified in 70. The principal final diagnoses were: left displacement of the abomasum (116), right displacement of the abomasum (77), abomasal (and omasal) volvulus (60), other gastro-intestinal conditions (73) and non-gastrointestinal conditions (40).

Tympany
Tympany is distension of a hollow organ with gas. (See TYMPANITES; BLOAT.)

Typhilitis
Inflammation of the caecum or first part of the large intestine, into which the termination of the small intestine opens.

Typhus of Rats and Mice
Typhus of rats and mice, caused by *Rickettsia mooseri*, may kill about 5 per cent of people infected by it.

Tyrosine
An amino acid closely linked to PHENYLALANINE. It is important for normal function of the pituitary, adrenal and thyroid glands. It also has a role in red and white blood cells, and in the production and release of growth hormone.

Tyzzer's Disease
This was first described in mice in 1917, and has since been reported in horses, cats and laboratory animals including rats, rabbits, gerbils and rhesus monkeys.

Cause The spore-forming, Gram-negative, motile *Bacillus piliformis*.

Signs The disease is characterised as a rule by severe diarrhoea, debility and death; though sudden death in foals without preliminary signs

has been reported in the USA. Jaundice, slight or marked, was a post-mortem finding, together with some liver necrosis and enteritis.

In the cat, the infection gives rise to signs of loss of appetite, depression, diarrhoea, collapse and death. Necrosis of the ileum and hepatitis are among post-mortem findings.

Tzaneen Disease

This is a tick-borne infection with *Theileria mutans* in cattle, the African buffalo, and the Indian water buffalo, and often occurs simultaneously with other infections. There may be only a mild fever or, less commonly, serious illness, and death. Antimalarial drugs are of use.

VetBooks.ir

U

UASCC

Udder
(See MAMMARY GLAND.)

UFAW
(See UNIVERSITIES FEDERATION FOR ANIMAL WELFARE.)

Uitpeuloog
'Bulging eye disease'– an oculovascular myiasis of domestic animals in South Africa.

Ulcer
A break on the surface of the skin, or of any mucous membrane of a cavity of the body, which does not tend to heal. The process by which an ulcer spreads, which involves necrosis (death) of minute portions of the healthy tissues around its edges, is known as ulceration. Most ulcers are suppurative; bacteria prevent healing and often extend the lesion.

An ulcer consists of a 'floor' or surface which, in consequence of the loss or destruction of tissue, is usually depressed below the level of the surrounding healthy structures; and an 'edge' around it where the healthy tissues end.

Callous ulcer is a type of chronic ulcer often encountered in horses and dogs, when there is any pressure or irritation that interferes with the blood supply but does not necessarily cause immediate destruction of the skin. In most cases it is covered by a hard, leathery piece of dead skin from under which escapes a purulent fluid. 'Bedsores' in all animals may be of this nature.

'Rodent ulcer' is a term reserved in human medicine for an ulcerating carcinoma of the skin, but it is often colloquially used by dog- and cat-owners for an EOSINOPHILIC GRANULOMA. Skin cancer occurs in domestic animals, and such malignant tumours may ulcerate.

Tubercular ulcers may occur in dogs' and cats' skin in the form of raised plaques which ulcerate.

Internal ulcers may occur in the mouth (See MOUTH, DISEASES OF), in the stomach (See GASTRIC ULCERS), in the bowels (See INTESTINES, DISEASES OF), and in other parts.

Glanders ulcers are typically encountered in the mucous membrane of the nostrils, and have a 'punched-out' appearance.

Lip-and-leg ulcers occur in sheep with ORF.

Causes Any condition that lowers the general vitality of the animal, such as old age, chronic disease, malnutrition and defective circulation, will act as a predisposing cause. Among direct causes may be bacteria gaining access to wounds; irritation from a badly fitting harness, pressure of bony prominences upon hard floors insufficiently provided with bedding, and application of too strong antiseptics to wounds.

Treatment In the smaller animals a vitamin supplement may be indicated. An antibiotic or one of the sulfa drugs may be used.

Local treatment aims at converting the ulcer into what virtually becomes an ordinary open wound. The surface is treated with some suitable antiseptic, such as cetrimide, gentian violet, dilute hydrogen peroxide, etc. If one or two days of such treatment does not result in a clean, bright-red, odourless wound, or where there are shreds of dead tissue adherent to the surface, it may be necessary to curette the surface so that the dead cells may be separated from the healthy ones below them.

Animal-owners should note that after the surface of the ulcer has been rendered as healthy as possible, use of strong antiseptics or (worse still) disinfectants should cease, as these retard healing by the destruction of surface tissues.

Corneal ulcers are referred to under EYE, DISEASES AND INJURIES OF - KERATITIS. (See also CRYOSURGERY.)

Ulcerative Dermal Necrosis
A disease of adult salmon which occurs when they enter fresh water on their way to spawning grounds. It was first reported in the British Isles in the 1960s. Grey lesions are seen above the eyes, on the snout and on the side of the opercula (gill coverings). If they do not heal, the lesions spread to the skin of the head, ulcerate, and become prone to infection by *Saprolegnia* fungus. The fungal infection may be treated with zinc-free malachite green. The cause is unknown.

Ulcerative Lymphangitis
Ulcerative lymphangitis, also called ulcerative cellulitis, is a contagious chronic disease of horses, cattle, and, rarely, sheep and goats. It is characterised by inflammation of the lymph vessels and a tendency towards ulceration of the skin over the parts affected.

Cause *Corynebacterium bovis (pseudotuberculosis).* It gains access through abrasions. Poor hygiene and lack of exercise are associated problems. Infection may be carried by grooming tools, harness, utensils, etc., from one horse to another.

Signs The commonest seat of the disease is the fetlock of a hind-leg. This part becomes swollen and slightly painful. Small abscesses appear; ulcers follow. The condition gradually spreads up the leg.

Treatment Antibiotics.

Ulcerative Spirochaetosis of Pigs

This has been reported in the UK, Australia, New Zealand, South Africa, and the USA. It may give rise to foot-rot in pigs, ulceration of the skin, and scirrhous cord.

Ulcerative Viral Dermatosis of Sheep

A viral infection, which has to be differentiated from ORF, and is characterised by ulcers on the face, feet, legs, and external genitalia. It is seen in many parts of the world including Europe, America and Africa.

Ulcerative Viral Enteritis of Chickens, Pheasants and Quails

Ulcerative enteritis is seen in chickens between 4 and 7 weeks of age, and in quails, turkeys, partridges and grouse at any age. Birds are depressed, with watery droppings; mortality can be very high, reaching 70 to 100 per cent. The cause is a virus. (See also QUAIL DISEASE.)

Ulcer Disease

A disease of young salmonids caused by *Haemophilus piscium* in Canada and North-Eastern United States. Symptomless adults are carriers.

Ulna

This is the inner of the two bones of the fore-arm. The shaft has gradually reduced in size as the number of digits has decreased, so that while the ulna is a perfect bone in the dog and cat, in the horse its shaft has almost completely disappeared and the bone is only represented by the olecranon process which forms the 'point of the elbow'. The shaft of the ulna is liable to become fractured from violence to the fore-limb, but the commonest seat of an ulnar fracture is the olecranon process. This occurs from a fall in which the fore-limbs slip out in front of the animal, and the weight of the body comes down suddenly on to the point of the elbow. (See FRACTURES.)

Ultra-High-Temperature Treatment of Milk (UHT)

Ultra-high-temperature treatment of milk (UHT) involves heating it to between 135° C and 149° C (275° F and 300° F) for a few seconds. Suggested in 1913, UHT is used to produce long-life milk, on sale in Britain from 1965 onwards. This process does not affect the calcium nor the casein, but destroys some vitamins and probably some serum proteins (immune globulins). Calves grow less well on it than on raw or pasteurised milk.

Ultrasonography

The use of sound waves to show internal organs of a body, including tendons. It can be used for diagnosis and pregnancy detection.

Ultrasound

Sound at a frequency above 20,000 cycles per second. Propagated by applying an electric current to one side of a piezoelectric crystal, which deforms and produces a sound wave.

Ultrasound is generally defined as an auditory frequency beyond that perceived by the human ear. Most humans hear and emit sound in the frequency range 2 to 20 kHz, while in some animals ranges are much greater. Bats, dolphins, many rodents and some insects have ranges that extend as high as 120 kHz – well beyond the limit of human detection. Pigs and poultry can detect higher ultrasound frequencies and may be disturbed by the noise given off by, for example, certain electronic equipment and dripping nipple-drinkers. Female rabbits communicate with their litters in ultrasound.

Ultrasound, in the range of 1 million to 10 million hertz, is used in non-invasive diagnostic imaging of internal body structures. It is widely used in pregnancy diagnosis of animals. (See also PREGNANCY DIAGNOSIS.)

In human medicine, ultrasound has been shown to be beneficial for wound healing, both in the treatment of pressure sores and in the preparation of trophic ulcers for skin grafting. Studies have shown that it influences the activity of fibroblasts.

Ultra-Violet Light

When applied to chicken eggs for one to two hours per day during incubation, ultra-violet light increases the embryonic development and hatching weights. Longer periods are deleterious.

Ultra-Violet Rays

Ultra-violet rays are used in the treatment of various skin diseases, etc., and in the diagnosis of ringworm and porphyria; also in the fluorescent-antibody test for various infections including rabies.

VetBooks.ir

VetBooks.ir

Ultra-violet rays and eye cancer Research has shown that ultra-violet radiation may be of primary importance in triggering cancer.

A source of ultra-violet light is important in the husbandry of tropical and equatorial species kept in captivity, especially reptiles (See IGUANA). Lack of ultra-violet light can lead to metabolic disorders in these animals due to a deficiency of VITAMIN D.

Umbilical Cord, Cutting The

(See under PARTURITION.)

Umbilical Hernia

The protrusion of abdominal contents through an opening in the abdominal wall at the umbilicus. The protruding material is covered by the skin and subcutaneous tissues. What protrudes depends on the extent of the opening. It may be just omental fat, or can include intestines. Usually the protrusion can be reduced by manipulation. However, if it is irreducible it may become strangulated, resulting in signs of pain and distress. Some are due to trauma or a weakened wall around the umbilicus. However some hernias in cattle and dogs can be inherited. Dog breeds involved include AMERICAN COCKER SPANIELS and BULL TERRIERS. (See also HERNIA - UMBILICAL HERNIA.)

Umbilicus

Umbilicus is another name for the navel.

Umgana Tree

Elephants seek out and gorge themselves on the fruits of this tree, leading to sexual excitement. Ostriches may behave similarly.

Uncinariasis

Infection with *Uncinaria stenocephala*, one of the hookworms of the dog.

Unconsciousness

(See under COMA; FITS; SYNCOPE; EPILEPSY; NARCOLEPSY.)

Undecylenate Ointment

A fungicide, used in the treatment of ringworm, etc.

Undershot

Used to describe the jaw, where there is front tooth malocclusion with a shortened maxilla (upper jaw) and protruding mandible (lower jaw). It is seen in all species and in certain dog breeds including BOSTON TERRIERS. (See PROGNATHISM.)

Undulant Fever in Man

Undulant fever in Man is caused by *Brucella melitensis*, *B. abortus suis*, or *B. abortus*. The latter organism is responsible for 'contagious abortion' (brucellosis) of cattle, and it is probable that most cases of undulant fever in man caused by *B. abortus* arise through handling infected cows or from drinking their milk. Infection can readily occur through the skin. Numerous cases have occurred in veterinarians, following mishaps with Strain 19 vaccine, e.g. accidental spraying into the eyes or injection into the hand. In America, *B. abortus suis* is an important cause of undulant fever in man; *B. canis* likewise.

Signs are vague and simulate those of influenza except that undulant fever lasts for a much longer time, even many months. Temperature is generally raised but fluctuates greatly; there are muscle pains, headache, tiredness and inability to concentrate. One or more joints may swell. There may be constipation. The organisms are present in the bloodstream and in the spleen.

The disease is serious, not so much because of its mortality (1 to 2 per cent), but because of incapacity occasioned by its long duration. (See BRUCELLOSIS and CHEESE.)

Prevention Anyone handling aborting cows, or their fetal membranes, or even calving an apparently normal cow, should wear protective gloves or sleeves (which nevertheless sometimes tear), and wash arms and hands in a disinfectant solution afterwards. Avoid drinking any cold milk that has not been pasteurised.

Unilateral

Occurring on one side of the midline of the body but not the other.

Universities Federation for Animal Welfare (UFAW)

Address: The Old School, Brewhouse Hill, Wheathampstead, Hertfordshire AL4 8AN. Telephone: 01582 831818; email: ufaw@ufaw.org.uk; website: www.ufaw.org.uk.

Unnecessary Suffering

The term is used in law to describe whether or not a person has been guilty of causing this to an animal. It is probable that all animals will suffer at times from disease, illness of other problems of a physical nature. However it is when the suffering could be alleviated or avoided and this suffering may be deliberate or not, but includes neglect again intentional or unintentional. (See ANIMAL WELFARE ACT 2006; FARM ANIMAL WELFARE COMMITTEE; 'FIVE FREEDOMS' FOR FARM ANIMALS; SUFFERING; WELFARE OF FARMED ANIMAL REGULATIONS 2007.)

Unowned Pets

A survey of just over 40 per cent of 1,380 animal welfare organisations contacted in a 2010 survey took in 89,571 dogs and 156,826 cats. Three quarters of all dogs and 77.1 per cent of cats were

re-homed, and 10.4 per cent of dogs and 13.2 per cent of cats were euthanased. (See STRAY DOGS AND CATS.)

Unpasteurised Milk

Also known as 'RAW' MILK or 'GREEN TOP' MILK. In England, Wales, and Northern Ireland it is legal to sell such milk without PASTEURISATION directly to customers provided it is clearly labelled. Such milk is also available and is used in milk products such as cheese, cream in many countries, and unpasteurised cheeses can be sold in UK shops. It has been illegal to sell such milk in Scotland since 1983, following an outbreak of LISTERIOSIS. Those producing and selling such milk need stringent regard to cleanliness and are TUBERCULIN TESTED annually. Some consumers are able to distinguish pasteurised milk from that unpasteurised, and the latter does have higher levels of some B vitamins and FOLATES. The reasons for pasteurisation are those of infections, some of which may be carried in the cow's udder in the UK or elsewhere. They include BOVINE TUBERCULOSIS, BRUCELLOSIS, CAMPYLOBACTER INFECTIONS, LISTERIOSIS and SALMONELLOSIS. There were been no recorded disease outbreaks in England and Wales from unpasteurised milk since 2002.

Unsaturated Fatty Acids

(See under LIPIDS; VITAMINS - VITAMIN E.)

Unstable Substances

(See under INJECTIONS.)

Upper Alimentary Squamous Cell Carcinoma (UACC)

A number of different conditions involving activation of warts in older suckler cattle by prolonged (over many years) ingestion of bracken, which contains activating factors. The lesions can occur in the mouth, oesophagus and reticulorumen and the signs vary according to the tumour site. There is no treatment but prevention is by improving the nutrition provided to the cattle.

U

Upper Respiratory System

This starts at the NOSE AND NASAL PASSAGES, passes through the PHARYNX, LARYNX, TRACHEA and ends in the BRONCHI. (See also LOWER RESPIRATORY SYSTEM.)

Uracil

A PYRIMIDINE base found in DNA and RNA.

Uraemia

(adjective, Uraemic)

Uraemia results when the waste materials that should be excreted into the urine are retained in the body, through some disease of the kidneys, and are circulated in the bloodstream. Blood urea is in excess. Death may be preceded by convulsions and unconsciousness. In the slower types there is usually a strong urinous odour from all the body secretions. In acute cases the administration of glucose saline subcutaneously may help; likewise, withdrawal of a quantity of blood (provided that saline is given). (See URINE - ABNORMAL CONSTITUENTS OF URINE; LEPTOSPIROSIS; KIDNEYS, DISEASES OF.)

Uranoschisis

A congenital cleft palate.

Urates

(See URIC ACID.)

Urea, Carbamide

Urea (carbamide) is a crystalline substance of the chemical formula $CO(NH_2)_2$, which is very soluble in water and alcohol. It is the chief waste product discharged from the body in the urine, being formed in the liver and carried by the blood to the kidneys. The amount excreted varies with the nature and the amount of the food taken, being greater in the carnivora, and when large amounts of protein are present in the food. It is also increased in quantity during the course of fevers. Urea is rapidly changed into ammonium carbonate after excretion and when in contact with the air, owing to the action of certain micro-organisms.

Determination of the blood urea level is an important aid to the diagnosis of kidney failure.

Urea As a Ruminant Feed

Some of the micro-organisms which inhabit the rumen can synthesise protein from urea. It was accordingly suggested that urea might be substituted for protein in concentrates fed to cattle. This has been called the protein-sparing effect of urea, which is a non-protein source of nitrogen.

The emphasis has now shifted more to the value of urea in increasing the intake and aiding the digestion of low-quality roughages, and it has been widely used as a dietary supplement for cattle and sheep on poor pasture in many parts of the world. Where extra energy, in the form of readily digestible carbohydrate, is provided in addition to the urea, both roughage digestibility and feed intake improve. In these circumstances the urea stimulates multiplication of cellulose-digesting organisms, so that the urea-fed animal may be able to make more effective use of roughage than the one receiving no urea.

In the ruminant animal, any injudicious feeding of urea can give rise to poisoning by ammonia, since it is this which is released in the rumen and

VetBooks.ir

then converted into microbial protein. Excess ammonia can cause the animal's death. It is essential, therefore, that urea is taken in small quantities over a period, and not fed a large amount at a time.

Urea is often added to molasses and fed via ball feeders which prevent rapid and excessive uptake of the liquid and ensure maximum utilisation of urea. Under optimum farm conditions only 15 to 30 per cent of the dietary protein can be replaced by urea. As a rule of thumb, urea, if incorporated uniformly within the dairy ration, has been shown to be safe at a level of 1 per cent. Combined with 5 per cent barley, that mix can replace 5 per cent ground-nut meal in the ration. In the diets of finishing beef cattle, the animals can gradually have the proportion of urea increased.

Mixing starch with urea at high temperatures and pressure results in the starch become gelatinised and forming a homogeneous mass. In the rumen this material decomposes slowly, gradually releasing urea and carbohydrates. This allows better utilisation of urea.

Some guidelines for urea feeding

1. Introduce urea feeding gradually, i.e. at a slowly increasing level over a period of three to four weeks, with adequate minerals and vitamins provided.
2. Avoid starting newly calved cows on it (but it may be included in the steaming-up ration), or giving it to calves under three months of age.
3. Ensure that urea is fed with adequate readily digestible carbohydrate, as is contained in cereals, molasses, sugar-beet pulp, maize silage, etc.
4. Do not exceed levels of urea recommended by the supplier.
5. Ensure that urea is fed little and often, and not irregularly or at long intervals.

Urea poisoning Signs include salivation, excitement, running and staggering, jerking of the eyeballs and scouring.

Acute urea poisoning killed 17 beef cows in a group of 29 in the south of Scotland. The animals died over an 8-hour period as a result of drinking water which had been carried to a trough in a tanker previously used for transporting urea fertiliser. It was calculated that as little as 10 litres of the water would have provided a fatal dose of urea to a 500 kg cow.

Ureaplasmas

Formerly known as T-mycoplasmas, these have been isolated from the lungs, and also the urogenital tract of several species of animals. They are a likely cause of pneumonia (See CALF PNEUMONIA) and infertility (See VULVOVAGINITIS, GRANULAR.)

Ureter

The ureter is the tube which carries the urine excreted by a kidney down to the urinary bladder. Each ureter begins at the pelvis (main cavity) of the corresponding kidney, passes backwards and downwards along the roof and walls of the pelvis, and finally ends by opening into the neck of the bladder. The wall of the ureter is composed of a fibrous coat on the outside, a muscular coat in the middle, and this is lined by a mucous membrane consisting of cubical epithelium.

Urethra

The urethra is the tube which leads from the neck of the mammalian bladder to the outside, opening at the extremity of the penis in the male, and into the posterior part of the urogenital passage in the female. It serves to conduct the urine from the bladder to the outside; also the semen.

Urethra, Diseases of

Owing to its extreme shortness in the female, the urethra is not subject to the same disease conditions as in the male, where the tube is considerably longer. In fact, disease of the urethra in the female hardly ever arises except as a complication of either disease of the bladder, on the one hand, or of the vagina on the other.

Urethritis Inflammation of the urethra is usually associated with CYSTITIS, and may be the result of an infection, or of some irritant poison (such as CANTHARIDES) present in the urine. The lining mucous membrane may also be inflamed by crystalline deposits. (See FELINE LOWER URINARY TRACT DISEASE; UROLITHIASIS; URETHRAL OBSTRUCTION.)

In most cases of urethritis there are signs of pain and distress whenever urine is passed or when the parts are handled. A little blood may be seen.

Stricture is an abrupt narrowing of the calibre of the tube at one or more places. In almost all cases of true stricture there has been some injury to the urethra or penis, resulting in the formation of scar tissue, which eventually contracts and decreases the lumen of the tube. A few cases, however, are caused by a rapidly-growing tumour.

Injuries to the urethra may follow a severe crush or blow which causes fracture of the pelvis or of the os penis in the dog, but this is rare. They are usually obvious when the injury has involved the surface of the body, and may be suspected if there is an inability to pass urine, or if the urine contains blood or pus following upon a severe injury to the hindquarters of the body. A complication of urethral injuries is abscess formation around the urethra and consequent stricture at a later period.

VetBooks.ir

Urethral Obstruction

In sheep, the injudicious use of hormones to increase liveweight gain has killed lambs, apparently as the result of urethral obstruction. In male calves and lambs, crystalline deposits of magnesium ammonium phosphate can occur, resulting in 'stones' which cause urethral obstruction if the animals are receiving an unbalanced diet, especially one with a high level of magnesium in their concentrate feed.

Reducing the levels of magnesium supplementation can stop further cases of urolithiasis in intensively fattened male lambs offered a cereal-based diet ad lib. (See also under URINARY BLADDER, DISEASES OF - URINARY CALCULI.)

(The AFRC recommendation is not more than 1.4 g/kg dry matter.)

Obstruction of the male urethra is a common condition in cats, and fairly common in the dog. (See FELINE LOWER URINARY TRACT DISEASE.)

Unless relieved, urethral obstruction can lead to rupture of the bladder and death.

Urethrostomy

Perineal urethrostomy is a surgical operation for the treatment of urethral obstruction; it consists of making a permanent opening in the urethra, the lining mucous membrane and the skin being joined by sutures. (Urethrostomy differs in this respect from URETHROTOMY, in which the urethra is incised – to remove a wedged calculus, for example – but immediately closed.)

Urethrostomy is performed mainly in cats suffering from FELINE LOWER URINARY TRACT DISEASE. It is not in itself a cure for this, but rather for the often-associated urethral obstruction. The operation is an alternative to euthanasia when the cat cannot be catheterised, or has already been subjected to this on two or more occasions, when repetition could be regarded as inhumane.

Urethrostomy, skilfully performed, can be successful, in both the short and the long term.

Complications can arise, however, after both urethrotomies and urethrostomies, and include: leakage of urine into surrounding tissues; haemorrhage; and stricture, as the result of scar formation. Should the latter occur, it leaves the cat in the same state as it was before the operation, so that nothing has been gained.

Urethrostomy makes the male cat anatomically similar to the female, so that ascending infections may occur.

Urethrotomy

An operation to gain access to the lumen of the urethra, usually to remove the cause of the obstruction. The opening is closed once the cause has been removed.

Uric Acid

Uric acid is a crystalline substance, very slightly soluble in water, white in the pure state, and found in the urine of flesh-eating animals in normal conditions. It is the end product of PURINE metabolism or oxidation in most species except primates, man and DALMATIAN DOGS. Other animals use uricase to convert the relatively insoluble uric acid to very soluble allantoin. It is also found in some kidney stones and urinary calculi, and may be present in joints affected with GOUT.

Urinary Antiseptics

Urinary antiseptics include hexylresorcinol, mandelic acid, hexamine (for acid urine; not effective in alkaline urine) and buchu. Their use is now rare.

Urinary Bladder

The reservoir for urinary waste products in mammals and CHELONIA. In some mammals the bladder is situated in the pelvis, but in the dog and cat it is placed further forward in the abdomen, while in the pig and cattle it may be almost entirely abdominal when distended. The size of the organ varies with the breed and sex of the animal, and its capacity depends upon the individual. Two small tubes – called URETERS – lead into the bladder, one from each kidney, and the larger, thicker URETHRA conveys urine from it to the exterior. The constricted portion from which the urethra takes origin is called the neck of the bladder, and is guarded by a ring of muscular tissue – the SPHINCTER.

Structure The wall of the bladder is somewhat similar to that of the intestine, and consists of a mucous lining on the inside, possessing flat, pavement-like epithelial cells; a loose submucous layer of fibrous tissue very rich in blood vessels; a strong, complicated muscular coat in which the fibres are arranged in many directions; and on the surface an incomplete peritoneal coat covering the organ. In places this peritoneal covering is folded across to parts of the abdominal or pelvic wall in the form of ligaments which retain the bladder in its position.

In young animals the bladder is elongated and narrow, and reaches much further forward than it does in the adult. In the unborn fetus its forward extremity communicates with the outside of the body until just before birth, when the passage becomes closed at the umbilicus, or navel, and the bladder shrinks backwards.

Urinary Bladder, Diseases of

Cystitis Inflammation of the bladder is often infective in origin, with micro-organisms coming either from the KIDNEYS via the URETERS, or, in

the female, in the reverse direction – i.e. via the URETHRA from an infected vagina.

Leptospirosis is a common cause of NEPHRITIS and cystitis in farm animals and in dogs. *E. coli* is another common pathogen in dogs; and *Corynebacterium suis* in pigs.

In dogs, cystitis is very occasionally found to be due to the bladder worm *Capillaria plica*; and in cats to *C. feliscati*. The parasites' eggs may be found in the urinary sediment. Anthelmintics may be used for treatment.

Inflammation of the bladder may be caused by the abrasive action of a sand-like crystalline deposit as in the FELINE LOWER URINARY TRACT DISEASE (FLUTD) or, to a lesser extent, by sizeable urinary calculi.

Signs In acute cystitis, small quantities of urine may be passed frequently, with signs of pain and/or straining on each occasion. Blood may be seen in the urine. The larger animals may walk with their hind legs slightly abducted, and the back is often arched in all animals.

Treatment This will naturally vary according to the cause. Therefore, analysis of urine from affected cases is usually required. An appropriate antibiotic may be used to overcome infection. Modifying urine pH is rarely done these days. If it is, urine acidifiers, such as ascorbic acid or ammonium chloride, or alkalisers, such as potassium citrate or sodium bicarbonate, may be used. Pain-relievers may be needed. Supportive therapy is also required (e.g. dietary changes to encourage alterations in the chemical composition of the urine and adequate fluid access to encourage dilution.)

Urinary calculi These, associated with high grain rations and the use of oestrogen, produce heavy losses among fattening cattle and sheep in the feed-lots of the USA and Canada. However, this condition does not seem to present the same problem in the barley beef units in this country, although outbreaks do occur in sheep fed high grain rations. The inclusion of 4 per cent NaCl in the diet has been shown to decrease the incidence of urinary calculi blockage.

In male calves and lambs, crystalline deposits of magnesium ammonium phosphate (STRUVITE) cause urethral obstruction if the animals are receiving too high a level of magnesium or phosphorus supplement in their concentrate feed. (See URETHRAL OBSTRUCTION.)

Urinary calculi may occur in an individual animal irrespective of its diet, or of hormone implants. There may be one large calculus present in the bladder, or several small ones, or the crystalline sand-like deposit already mentioned. In such cases, although hyaluronidase might be tried, treatment usually has to be surgical, i.e. cystotomy.

Rupture of the bladder This condition is usually quickly fatal, and is brought about by a painful over-distension of the bladder due to urethral obstruction. The condition may be seen in foals, mainly colts, at parturition. Diagnosis is based on clinical findings together with ultrasonography. Prompt surgery is usually successful.

Tumours These may cause difficulty in passing urine, and sometimes the presence of blood in the urine.

In a study of 70 cases in the dog, no urinary signs were found in nine. In the other 61, signs included haematuria, dysuria, tenesmus, incontinence, and polyuria. Sixty-two dogs had primary tumours; 44 of these were carcinomas. Several papillomas were found during cystotomy for urinary calculi.

A squamous cell carcinoma occurs in the bladder of older suckler cows following ingestion of bracken over many years. The main sign is blood in the urine with frequent MICTURITION and, often, a loss of condition.

Urinary Bladder Matrix

This is a naturally occurring extracellular matrix obtained from specially bred pigs that promotes remodelling of damaged and injured tissue. It is used as a dehydrated membrane or hydrated membranes or an injection of powdered material. It recruits cells for tissue differentiation from the circulatory and local tissues. It has been used in the USA for the treatment of tendon injuries when other treatments have failed.

Urinary Calculi

(See above, and under CALCULI - URINARY CALCULI; URINARY BLADDER, DISEASES OF.)

Urinary Incontinence in Dogs and Cats

(See INCONTINENCE.)

Urinary Organs, Urinary System

(See KIDNEYS; URETER; URINARY BLADDER; URETHRA.)

Urination

The act of passing urine. (Synonym: MICTURITION)

Urine

A brief outline of the formation of urine is given under KIDNEYS - FUNCTION. (See also HOMEOSTASIS.)

Not only are waste products removed from the bloodstream by the kidneys, but most poisons taken into the body are eliminated from the system

VetBooks.ir

by way of the urine; thus, quinine, morphine, chloroform, carbolic acid, iodides and strychnine can be recognised in the urine by means of appropriate tests, while there is abundant evidence to show that during bacterial diseases, the kidneys eliminate toxins.

Specific gravity The specific gravity of the urine of animals varies between wide limits; for average purposes the following figures are given:

	Lowest	Average	Highest
Horse	1014	1036	1050
Cow	1006	1020	1030
Sheep	1006	1010	1015
Pig	1003	1015	1025
Dog and cat	1016	—	1060

Reaction The urine of the herbivorous animals is usually alkaline, and that of the flesh-eating animals, acid. The alkalinity in herbivores is due to the salts of the organic acids that are taken in with the vegetable diet, such as malic, citric, tartaric and succinic; these acids are converted into carbonates in the body, and these latter are excreted in solution. In the case of some foods, such as hay and oats, an acid urine may be produced when they are fed to the horse. In the carnivorous animals the acidity is due to sodium acid phosphate. The pig's urine may be acid or alkaline according to the nature of its food.

Amount The quantities of urine excreted depend upon many factors, among which may be noted: season, diet, amount of water consumed, condition of the animal, secretion of milk, pregnancy, age, and size of the animal. (See also PREGNANCY DIAGNOSIS.)

The following are average figures of the amounts excreted during 24 hours:

Horse: 3 litres to 11 litres (5 pints to 20 pints), average 5 litres (9 pints)

Cow: 5.7 litres to 22 litres (10 pints to 40 pints), average 12.5 litres (22 pints)

Sheep: 285 ml to 855 ml (0.5 pints to 1.5 pints), average 570 ml (1 pint)

Pig: 1.4 litres to 8 litres (2.5 pints to 14 pints), average 4.5 litres (8 pints)

Dog: 440 ml to 995 ml (0.75 pints to 1.75 pints), average 680 ml (1.25 pints)

Abnormal constituents of urine Albumin may be excreted when there is some disease of the kidneys. Sugar is found in DIABETES MELLITUS and it is also found in smaller amounts after an animal has been fed on a diet that is too rich in sugar. In this latter case – known as glycosuria – the sugar disappears when the feeding is corrected. Pus and tube-casts are the signs of inflammation or ulceration in some part of the urinary system. Bile in the urine is a sign that there is some obstruction to the outflow of bile into the intestines, and that the bile is being reabsorbed into the bloodstream and excreted by the kidneys.

Urine, Analysis of

Urine samples offer a useful source of information about the health status of the URINARY ORGANS of animals and also of certain other organs, and their metabolic status. The tests used vary with the species. The tests may be simple biochemical analyses using proprietary 'dipstick' tests to detect protein, sugar, biliary products, blood, haemoglobin, and nitrates. The use of sulphosalicylic acid to detect the presence and quantity of protein, microscopy of any sediment to observe cells, (including blood as well as cells from the urinary tract itself), casts from the kidney tubules. On rare occasions in mammals (but frequently in reptiles and birds, sometimes due to the presence of intestinal waste products) parasites may be seen. Bacteriology can also be performed. In ruminants tests for pH, ketone bodies including BOHB, MAGNESIUM, etc. are used.

Urine-Drinking, Urine-Licking

Urine-drinking, or licking, by cattle may be a sign of sodium deficiency. (See 'LICKING SYNDROME'.)

Urine Pooling

(See UROVAGINA.)

Urine Scald

Loss of hair and inflammation of the skin caused by persistent wetting with urine. It is a common problem in obese rabbits or those fed a diet with excessive amounts of concentrates.

Urine-Spraying by Cats

This is the normal method used by the male cat to mark out its territory. Under natural conditions this may be some 2 km² (5 acres) or so in extent. The territory-marking serves as a warning to other males to keep out and, perhaps, also as an invitation to females in oestrus to enter.

Urine-spraying is not confined to the entire male, but may also be indulged in by the entire female, and even by neuters of either sex. It may also be an expression of sexual excitement.

Spraying indoors is often the result of the invasion of a cat's territory by an intruder such as a new person (if the owner takes on a new partner, for example), the arrival of a baby or another pet. The appearance of a cat at the window of a house or in the garden may trigger spraying. Another cause is the installation of a cat flap, if the flap does not keep other cats out of the house. A move to a new home, or even the rearrangement of furniture,

may initiate urine-spraying indoors. Spraying is common in households where several cats are kept.

Hormonal drugs such as progestins, which block the effects of male hormones, can be used to prevent spraying in male cats. Tranquillisers may be of benefit in more intractable cases. If a particular area is targeted, the cat's food bowl can be placed there, as cats will not spray close to where they eat. Feline pheromone, in an aerosol, is said to inhibit the cat's desire to spray. A-casozepine (Zyllere), a milk protein used in the management of stress-related problems may be effective. (See BEHAVIOUR PROBLEMS.)

Urinometer
An instrument designed for the estimation of the specific gravity of urine.

Urogenital
Resulting to the urinary and genital systems.

Urogenital Papilla
A small projection at the urogenital opening of fish. Damage or infection at this area can lead to problems in shedding eggs or semen ('milt').

Urolithiasis
The formation of calculi (stones), or of a crystalline sand-like deposit, in the urinary system. A bacterial or viral infection may precede or follow the condition. Certain proteins and peptides are associated with the human condition and it appears to be the same for dogs although these proteins and peptides have not been identified. (See URETHRAL OBSTRUCTION; URINARY BLADDER, DISEASES OF; FELINE LOWER URINARY TRACT DISEASE; and URETHRA, DISEASES OF.)

Uroliths
The mineral composition of 2700 of these were studied, after their removal from dogs. Their composition was STRUVITE in nearly 60 per cent of those tested followed by calcium oxalate (31per cent). They were detected more frequently in males (52.4 per cent). In horses the most common mineral was calcium carbonate.

Uropygial Gland
An oil-secreting bi-lobed gland, situated on the PYGOSTYLE of birds. It is also called the PREEN GLAND. This gland contributes a small amount of lipid to the skin of birds, the majority being contributed by the epidermal cells. (See SKIN.)

Urotropine
(See HEXAMINE.)

Urovagina
Also known as URINE POOLING or VESICOVAGINAL REFLUX. There is urine accumulation in the vaginal fornix, and the long-term often interferes with breeding in mares because of VAGINITIS, CERVICITIS and ENDOMETRITIS. Diagnosis can only be made with a VAGINOSCOPE, best done during OESTRUS, but may be difficult to confirm, as some mares intermittently pool urine. Usually treatment is surgical.

Urticaria, Nettle Rash
Urticaria (nettle rash) is a disease of the skin in which small areas of the surface become raised in weals of varying sizes. It occurs in horses, cattle (when it is often called 'blaines' or 'hives'), pigs and dogs.

Causes The condition is not necessarily specific. It may follow exposure to the leaves of the stinging nettle (hence one of its names); insect bites may produce it; and it may be associated with diet. It may occur in certain specific conditions in the horse, such as PURPURA HAEMORRHAGICA, DOURINE, INFLUENZA, etc. Urticaria is usually, if not always, of an allergic nature.

Factitious urticaria, where weals are formed following rubbing or scratching, should be called DERMATOGRAPHISM and is uncommon in the dog and other species.

Signs As a rule there is little to be seen beyond the local swellings of the skin. These may vary in size from a pea to a walnut, and are generally more or less almond-shaped. They are painless to the touch, show no oozing discharge, are scattered irregularly over the whole body, and sometimes involve the skin of the eyelids, nostrils and perineum. In cattle especially they may attain a great size in the throat region and produce difficulty in breathing.

Treatment Consists of the use of ANTIHISTAMINES, a light diet, and calamine lotion. An antibiotic may be used to prevent infection from occurring.

Usutu Virus
Usutu virus is a FLAVIVIRUS closely related to WEST NILE VIRUS. An outbreak in Vienna in 2000 is thought to have been carried by swallows migrating from Africa and resulted in many blackbirds around the city dying. Blue tits and sparrows can be infected. The disease is transmitted by mosquitoes, In humans, the signs are fever and a rash, but serious illness has not been reported. Humans and primates are terminal hosts for the virus and so are not a source of infection for other animals. Between 2005 and

VetBooks.ir

2011, examination of British wild birds has not identified its presence.

Uterine

Relating to, or pertaining to the UTERUS.

Uterine Infections

These are discussed under UTERUS, DISEASES OF and INFERTILITY. A list of the principal organisms which infect the uterus in the various species is given under ABORTION; but for the mare, see EQUINE GENITAL INFECTIONS IN THE MARE.

Uterus

The uterus is a Y-shaped organ consisting of a body and two horns, or cornua; it is lined by an elaborate mucous membrane which presents special features in different species of animals. The uterus lies in the abdomen below the rectum and at a higher level than the bladder. It becomes continuous with the vagina posteriorly. Its most posterior portion, known as the cervix, usually lies partly in the pelvis. From the tip of each horn to the ovary on the corresponding side runs the Fallopian tube or oviduct, which conducts the ova from the ovary into the uterus.

In the human female the body is large and horns, for practical purposes, do not exist. In rabbits the two horns open into the vagina separately. The uteri of domesticated animals are intermediate between these types.

The walls consist of three coats: a peritoneal covering on the outside continuous with the rest of the peritoneum; a thick muscular wall arranged in two layers, the fibres on the outside being longitudinal and those on the inside circular; an innermost coat, which is mucous membrane. This latter is very important, since it is by its agency that the ovum and the sperms are nourished before they fuse; it is through the mucous membrane that nutrients and oxygen are conveyed from dam to fetus, and that much of the waste products leave the fetal circulation to pass into the maternal bloodstream. It consists of epithelial cells, amongst which lie the uterine glands which secrete the so-called 'uterine milk' serving to nourish the newly fertilised ovum.

The most posterior extremity of the uterus is called the os uteri, and this forms the opening into the cervix uteri, which is a thick-walled canal guarding entrance into the cavity of the body of the uterus. Normally this is almost or completely shut, but during oestrus it slackens, and during parturition it becomes fully opened to allow exit of the fetus. The uterus is held in position by means of a fold of peritoneum attached to the roof of the abdomen, which carries blood vessels, nerves, etc. This is known as the 'broad ligament'; it is capable of a considerable amount of stretching.

(See PREGNANCY AND GESTATION; PARTURITION.)

The mare The shape of the uterus of the mare most nearly approaches that of the human being. It possesses a large body and comparably small horns. During pregnancy the fetus generally lies in horn and body. The mucous membrane is corrugated into folds.

The cow The body is less in size than the horns, which are long, tapering, and curved downwards, outwards, backwards, and upwards to end within the pelvis at about the level of the cervix. The fetus lies in the body and one horn in single pregnancy, and when twins are present each usually occupies one horn and a part of the body. The mucous membrane presents upon its inner surface a large number (100 upwards) of mushroom-shaped projections – cotyledons. The fetal membranes are attached to the dome-like free surface of the cotyledons, in which are a large number of crypts, which receive projections called villi from the outer surface of the chorion.

The ewe has a uterus similar to that of the cow except that it is smaller and that the cotyledons are cup-shaped.

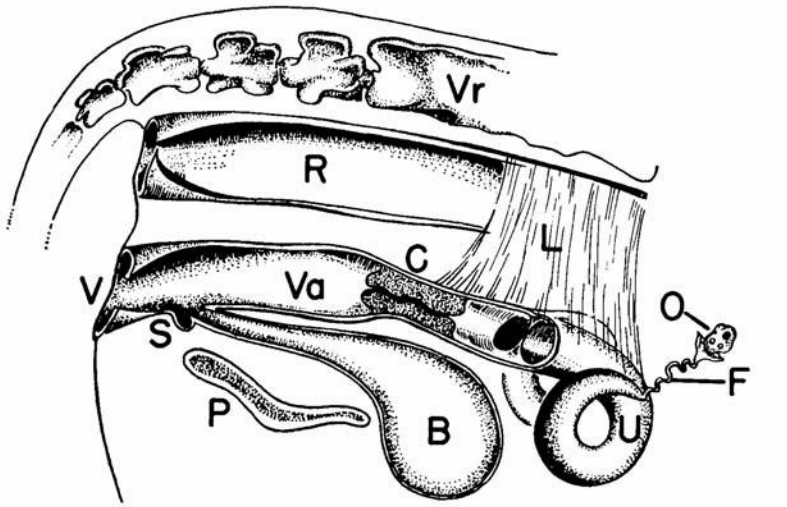
The sow has a small uterine body and a pair of long convoluted horns that resemble pieces of intestine. The mucous membrane is ridged but has no cotyledons. The young lie in the horns only.

The bitch and cat have uteri with comparatively short bodies and long, straight, divergent horns that run towards the kidneys of the corresponding sides.

The rabbit has a uterus with a short body and long straight horns. There is a double cervix and caudal to this, the urogenital sinus, a dilation of the cranial vagina.

(See PREGNANCY AND GESTATION; PARTURITION.)

Uterus, Diseases of



Inflammation of the uterus (metritis) may be acute or chronic, localised (e.g. confined to the cervix), or involving more than one uterine tissue.

A list of uterine infections giving rise to infertility and abortion in the various species will be found under ABORTION, but for the mare, see under EQUINE GENITAL INFECTIONS IN THE MARE.

The mare

Acute Metritis This may occur either before or after foaling. When it takes place prior to the act it

VetBooks.ir

The reproductive tract of the cow (side view). *B*, Urinary bladder; *C*, cervix; *F*, Fallopian tube; *L*, broad ligament; *O*, ovary; *P*, pelvic bone (*os coxae*); *R*, rectum; *S*, suburethral diverticulum; *U*, uterine horn; *V*, vestibule; *Va*, vagina; *Vr*, vertebral column. (Hafez, *Reproduction in Farm Animals*, Lea & Febiger as reproduced in R. D. Frandson, *Anatomy and Physiology of Farm Animals*, Baillière, Tindall.)

is usually associated with the death of the foal and its subsequent abortion, with or without discharge of the whole or a part of the membranes. In such cases the inflammatory condition may persist in an acute form and cause the death of the mare, or it may assume a chronic form after the abortion and render the mare incapable of further breeding; other cases are followed by recovery. Acute metritis occurring after normal foaling may arise through the conveyance of infection into the uterus by the arms or hands of the attendants, or by the ropes, instruments, or other appliances that are used to assist the birth of the foal; or it may be the direct result of retained membranes that undergo bacterial decomposition. (This may happen after most, but not all, of the fetal membranes have come away.)

Signs Acute metritis is a severe and often fatal condition. Within 24 to 48 hours, the mare becomes greatly distressed and loses all interest in the foal. She lies most of the time and refuses food; her temperature is usually high. Greyish blood-flecked discharge escapes from the vagina and soils the tail and hindquarters. The mare may become tucked up in her abdomen and stands with her back arched.

LAMINITIS may develop.

Prevention During foaling and after the act the greatest attention should be paid to the cleanliness of everything that is to come into contact with the genital tract of the mare. The attendant's fingernails should be trimmed short, and the hands and arms should be well scrubbed with soap and water containing some antiseptic, such as Dettol. Finally the hand and arm should be lubricated with a suitable preparation marketed for this purpose. All appliances that are to be used should be boiled and kept in a pail of hot water when not actually in use.

One other factor is of the greatest importance: after a mare foals, the fetal membranes should be given attention. Normally they are discharged by means of a few comparatively mild labour pains within an hour of the birth of the foal. If, however, they are retained for longer than this period, the person in attendance should suspect that something may be wrong and seek veterinary advice.

In other cases, a series of violent pains may commence, when the bulk of the membranes are passed to the outside, where they hang suspended. Should this happen a sack or sheet should be placed under the dependent mass, and held so as to support the weight and relieve the tension on that portion that is still retained in the uterus. This is necessary lest the weight of the external membranes causes a tearing away from the non-separated part. **Gentle** traction should then be exerted upon the imprisoned portion; as a rule it will gradually detach itself and come to the outside. If no progress is made, veterinary assistance should be sought promptly.

Injections of PITUITRIN may obviate manual removal of the fetal membranes. A synthetic oestrogen may be preferred. (See HORMONE THERAPY.)

Regarding complete retention of the fetal membranes – when only a very small portion is seen hanging from the vagina – professional help should be obtained if there is no sign of any attempt at expulsion within 4 to 6 hours after foaling.

VetBooks.ir

Generally speaking, membranes that have remained in position for 8 to 12 hours are starting to decompose, and decomposition means bacterial infection of the uterus (i.e. metritis) in almost every case.

Treatment The case must be considered most serious. The use of antibiotics or one of the sulfa drugs is indicated. (See also under NURSING OF SICK ANIMALS.) Any retained fetal membrane must be removed from the uterus using oxytocin injections. If unsuccessful, 5 litres of a sterile isotonic solution should be instilled through the cervix using a sterile catheter manufactured for the purpose. An oxytocin injection should be repeated after two hours if, again, unsuccessful. This should be repeated until the placenta is removed. The mare should be given NSAIDs as well as antibiotics. Further treatment and uterine irrigation should be repeated daily until the discharge is clean. When complications such as LAMINITIS or PNEUMONIA co-exist, they must receive separate attention.

Chronic Metritis This may originate as a sequel to an acute attack in some cases, but more commonly it is directly due to an injury or infection which is not sufficiently severe to produce an acute attack.

Signs There may be a general unthriftiness following foaling. The mare's appetite is capricious, but her thirst is unimpaired. The temperature fluctuates a degree or two above normal. There may or may not be a dirty, sticky, grey, or pus-like discharge from the vagina, which causes irritation and frequent erections of the clitoris. The mare resents handling of the genital organs, but if the lips of the vulva are gently separated the mucous membrane is seen to be inflamed and swollen.

In other cases the pus collects in the cavity of the uterus and is retained there through closure of the os (see PYOMETRA). It sometimes happens that after the pus has collected for a certain period the os suddenly opens and 4.5 litres (1 gallon) or more of pus is discharged. The os then closes once more. Intervals between these evacuations may vary from a few days to three or four weeks. The mare's general condition shows an improvement immediately following a sudden discharge of pus, but as it re-accumulates she relapses into her former chronic state. Chronic metritis may get gradually worse, and the mare dies. Cases taken in time usually recover with treatment, but further breeding is often impossible.

Treatment An early opportunity should be taken to evacuate the pus from the uterus, by douching and siphonage, or by irrigation as already described under 'Acute metritis'.

Sulfa drugs or antibiotics may be used.

It should be emphasised that expert advice should be sought at the earliest opportunity.

(See also CONTAGIOUS EQUINE METRITIS.)

Torsion In the mare this tends to occur in the last third of pregnancy, but prior to foaling. It is a true torsion of the uterus and not of the anterior vagina, as in the cow. Diagnosis has to be carried out per rectum. There may be colic pains. Rolling the mare, like in the cow, is not an option. Correction should either be carried out standing with an arm through a small lower flank incision, with the mare needing sedation and a local anaesthetic block, or correcting through a mid-line ventral incision under a general anaesthetic.

The cow In the following brief account, much of what has been said in relation to the mare will apply to the cow as well, and only the main differences will be stated.

Acute Metritis In some cases where birth of the calf has taken place easily and naturally, metritis supervenes in the course of the first week or 10 days after calving, but in the majority of cases there has been some injury or infection at, or shortly after, parturition. Retention of the fetal membranes, which is so much more common in the cow than in other animals, is very often the contributory factor to an attack of acute metritis. The conveyance of infection by the hands and arms of the attendant, in his capacity of *accoucheur*, or insemination of a cow not in oestrus, are other causes.

Signs The cow generally becomes obviously affected between the second and eighth day after calving. The vulval lips swell and are painful when touched; the lining membrane of the vagina is intensely reddened and swollen. There are frequent and painful attempts at the passage of urine, the temperature rises to 41.5° C or 42° C (107° F or 108° F), the appetite is lost and there is a gritting of the teeth. Rumination is suppressed, the pulse is hard and fast, the milk secretion falls off or stops altogether. A discharge appears at the vulva.

Treatment Acute metritis in the cow should be looked upon as a contagious disease and precautions taken to prevent infection being conveyed to other cows that are soon due to calve. Actual treatment is similar to that as applied to the mare.

Chronic Metritis very often follows an acute attack in the cow. The animal partially recovers, the more acute signs subside, and there is apparently little or no pain. Milk yield may be reasonable, and the animal may appear bright. The

general health, however, remains indifferent and there may be either a constant or an intermittent discharge from the vulva, which soils the tail and hindquarters, and has in many cases a putrid smell.

Chronic metritis may be due to *Brucella abortus* (see BRUCELLOSIS), *Trichomonas fetus, Arcanobacterium (Actinomyces) pyogenes*, or *Campylobacter fetus*, among other organisms. Another form of chronic metritis that attacks cattle is seen in virgin heifers that have never bred.

Pyometra (a collection of pus in the uterus) may result from infection introduced during natural service, insemination, or at or after calving. Treatment with CLOPROSTENOL may be helpful.

Treatment of chronic metritis in the cow is much the same as that in the mare, but see also under HORMONE THERAPY.

The ewe, sow and goat What has been said in respect to the larger animals applies to these animals to a great extent. It should be remembered that flesh from an animal that is suffering from a severe inflammatory condition, such as metritis, is not fit for human food. (See also SOWS' MILK, ABSENCE OF.)

The bitch and cat In these carnivores, owing to the diffused placenta, and to the consequent sudden stripping bare of protective covering of a large surface, inflammation of the uterus is very prone to follow protracted or difficult parturition, especially when manual assistance from unskilled persons has been undertaken. As in other animals, an acute and a chronic form are recognised.

Acute Metritis may follow difficult whelpings, and retention of one or more fetal membranes. The membrane most commonly retained is that which belonged to the fetus that was born last and occupied the extremity of one of the horns of the uterus.

Signs The onset of inflammation of the uterus generally occurs within a week after whelping, but some cases are delayed a little longer than this, especially in cats. A rise in temperature, increased pulse and respiration rates, dullness, disinclination for movement, and an absence of appetite occur.

Cats and dogs seem to get ease from the pain by sitting crouched in an upright position on their hocks and elbows, and this posture is almost continually assumed. A discharge appears at the vulva. Vomiting may occur. The secretion of milk ceases and the puppies or kittens become clamorous for food. The sides of the abdomen are held tense and rigid, and any attempt at handling these parts is resisted. The animal may groan or grunt if the flanks are firmly pressed between the hands.

Treatment The use of antibiotics or sulfonamides is important. The uterus is syringed out with a non-irritant antiseptic such as dilute cetrimide solution; and pituitrin, ergometrine or dinoprost is given. Antiseptic pessaries may be introduced into the uterus. (See NURSING OF SICK ANIMALS; NORMAL SALINE; ANTIBIOTICS.) The puppies or kittens should be removed from their mother and may be reared either by hand of through the agency of a foster-mother.

Chronic Metritis is very common in the smaller animals, and is sometimes the sequel of an acute attack that has never completely cleared up. The cervix remains closed in most cases, so that the uterus becomes filled with pus (PYOMETRA) and the abdomen consequently enlarges. It is this increase in size that first draws attention to the condition, as a rule.

Treatment In cases of pyometra where some pus is coming away, a course of pituitrin injections may be useful (and it may be tried even where the cervix is closed). (See PITUITRIN) STILBOESTROL is no longer an alternative in EU countries. A two-way catheter may be used to wash out the pus. Penicillin or acriflavine may be used for irrigation of the uterus, and antibiotics or sulfonamides systemically. Ovario-hysterectomy is indicated in a number of cases but should not be postponed until toxaemia is far advanced or the animal too weak to stand the operation. Shock is severe.

Stricture of the cervix is one of the results of an inflammatory condition of this part. When inflammation has been severe, a certain amount of fibrous tissue is laid down around the canal, contracts and causes a narrowing of the passage.

Treatment is described under 'RINGWOMB' – a term used only for stricture in ewes, in which it is most often seen.

Tumours Benign tumours include lipoma, fibroma, papilloma, myoma and haemangioma (rare). Malignant tumours include lymphosarcoma, adenocarcinoma and squamous cell carcinoma.

Prolapse A partial or complete turning-inside-out of the organ, in which the inside comes to the outside through the lips of the vulva and hangs down, sometimes as far as the hocks. When the displacement is only slight nothing may be seen at the outside – as, for example, when one horn only is inverted into the body of the uterus. It is most common in ruminants, less frequent in the mare.

Signs With an incomplete inversion, the uterine horn that carried the fetus becomes turned in

VetBooks.ir

VetBooks.ir

upon itself like the finger of a glove, but it remains inside the passages, and nothing is seen to the outside. The animal is distressed for a time, paws the ground, stamps, lies and rises from the ground frequently, and a series of mild or violent labour pains occurs. She may settle down in a short while, but in a few hours she generally has a repeated attack, when the bulk of the uterus will be expelled to the outside of the body. In the early stages of such a case the real nature of the condition is seldom suspected unless a large pear-shaped mass is seen hanging from the vulva.

The state of the mucous membrane lining of the uterus, which in the prolapse is of course on the outside of the mass, serves as a rough guide to the length of time that has elapsed since the accident occurred. For the first two or three hours the mucous membrane appears moist and of a reddish or brownish colour over the whole surface in the mare and sow. In the cow, sheep and goat, the general surface is red or pink, but the cotyledons show as deep-red mushroom-like eminences scattered over the outside of the tumour. In the bitch and cat there is a wide dark-brown zone. Later, the surface becomes dry – owing to its exposure to the air – and becomes deep reddish, violet or purple, according to the amount of congestion and strangulation.

In the cow the whole of the outer upper surface may be covered with the faeces that are passed as the result of the severe straining. In all animals – but especially in ruminants – parts of the fetal membranes may be adherent to the outer surface of the mass, and can be easily recognised.

The surface is not sensitive to the touch, but any manipulation of the mass is provocative of further straining.

Various complications may occur. The vagina is always displaced when the prolapse is complete; this obstructs the urethra, and dams back the urine.

Treatment Prolapse of the uterus is always an extremely serious condition in any animal, and in the mare and sow very often proves fatal. A percentage of cows and ewes recover, when the prolapse is replaced without loss of time, and when there are no complications.

When treating a case – in whatever animal – it is absolutely necessary to comply with certain essentials as follows:

1. The prolapsed uterus must be protected from further damage. To ensure this the animal must be secured at once, and a large sheet or blanket – which has been previously dipped in mild antiseptic solution – must be placed under the mass, and held by two people so that the tension is relieved from the neck, and so that it cannot be further contaminated or injured.
2. The surface of the organ must be carefully cleansed. For this purpose a clean pail containing a warm solution of potassium permanganate and common salt (1 teaspoonful of the former and 100 g (4 oz) of the latter to 4.5 litres (1 gallon) of water) or diluted Dettol or cetrimide solution may be used. All the larger particles of straw, debris, etc., are picked off, and the smaller pieces removed by gentle washing. Care must be taken not to make the surface bleed.
3. The prolapsed portion must be replaced. To effect this the larger animals may require epidural or general anaesthesia to prevent the powerful expulsive pains that otherwise accompany the process, and make return difficult. When the animal has been anaesthetised the hindquarters should be raised as high as possible by building up the floor with straw bales, by hoisting the hind-legs, or by other means. When the protruded mass is very large and has a distinct neck, the main bulk should be raised to a slightly higher level than the external passage, and a process of 'tucking in' is begun near the vulva. This is carried out by the two hands – one at either side – using the hands half closed, so that the middle joints of the fingers come into contact with the uterus. The fingertips should not be employed owing to the danger of laceration or even puncture of the walls. The resistance is gradually overcome and the mass eased along the passages back into the pelvis – a labour that often makes great demands upon the strength and endurance of the operator, and frequently takes an hour or more to effect. Moreover, when once the organ has been returned, unless it is straightened out into its normal position, it may be reinverted a second time.
4. Measures must be taken to retain the uterus in position: the animal may be given an analgesic or a tranquilliser to lessen the chance of subsequent straining; and sutures may be inserted.

Bedding, etc. is arranged so that the animal is compelled to both stand and lie with the hindquarters raised above the level of the forequarters. This throws the abdominal contents forwards, and helps to maintain the uterus in place. It is, of course, mainly applicable to mares and cows. Bandages may prove helpful.

Amputation of the prolapsed uterus becomes necessary when all attempts at its reduction are futile; when the organ has received so much injury or has become so decomposed and gangrenous that it would be certainly fatal to return it to the abdomen; or when prolapse occurs time after time in spite of all attempts at retention.

In a survey of 103 cases of uterine prolapse, 19 cows died within 24 hours of replacement of the uterus.

VetBooks.ir

Hydrops amnii A condition in which the quantity of amniotic (see AMNION) fluid is greatly in excess of normal. It is often associated with a similar condition of the ALLANTOIS, which is sometimes erroneously called hydrops amnii.

Occurring mainly in cattle, and only rarely in other farm/domestic animals, hydrops amnii is often associated with 'bulldog' calves and monsters. Sometimes a recessive gene is responsible. It may also occur when crossing an American bison on a cow, i.e. when producing hybrids.

Where oedema of the allantois alone occurs, the cause may be disease of the uterus, especially of the caruncles.

Sometimes oedema of both the fetal membranes and the fetus occurs. In mild cases the condition may not be suspected until calving, when an unusually large amount of fluid will be expelled. Retention of fetal membranes and subsequent metritis may follow.

In severe cases, the cow may lose appetite, appear distressed, be constipated, with rumination adversely affected or depressed. Abdominal swelling may suggest bloat. In extreme cases, the cow may be unable to get to her feet. Cases of dislocation of the hips or backward extension of the hind-legs have been seen in combined fetal and fetal membrane oedema involving amnion and allantois, and uterus (hydrops uteri).

Rupture, involving the uterine wall, may occur before or during parturition in any animal, during the reduction of a torsion or prolapse, or, in the bitch or cat, as the result of a car accident. (See ECTOPIC, PREGNANCY AND GESTATION.)

Torsion, or twisting, of the uterus is commonest in the cow and other ruminants, and rare in other domestic animals. This accident consists of a partial or complete rotation of the uterus around its long axis, and usually involves the neck of the organ.

Signs As a rule there is no indication of the presence of the displacement until parturition is due to commence. The animal is then seen to prepare herself in the usual way, but the preliminary labour pains are exceptionally feeble and separated by long intervals. After the lapse of some hours – when the 'waterbag' and other signs of the approaching act should have become evident in an ordinary case – nothing happens. The animal is slightly disturbed, shows an occasional pain, walks around aimlessly, may feed spasmodically, but does not appear to be greatly distressed. This condition may persist for as long as 48 hours. In other cases the animal is very much distressed. It has spasms of violent and painful uterine contraction.

Treatment In the small animals laparotomy is performed, and the twisted organ untwisted. In the cow, it may be possible to rectify the twist by rolling the animal.

Congenital defects (See the diagram under INFERTILITY; also HYDROMETRA.)

Tumours In the rabbit, there is a marked tendency to develop cancerous diseases of the uterus. This is the main reason for spaying does (the operation is usually performed before six months old). The condition is markedly malignant, metastasises readily spread to lungs, liver and other viscera; it is rapidly fatal.

Uvea
(adjective, Uveal)

This consists of CHOROID, CILIARY APPARATUS and IRIS of the eyeball. (See EYE – The Choroid.)

Uveal Tract

This is a coat of blood vessels made up of the CHOROID, CILIARY APPARATUS and IRIS (See EYE – The Choroid.)

Anterior Uveal Tract This comprises the CILIARY APPARATUS and IRIS. (See EYE – The Choroid.)

Uveitis

Inflammation of the uvea (iris, ciliary body and choroid coat of the eyeball).

Uveo-Dermatological Syndrome

This is a rare condition, but probably inherited. It involves both the skin and eye and is mainly seen in JAPANESE AKITA DOGS. There is an UVEITIS, with inflammation of the eye's pigmented part. It often leads to retinal degeneration and secondary GLAUCOMA with blindness. The skin and hair around the eyes and muzzle lose their pigment but this may occur after ocular signs start. It is similar to the human condition of Vogt-Koyangi-Harada which is associated with genetically determined tissue types.

Uvula

The small downward projection that is found on the free edge of the soft palate of the pig. It is not present in the other domesticated animals.

VetBooks.ir

V

Vaccination

A method of producing active immunity against a specific infection by means of inoculation with a vaccine, i.e. a preparation of the necessary antigen(s). (See IMMUNITY; IMMUNISATION; IMMUNE RESPONSE; VACCINE.)

Vaccination in mammals is normally carried out by inoculating individual animals. The method of administration depends on the type of vaccine. Most inactivated vaccines are injected intramuscularly or subcutaneously; temperature-sensitive live vaccines may be administered as drops into the nasal passages; vaccines against PARASITIC BRONCHITIS are given orally.

Mass vaccination of poultry against NEWCASTLE DISEASE may be achieved by dispersing aerosols of vaccine over the heads of the birds with fine spray pumps or adding vaccine to the drinking water. Some fish are vaccinated by dipping the fish in a solution of the vaccine. Fox populations in Europe have been vaccinated against RABIES by impregnating chicken heads or other baits and spreading them in known fox runs. Multiple-component vaccines containing antigens against a number of diseases are available. For example, sheep can be simultaneously immunised against PULPY KIDNEY DISEASE, LAMB DYSENTERY, BRAXY, BLACKLEG, BLACK DISEASE, *Clostridium haemolyticum* infection and TETANUS by a single 8-in-1 vaccine. There are also 10-in-1 vaccines which include *Cl. sordellii*.

(In connection with foot-and-mouth disease, see also RING VACCINATION.)

Vaccine

When an animal is inoculated with a vaccine as protection against a specific disease, e.g. blackleg, this is carried out with the object of stimulating production of antibodies in its system, which will confer active immunity against blackleg organisms.

Vaccines may be prepared from live micro-organisms; from inactivated (killed) micro-organisms; from genetically engineered subunits of the pathogenic fraction of the organism; or from toxoids – heat- or chemically-treated micro-organisms that have lost their virulence but retain their antigenicity, i.e. ability to create resistance to disease.

Live vaccines are vaccines prepared from bacteria or viruses whose virulence is reduced by heat, chemicals or passage through an animal other than the normal host species. For example, cattle plague vaccine may be prepared from the virus *passaged* through (i.e. grown in) chick embryos. Occasionally the live viruses used are related but non-pathogenic strains, useful because they will stimulate antibody production but will not produce the disease.

Viruses may be inactivated by phenol or ultraviolet rays, for example; or they may be modified in some way, such as by artificially induced mutation, to produce a temperature-sensitive virus which will replicate in the nose but not in the lungs. Such a virus vaccine can be administered by nasal spray.

Tissue culture vaccines – live vaccines grown on cell cultures – are used in the prevention of canine distemper, rabies, etc., and in treatment of benign skin papillomata (warts) of cattle.

Vaccines are sometimes used for treatment as well as for prevention of a particular disease.

X-irradiated worm larvae vaccine is used in the prevention of PARASITIC BRONCHITIS.

It is important that, in the commercial production of live vaccines involving the use of chicken embryos (or of tissue cultures derived from them), contaminant viruses are eliminated. For example, the AVIAN LYMPHOID LEUKOSIS virus has contaminated distemper vaccine and would represent a risk to vaccinated poultry if contaminating vaccines for them. SCRAPIE was accidentally spread by an early LOUPING-ILL virus contaminated by the scrapie agent. In Europe, BOVINE VIRAL DIARRHOEA virus contaminated marker INFECTIOUS BOVINE RHINOTRACHEITIS vaccine.

It is essential that vaccines are stored under suitable conditions of temperature, etc.; that they are not used after the expiry date shown on the package; that where two doses are stated to be necessary, both are given – and at the correct interval. Failure to observe these rules can mean that the vaccinated animal does not become immunised; it has led to dogs presumed properly vaccinated against rabies becoming rabid after exposure to a natural infection. Another problem that can be encountered when using improperly stored vaccine can result in hyper-immunisation and anaphylactic shock. (See also INJECTIONS; GENETIC ENGINEERING.)

Inactivated vaccines are prepared from killed micro-organisms that retain sufficient antigenic activity to promote immunity. They are not as potent as live vaccines, and two doses at specified intervals are usually necessary to produce effective immunity. Inactivated vaccines often contain an adjuvant, usually an aluminium salt such as aluminium hydroxide, which enhances the immune reaction. Some are water-based, others formulated in an oily medium. Oil-based vaccines can cause serious reactions if accidentally self-injected into the

operator. It is essential that the person injected receives immediate medical attention and the product data sheet or specification of product characteristics accompanies the person.

Subunit vaccines are genetically engineered so that only the antigenic fraction of a pathogen is utilised. The vaccine does not cause infection but does stimulate immunity. FELINE LEUKAEMIA vaccine and AUJESZKY'S DISEASE vaccine are examples. The virus component of the subunit vaccine has difficulty in penetrating the cells of the vaccinated animal; it does not multiply well within the cells and the animal does not shed the virus. By testing for the fraction missing from the vaccinial strain of virus, a vaccinated animal can be determined from one carrying the infection.

Toxoid vaccines are produced by treating toxins from micro-organisms so that their harmful effects are removed but the antigenic properties remain. TETANUS vaccine is an example.

Marker Vaccines Vaccination can cause a problem when making a diagnosis of disease due to the same organism, as usually it is not possible to distinguish between antibodies produced by infection and those from vaccination. This has been overcome in a few vaccines by making them 'marker' vaccines. Marker vaccines have either a gene deletion which can then be detected, such as with INFECTIOUS BOVINE RHINOTRACHEITIS marker vaccine, or they can be produced by adding one or more genes.

Vaccinia Virus

This term may refer to the virus of naturally occurring cow-pox, or to a strain which has undergone mutation and was used for vaccination against smallpox. The virus was also used as the carrier for the antigen of rabies virus in the live vaccine that has been used to eliminate rabies from wildlife in Western Europe and the USA. (See POX.)

Vacuole

A cavity within a cell.

Vacuum-Dipping of Eggs

A technique used in assisting the eradication of *Mycoplasma* spp. in poultry. Fertile eggs are dipped in a concentrated solution of antibiotic (usually TYLOSIN) and subjected to a negative pressure. Some of the air in the egg's air pocket is thus extracted and about 0.5 ml of antibiotic drawn through the shell into the egg and absorbed. This process is more effective in helping to eliminate *M. gallisepticum* than other mycoplasmas.

Vagina

The vagina extends from the cervix of the uterus to the vulva. Vaginal mucus is altered in character during pregnancy, a fact which can be made use of in pregnancy diagnosis. (For inflammation of the vagina, see VAGINITIS.)

An artificial vagina is used at AI centres for the collection of semen.

Vaginal prolapse in ewes This may precede lambing by up to 55 days, but most cases occur within the last 21 days of pregnancy.

Rupture of the vagina, with protrusion of the intestine and rapid death, occurs not uncommonly in ewes of a large breed, of mature age, carrying a twin – a week or two before lambing is due. Bulky foods – swedes, turnips, kale – are often involved.

Vaginoureteral fistula This has been recorded in dogs and cats, as a complication of ovario-hysterectomy or a caesarean operation, and leads to urinary incontinence. It has been suggested that the fistula may occur following accidental ligation of the ureter during surgery, or because the ureter becomes involved in an inflammatory adhesion originating in the vaginal stump.

Intermittent haemorrhage occasionally occurs in mares having very prominent varicose veins at the dorsal aspect of the vulvo-vaginal area; it does not appear to affect health or fertility. Persistent vulval haemorrhage from varicose veins of the dorsal wall of the vagina has also been described. It yields to local haemostatic treatment.

Vaginitis

Inflammation of the vagina. (See under INFERTILITY – Diseases of the genital organs in female; also 'WHITES'; EPIDIDYMITIS – Epivag; VULVOVAGINITIS, GRANULAR; PROLAPSE.)

Vaginoscope, Vaginoscopy

An instrument used to examine the vaginal lining and is introduced via the VULVA.

Vagotomy

Severing of the vagus nerve. (See HYPERTROPHIC OSTEOPATHY.)

Vagus, Pneumogastric Nerve

The vagus (pneumogastric nerve) is the 10th cranial nerve. This nerve is remarkable for its great length, and for the attachments which it forms with other nerves and with the sympathetic trunks. It arises from the side of the medulla, passes out of the skull, and runs down to the jugular furrow of the neck, where, along with the sympathetic, it accompanies the carotid artery to the entrance to the chest. From this point the right and left vagi differ from each other in their course. They both

VetBooks.ir

VetBooks.ir

pass through the chest cavity, giving branches to the pharynx (which run up the neck again), to the heart, bronchi, oesophagus, etc. Each nerve then splits into two parts and the two upper branches fuse with each other to form the dorsal trunk, the lower branches behaving similarly to form the ventral trunk. These two branches now pass through the diaphragm, with the oesophagus, into the abdominal cavity, and end by giving branches to the stomach, duodenum, liver, and various ganglia nearby. (See PARASYMPATHETIC NERVOUS SYSTEM; also BRAIN.) (See GUTTURAL POUCH DISEASE.)

Valerian

A herb long used in human medicines that help in relieving anxiety and tension; its mode of action is unknown. It is found in herbal preparations for dogs and cats, as a sedative, for travel sickness, and as adjunct in treating EPILEPSY. Tincture of valerian produces an odour that is attractive to male cats.

Valgus

A bone growth-plate defect. (See under BONE, DISEASES OF.) This results in a bending outwards usually of a limb or the pelvis, with angulation away from the midline. The opposite also occurs and is known as VARUS.

One-month-old foal with bilateral carpal valgus. (With acknowledgements to Professor L. C. Vaughan and the Royal Veterinary College.)

Valine

One of the essential amino acids which must be supplied in a well-balanced proportion with leucine and isoleucine. It is glycogenic and is metabolised in the muscles.

Valnemulin

An antibiotic licensed for treating respiratory and intestinal infectious diseases of pigs. It is toxic to rabbits and it reacts with ionophores, resulting in a syndrome like ionophore poisoning. (See MONENSIN SODIUM.) In Scandinavian countries there have been adverse reactions reported in LANDRACE breeds and so care should be taken when using in these breeds.

Valves

Valves are found in the heart, veins, lymph vessels, etc., and serve the purpose of ensuring that the fluids will only circulate in one direction. (See HEART; VEINS; ILEOCAECAL.)

Valvular Disease

(See HEART DISEASES.)

Vampire Bats

Vampire bats are important transmitters of rabies in parts of South and Central America, the West Indies, etc. The bat laps blood from the wounds inflicted with its upper incisor teeth on cattle, horses, etc. In Mexico infected vampires have made necessary the preventive inoculation of 800,000 cattle a year. Trypanosomiasis can also be transmitted by vampire bats. Vampire bats imported into the UK remain in quarantine for the rest of their life.

Vanadium

A trace element essential in minute quantities for the growth of chicks; as little as 10 mg/kg of diet is an overdose that will suppress growth. It works with insulin to increase the amount of glucose and amino acids taken up by muscle.

Vane

The outer part of a contour feather composed of tightly-held barbs. (See SKIN - APPENDAGES OF THE SKIN.)

Varicose Veins

(See under VEINS.)

Varied Diet, Need for

(See DIET AND DIETETICS; AMINO ACIDS; CAT FOODS; DOGS' DIET.)

Variocele

Variocele is a condition in which the veins of one or both testicles are greatly distended.

Variola, Pox

Variola (pox) is the inclusive term for fevers of animals and man, in which a skin eruption takes the form of a 'pock', caused by a POX virus.

VetBooks.ir

Varroasis
Varroasis is a parasitic disease of honey bees, *Apis melifera,* caused by the mite *Varroa jacobsoni.* The mite feeds on the developing larvae and on the adult bees. The result is weak bees and sometimes the death of the queen. Whole hives can be wiped out, causing great economic loss not only to the apiculturalist but also to fruit and arable farmers; beekeepers often supply hives to fruit growers and to fields of rape and LINSEED. Varroasis is prevalent in the UK and is a NOTIFIABLE DISEASE.

As both parasite and host are arthropods, products used for control of the disease must have a fine division between toxicity to the mite and toxicity to the bee. Suspending strips impregnated with flumethrin or fluvalinate in the hive can be effective. Other treatments include tobacco smoke or a vaporising block containing thymol and aromatic oils. Eradication, however, is difficult. The disease came from Asia, where it does less harm because Asiatic bees groom each other, thus removing the mites. Long term, it has been suggested that European and Asian bees may be cross-bred to try to introduce the grooming habit into the European bee population. A variant bee has been found in the English Midlands that will groom other bees and destroy the mites by biting them. A leaflet available from DEFRA gives more details of the disease and its control.

Varus
A bending inwards towards the midline usually of a limb or the pelvis. The opposite is VALGUS.

Vascular
Pertaining to, consisting of, or containing (a high proportion of) blood vessels.

Vascularisation
The establishment of blood vessels within an organ or body part.

Vascular Rings
A congenital condition found in dogs; it involves the great vessels in the thorax. Often there is aortic transposition from left to right side of the heart. The signs are vomiting in a newly-weaned puppy. Diagnosis is to eliminate MEGAOESOPHAGUS. Surgery should be performed as soon as possible. (See HEART DISEASES.)

Vasculitis
Inflammation of a blood vessel.

Vas Deferens
(See under TESTICLE.)

Vasectomy
An operation in the male animal in which the vas deferens is cut. Such an animal is sterile though it retains its libido and may be used for the detection of oestrus (e.g. in cattle). In breeding catteries one or two toms are sometimes vasectomised for the sake of peace, quiet and contentment of queens not being bred from until a later oestrus. In sheep they are often used to initiate oestrus before or at the start of the breeding season.

Sterility does not immediately follow vasectomy (or castration), as some sperms will be in the seminal vesicles and can lead to conception after mating. It may be three weeks or more before the animal is sterile.

Vasoconstriction
Decreased diameter of blood vessels.

Vasoconstrictor
Anything which reduces the size of blood vessels.

Vasodilation, Vasodilatation
Increased diameter of blood vessels.

Vasodilator
Anything which causes dilation of blood vessels. A drug used for this purpose is ISOXSUPRINE hydrochloride. (See NAVICULAR DISEASE.)

Vasomotor Nerves
Vasomotor nerves are the small nerve fibres that lie in or upon the walls of the blood vessels and connect the muscle fibres of the middle coat with the nervous system. By the continuous action of the nerves the muscular walls of the vessels are maintained in a moderate state of contraction. Any continuous and generalised increase in this action results in a raising of the blood pressure of the body, while a diminution produces a lowering of the pressure. Such vasomotor nerves are called vasoconstrictors, but there are vasodilators as well. The latter are able to dilate the vessels, and cause either a general or a local fall in the blood pressure, along with an increased supply of blood to the part.

Vasopressin
A hormone secreted by the posterior lobe of the pituitary gland. It is also called ANTIDIURETIC HORMONE (ADH). (See PITUITARY GLAND.)

Vasotocin
A hormone found in non-mammalian vertebrates such as birds, amphibians, fish and foetal mammals. It is secreted by the PITUITARY GLAND and has the biological properties of both OXYTOCIN and VASOPRESSIN.

Vector
The carrier which transmits a disease from one animal to another. For example, the mosquito

VetBooks.ir

transmits malaria to man and a variety of diseases to animals. In most cases the infective organisms live and multiply in the vector. For example, the mosquito transmits malaria to man and a variety of diseases to animals.

Vector-Borne

Used to describe infections transmitted from an infected animal to another animal by a VECTOR.

Vectored Vaccines

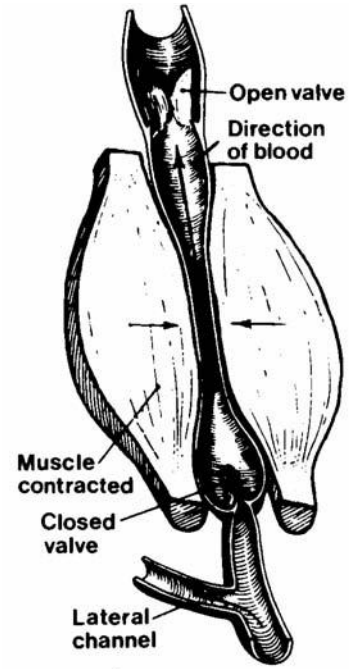
Many are CANARYPOX VECTORED VACCINES and they are used in horses, dogs, cats and ferrets against a variety of infectious diseases including FELINE LEUKAEMIA virus, CANINE DISTEMPER, RABIES, EQUINE INFLUENZA and WEST NILE VIRUS. Vectored vaccines are also used to control RABIES in wildlife populations.

Vedaprofen

This is an NSAID licensed for use in horses for the reduction of inflammation and treatment of pain in musculo-skeletal disorders and soft tissue injuries and surgical trauma. It can be given at least three hours before surgery.

Veins

With one or two exceptions, the veins lie alongside or near to the corresponding arteries – thus the renal vein brings back blood that has been carried to the kidney by the renal artery and lies alongside it. The veins are, however, more numerous and more irregular in their courses than are the arteries, especially on the surface of the body. In regions, such as the cheeks, brain meninges, and in the abdomen and thorax, there are veins arranged quite irrespective of the distribution of the arteries.



Structure A vein is a thin-walled tube which possesses a structure similar to that of an artery, and consists of three coats, viz. an outer fibrous, a middle composed of muscular and elastic fibres, and an inner coat composed of an elastic membrane and flattened epithelial cells. If an ordinary vein is split open along its length, there are seen to be a number of flap-like valves attached to its inner surface. These are like little pockets, and are so arranged that they offer no resistance to the blood when it is flowing in the right direction, but prevent any back-flow. These valves are most numerous in the veins of the limbs, where gravity would naturally tend to produce a back-flow, and least numerous in the veins of the internal organs.

Chief veins The arrangement and relations of the veins are very different in animals of varying species, and even in different individuals, so that only a general description can be given here.

Pulmonary veins – as many as eight or nine in the horse and fewer in other animals – return the oxygenated blood from the lungs to the left auricle of the heart. They possess no valves. Opening into the right auricle are four veins: (1) coronary sinus; (2) anterior vena cava; (3) posterior vena cava; and (4) azygos vein. The coronary sinus is a short thick trunk that discharges the blood used by the heart walls back into the general circulation. The anterior vena cava drains the blood from the head, neck, two fore-limbs and much of the chest wall. It is formed by the confluence of the jugulars and the brachial veins, and receives other branches from the neck, vertebral region, and the chest wall. The posterior vena cava drains all the remainder of the body except the region of the diaphragm, the posterior intercostal areas, the oesophagus, and the bronchial tubes, the blood from these parts being collected into the azygos vein which joins the right auricle separately in most animals. The posterior vena cava is formed under the lumbar region by the union of the right and left common iliac veins, which drain the blood from the pelvis and hind legs, and which are distributed in a more or less similar manner to the corresponding arteries of these parts. From here it passes forwards below the lumbar muscles in company with the abdominal aorta, until at the level of the last thoracic vertebra it passes downwards and forwards, past the pancreas and reaches the liver.

Its further course is partly embedded in the liver substance until it arrives at a special opening in the diaphragm, called the foramen venae cavae, by which it gains the thoracic cavity. From here it passes along in a groove in the right lung to reach the right auricle. Its main tributaries are as follows: (1) lumbar veins, which empty blood from the lumbar muscles, etc.; (2) internal spermatics in the male, and utero-ovarian veins in the female, from the generative organs in either sex; (3) two renal veins, one from each kidney, satellites of the corresponding arteries; (4) several large hepatic veins, which return not only blood carried to the liver by the hepatic arteries, but also that which comes from the digestive organs by the portal vein to undergo a second capillary circulation in the liver (see PORTAL VEIN); and (5) phrenic veins returning blood from the diaphragm.

In the venous system, even more so than in the arterial system, there is an intricate arrangement of anastomoses by which, when one vein becomes damaged or diseased, lateral branches from it may enlarge and carry away the excess blood into other veins so that no great hindrance to the return flow of the blood to the heart may be occasioned. If this were not so, the circulation might be from impaired minor causes.

Valves of a vein showing pumping action of adjacent muscles. (Grollman, *The Human Body*, Macmillan Co., as used in R. D. Frandson, *Anatomy and Physiology of Farm Animals*, Baillière, Tindall.)

Veins, Diseases of

Those lying near to the surface are frequently injured along with other tissues when contusions or lacerations have been sustained, but so extensive is their communication with neighbouring veins that it is usually possible for these latter to enlarge and undertake the functions of the damaged vessels, and thereby prevent serious consequences. The deeper veins are protected from all but the most severe, and usually fatal, injuries.

Inflammation of a vein, or phlebitis, may follow the collection of blood samples when unclean instruments have been used, or when the resulting skin wound has not received attention. In other cases it follows THROMBOSIS and infection.

Varicose veins are those which have become stretched or dilated to an extent not justified by the blood flow. (See VARIOCELE and under VAGINA.)

Veld Sickness

(See HEARTWATER.)

Vena Cava

(plural, Venae Cavae)

Each of the two large veins that open directly into the right auricle of the heart. (For further details, see under VEINS.)

Thrombosis of the posterior vena cava, which may follow abscess formation in the liver or elsewhere, is in cattle not infrequently followed by the presence of clots in the pulmonary vessels, abscess formation and sometimes erosion of the pulmonary artery wall – giving rise to a fatal haemorrhage. Signs may include dullness, rapid breathing, a cough, chest pain, the presence of blood in material coughed up, anaemia, and widespread rhonchi. (See RECUMBENCY.)

Venereal Diseases

Animals, with the exception of the monkey, are not subject to infection by the two great human venereal diseases of syphilis and gonorrhoea, but there are several important contagious diseases that can be transmitted from animal to animal by coitus. These include brucellosis, trichomoniasis, *Campylobacter fetus* infection, and infectious vaginitis of cattle, venereal granulomata or venereal tumours of dogs, DOURINE or mal du coit of horses and *Mycoplasma meleagridis* in turkeys. (See PROTOZOA; EPIDIDYMITIS; VULVOVAGINITIS, GRANULAR; CONTAGIOUS EQUINE METRITIS.)

Venereal Tumours, Infective Granulomata

Venereal tumours (infective granulomata) characterise a contagious disease of dogs.

Signs In the female the original tumour is a warty excrescence which soon grows and becomes cauliflower-like. In advanced stages there is a large mass of pinkish or greyish-red tissue, which easily bleeds when touched, occupying the greater part of the vaginal passage and often causing a bulging and swelling of the perineal region. A dirty sticky blood-stained discharge accompanies the condition, and the animal's general health suffers. In the male the watery growths usually have a distinct stalk, and are attached to the skin or mucous membrane of the prepuce, or to the penis. (See also under WARTS.)

Venezuelan Equine Encephalomyelitis

A strain recognised in the 1930s. A severe outbreak occurred in Venezuela and Colombia in 1962–4, when thousands of horses died and about 30,000 people were infected. A later outbreak spread to Mexico in 1970 where 6000 or more horses died, and then to Texas, USA. (See also EQUINE ENCEPHALITIS.)

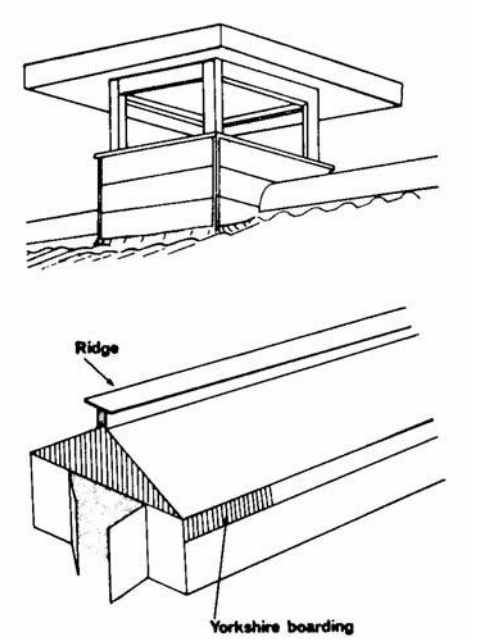
Venom

(See SNAKES; TOADS; BUFOTALIN; SPIDERS; SCORPIONS.)

'Vent Disease' in Rabbits

(See 'RABBIT SYPHILIS'.)

Vent Gleet



This condition in poultry is an inflammation of the cloaca, with which is associated a thin yellowish watery discharge which has a characteristic and particularly unpleasant odour. The cloaca and adjacent skin appear swollen and congested, and the bird exhibits signs of irritation. Other birds attracted by the reddening of the region may peck at vent; this leads on to cannibalism.

Egg production drops, and in some cases egg-binding and impaction of the oviduct result. Culling is advisable. There is a similar condition in ducks but the material round the vent is more solid. This must be removed and the affected area treated with antibiotic cream.

Cases of severe infection of the eyes of poultry-keepers treating this condition are not uncommon.

Ventilation

Ventilation may be summed up as 'the measures necessary to rectify the pollution of the air in a building – without the production of a draught'. Whenever animals are enclosed in a confined building they gradually use up the oxygen and discharge into the air quantities of carbon dioxide and water vapour, until, if no fresh air is supplied, the percentage of oxygen decreases below the amount required.

Ventilation methods for cattle houses: Top, Chimney; Bottom, Continuous ridge outlet. (With acknowledgements to *The UFAW Handbook on Care and Management of Farm Animals*, Churchill Livingstone.)

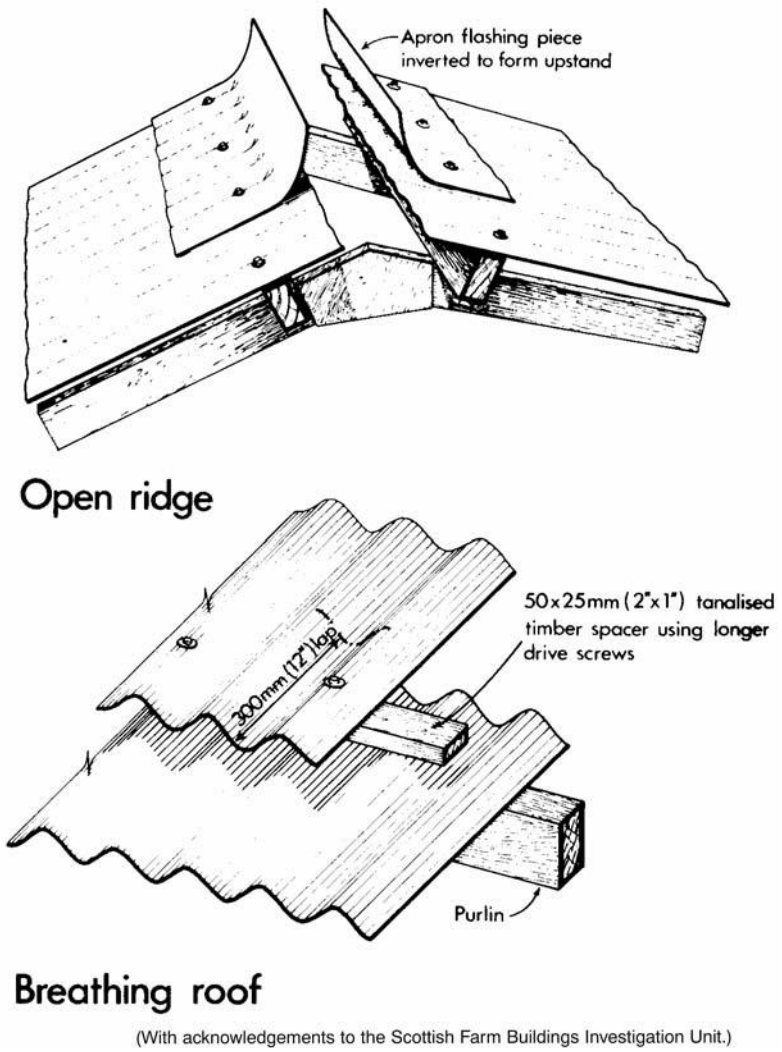
One of the problems in livestock buildings is condensation, which can lead to bronchitis and pneumonia. For buildings used for cattle and sheep, provision of Yorkshire boarding is one of the best and least expensive methods of avoiding or curing condensation.

Necessary air space

	m^3	ft^3
Cow, horse		
(Byre or stable)	5.6	200
(Loose box or yard)	16.8–33.6	600–1200
Bacon pig	1.7	60
Poultry		
(layers on slats)	0.17	6
(layers on deep litter)	0.34	12

The required amount of air for each animal must be continuously brought in from the outside, and an exit must be provided for an equal amount. This is arranged for by the provision of inlet and outlet ventilators.

Inlets These include windows, direct inlet pipes, perforated bricks and gratings, Yorkshire boarding, and electric fans.



Windows, of which the Sheringham Valve type is the most common and useful, serve the dual purpose of lighting and ventilation. Those on the lee side of a building serve as outlets when the wind is strong. In the Sheringham Valve windows, the incoming air is deflected upwards by the hopper-like flap that falls inwards, so that it is spread over a greater area than is the case with other openings. Inlet pipes are used, often in conjunction with windows, to ensure a supply of fresh air in the region of the animals' heads.

Ventilation rates – (maximum)

	Changes of air per hour	m^3 per hour	ft^3 per hour
Bacon pig	20	5.7–34	200–1,200
Broiler chicken	40	6.8	240
Laying birds	30	10	360

Outlets These include an open ridge, louvre-board ventilators, outlet shafts, open eaves, exhaust fans, and other devices. The most satisfactory outlet is undoubtedly an open ridge along the whole length of the building. The heated impure air rises and is drawn through the open space by the suction of the wind. The disadvantages of this system are that the open space will allow entrance to a certain amount of rain or snow in bad weather; the system is also inapplicable to buildings possessing lofts.

VetBooks.ir

(With acknowledgements to the Scottish Farm Buildings Investigation Unit.)

Extraction area

(Necessary with natural ventilation)

Outlet per animal:	cm^2	sq. ins
Cowhouse	930	144
Farrowing house	95	15
Fattening house	65	10
Calf house	65	10
Poultry (adult) house	13	2

Mechanical ventilators may be either of the plenum or in-forcing type, or of the vacuum, exhaust, or out-forcing variety. In the former a larger power-driven fan is enclosed in a chamber with communication to the outside of the building, and is connected by ducts or shafts with all parts that are to be ventilated. In the exhaust variety one or more electric fans are enclosed in turrets placed along the ridge of the roof.

Ventilation tunnel These have a fan to draw air into the building and force it out through vents over the stock.

The temperature in a livestock building is a result of the heat released from the stock (for example, a dairy cow gives off heat equivalent to 0.5 kW; and with a heavy milker the figure may be 1 kW) and the varying quantity of ventilating air drawn from outside. 'Because heating and refrigeration are only economic for young stock, the properties of the air entering the building are those of the outside air and vary considerably, depending on the weather. In hot weather a large amount of air

is used, but in cold weather only a small amount is required and in many traditional systems this gives rise to different patterns of internal air flow. By studying the relevance of airflow patterns to the conditions near the stock and to the response of the ventilation system the Environment Department, NIAE, has designed a ventilation system which provides near uniform internal conditions as the outside temperature changes. The system ensures a desired airflow pattern by automatically adjusting the inlet gap to maintain an air speed of about 5 m/s. Calculations and experiments have shown that this system will maintain the required airflow pattern for outside temperatures down to 0° C (32° F).

'Another shortcoming of traditional systems is the influence of wind on ventilation rates, particularly in cold weather when fans are running slowly. For this reason the NIAE have discarded the method of varying fan speed to control rate of ventilation and recommends switching the fans on or off. When fans are off they are covered by simple backdraught shutters and when on they are at full speed and so are least affected by wind. The fans are switched on or off in predetermined steps and the inlet gap is adjusted automatically to match the steps in ventilation rate.

'The diagram below shows the essence of the system which has proved effective in fattening piggeries, broiler houses and turkey buildings and is fully described in the NIAE Report No. 28.' (See also HOUSING OF ANIMALS; CARBON MONOXIDE.)

Fan failure (For this and the resulting mortality, see under CONTROLLED ENVIRONMENT HOUSING)

Ventral

Ventral in anatomy indicates that a particular organ or structure is situated towards the abdominal surface of the body, as distinct from the spinal or dorsal aspect.

Ventricle

A chamber of the heart, or a small cavity in the brain. (See HEART; BRAIN.)

Ventriculus

(See GIZZARD and diagram for PROVENTRICULUS.)

'Verminous Aneurysm'

'Verminous aneurysm' is a misnomer for EQUINE VERMINOUS ARTERITIS.

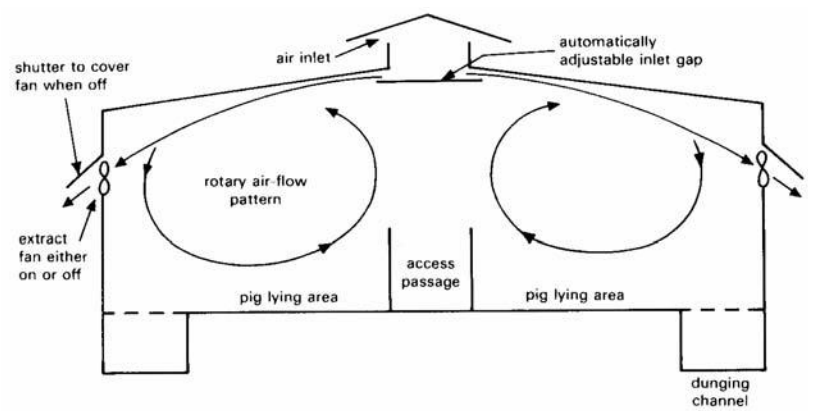
Verminous Arteritis

Inflammation of arteries by parasitic worms. It occurs in horses, usually due to Strongylus vulgaris and can result in COLIC.

Verminous Bronchitis

(See PARASITIC BRONCHITIS and GAPES.)

Verminous Dermatitis



(See STEPHANOFILARIASIS; SUMMER SORES.)

Verminous Ophthalmia

(See under EYE, DISEASES AND INJURIES OF.)

Vero Cells

A continuous heteroploid cell line derived from African green monkey (*Cercopithecus aethiops*) kidney tissue. These cells are approved as a substrate for the production of virus vaccines, including rabies. They are much easier to grow than human diploid cells, and provide a better yield; so that manufacturers are keen to use them for vaccine production. Latent virus in these cells is a potential danger. The cells can be used to grow viruses as they do not contain INTERFERON. They are used to screen for VEROTOXIN or Shiga-like toxin of E. coli, and to test whether the cells multiply or not in the presence of pharmaceutical compounds.

The NIAE ventilation system.

VetBooks.ir

VetBooks.ir

Verotoxin (VT)

A total of 1,012 milk filters were collected from 498 diary farms in south-west Ontario. The supernatants of 20 (2 per cent) of the milk filter cultures had verocytotoxic activity. Seven verotoxin-producing *E. coli* strains were isolated, two of which had been previously associated with disease in humans including *E. Coli* O157. The toxin is now usually referred to as 'Shiga-like toxin' as it resembles the toxin of Shigella dysenteriae.

Verruca

(See PAPILLOMA.)

Verrucose

Covered with warts or vegetative growths. In pigs a verrucose endocarditis is recognised, the growth being found on the heart valves. The condition may be associated with swine erysipelas or be caused by staphylococci or streptococci.

Verrucous Pastern Dermatitis

A condition originally eliminated from British war horses during the Crimean War. It has reappeared through horses standing too long in damp and muddy conditions. Outgrowths appear in the region of the pastern that become infected or the area may be invaded by insect larvae.

Version, Turning

Version (turning) means the changing of a presentation at parturition so that some other part of the fetus than that which was presented originally comes through the pelvic opening first.

Vertebra

(plural, Vertebrae)

(See SPINAL COLUMN.)

Vesicle, Small Blister

A vesicle (small blister) is a collection of fluid in the surface layers of the skin or of a mucous membrane. Vesicles are present in a number of diseases, and according to their location, some assistance is afforded for diagnostic purposes. For example, in foot-and-mouth disease the vesicles are present in the mouth and on the feet, while in cow-pox they are found on the teats, udder, and other parts.

Vesicles, Seminal

These secondary sex glands, like the prostate, have openings into the urethra and are situated close to the neck of the urinary bladder. (See also under SEMEN.)

Infected seminal vesicles can (rarely) cause problems. At a bull-rearing unit, four yearlings appeared fit and well. Their appetite was good and they showed no signs of pain or discomfort. When, however, samples of their semen were taken, clots of pus were noticed. This finding led to a careful examination of the bulls being made, and it was then discovered that each had a hard, painful swelling of one of their seminal vesicles. Inflammation was found to be due to infection with *Actinobacillus actinoides*. Other organisms sometimes involved include tubercle bacilli, *Brucella abortus*, streptococci, and *Trueperella pyogenes*.

Vesicovaginal Reflux

(See UROVAGINA.)

Vesicular Disease of Pigs

Vesicular disease of pigs is described under SWINE VESICULAR DISEASE. (See also VESICULAR STOMATITIS.)

Vesicular Exanthema

A viral disease of pigs (and rarely of horses but not of cattle) which has to be distinguished from foot-and-mouth disease. It was eradicated from the USA in 1959 and has never been recorded elsewhere. It is thought that the vesicular exanthema virus may have been a 'land variant' of the San Miguel sea-lion virus, isolated from sea-lions off the coast of California.

Vesicular Stomatitis (VS)

Vesicular stomatitis is caused by a rhabdovirus transmitted by mosquitoes and biting flies, and may affect horses, cattle, pigs and, occasionally, sheep. It is a NOTIFIABLE DISEASE in the EU. The blisters seen on the tongue have occasionally caused confusion with FOOT-AND-MOUTH DISEASE, and vice versa – with serious consequences. Lesions can also occur on the udder or around the coronets. It is a disease of the summer, and mainly of the western hemisphere, especially in the Caribbean area.

In man the disease is influenza-like, with fever, sore throat and several days' malaise.

Two strains of the virus are recognised – the New Jersey and the Indiana. Experimentally, numerous mammalian species can be infected – likewise ducks. Although the disease is not present in the UK, the standard method of assessing interferon-like drugs is to titrate them against vesicular stomatitis virus.

Vesicular Vaginitis

(See VULVOVAGINITIS, GRANULAR.)

Vesiculitis

(See SEMINAL VESICLES.)

Vestibular Organ

This is in the inner ear and is the bony labyrinth containing a membranous labyrinth. The vestibular

organ is the non-acoustic part of this membranous labyrinth, and it contains the semicircular canals, and the membranous saccule and utricle. The organ is essential for maintaining balance.

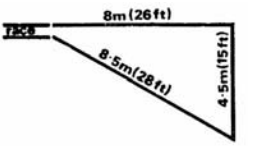
Veterinarian

A formal definition of a veterinarian was produced by FVE in November 2012. It said that a 'Veterinarian' was a 'professional with a comprehensive scientific education, licensed by the legal authority, to carry out, in an independent, ethical and personally responsible capacity, all aspects of veterinary medicine, in the interest of the health and welfare of the animals, client and society'.

Veterinary Degrees

Veterinary degrees are conferred on graduates from the veterinary faculties of Bristol, Cambridge, Edinburgh, Glasgow, Liverpool, London and Nottingham universities. In October 2014 the first intake occurred at Surrey University. They lead to membership of the Royal College of Veterinary Surgeons (MRCVS) which allows the graduate to practise in the UK as a veterinary surgeon. Higher degrees (PhD, MSc, etc.) are available after postgraduate study, as well as certificates and diplomas in specialist areas of veterinary medicine and surgery. Members of the RCVS are able to gain Fellowship of the RCVS by submission of a thesis or for meritorious contributions to learning. Graduates of veterinary schools in other EU countries may also become MRCVS. University degrees in veterinary nursing are also available although VNs can be registered without a degree. There are also veterinary science degrees courses at several universities, but these do not lead to registration as a veterinary surgeon.

Veterinary Facilities on the Farm



Every breeding cow and heifer in Britain has, during its lifetime, to be caught, ear-tag read, restrained and a blood sample taken from neck or tail vein. This will take place at least two or three times, quite apart from any herd or individual handlings necessary for clinical reasons or breeding management. Taking a blood sample can take as little as 30 to 45 seconds given efficient holding facilities; 200 cattle could be sampled in a morning's work. On most farms there is a lack of cattle-handling facilities of the right type, so that the catching of a single animal can and does take all the farm staff about 20 minutes with the very real possibility of broken gates and fences and varying degrees of personal injury, even before blood-sampling is attempted.

Experience in the design and erection of cattle handling units for dairy and beef cattle has shown the main points to be as follows:

Collecting pens should be large enough to hold all stock to be handled, or all the stock in units as they are housed, e.g. 50s or 100s. A post-and-rail pen 9 m × 18 m (30 ft × 60 ft) or 12 m × 13.5 m (40 ft × 45 ft) will hold 100 cows with calves at foot. A pen of 9 m × 12 m (30 ft × 40 ft) will hold 60 adult cattle or 80 young cattle.

The forcing pen leads from the collecting pen to the race or chute, and should be funnel-shaped. It should hold no fewer than 12 cows plus calves, or 15 adult cattle – enough to provide a group for handling without having repetitive stops while twos or threes are run into the cow-race. The optimum dimensions are as shown in the diagram, and should not be made larger for large units. The dimensions are those within which cattle cannot evade pressure to go into the race by adopting a whirlpool movement.

Race An 18 m (60 ft) long race, 680 mm (2 ft 3 in) wide internally and 1.680 m (5 ft 6 in) to the top rail, will hold 10 to 12 cattle. It should be made up of verticals (sleepers) 2 m (6 ft 6 in) between centres sunk 900 mm (3 ft) into the ground, the bottom concreted with a brushed surface. There should be four horizontal rails. Height above ground of the second and third rails is specific in that it accommodates the large, fat or pregnant animal.

Catwalk and working space Catwalks should be provided on both sides of the cow race, 760 mm (2 ft 6 in) above ground level and not less than 300 mm (12 in) wide, in wood. Space should always be provided for two catwalks, even when building in close proximity to an existing wall – i.e. the face should be stood off from the wall, however tempting it may be to use an existing wall for one side. Cattle can then be run in either direction for procedures on either flank (vaccinations, branding, testing, etc.).

Crush and veterinary gates The crush should be stood off 1.079 m (3 ft 6 in) from the end of the cow race with the same internal width of 680 mm (2 ft 3 in), and suitable gates to hold animal No. 1 firmly, stop animal No. 1 from backing out of crush before being held and prevent animal No. 2 from pushing up. The materials and sizes are the same as for the race.

Yoke or headstock A device for restraining cattle by the neck, strongly made from wood or

VetBooks.ir

metal and designed so that the head cannot jerk about. While securing the animal firmly, it incorporates a quick-release frame to free it in an emergency.

Three-way cattle shedder If fat cattle are weighed, cows examined for breeding function or large stores sexed, then this at once dictates grouping by weight, pregnancy or other findings. A three-way shedder immediately after the crush renders this separation an easy task.

Dispersal and recirculation Having dispersed any large group of cattle to their appropriate categories of in-calf, empty, etc., there should be a series of gates in the far end of all holding pens, allowing cattle to be recirculated, retained or individually extracted.

Suckler cows and calves Suckler cows are usually handled for clinical reasons (vaccinations, treatment, blood-sampling) or to find out breeding status at that time (in-calf, ovulating, empty). This usually means that calves are at foot. To simplify handling, calves can go with their dams right into the forcing pen without any attempted separation. If a calf race is then sited to run from near the mouth of the cow race, with a shedder gate, then calves of one to seven months can be run off separately. This allows vaccination, castration, dehorning or weighing to be done very quickly with no time and energy dissipated on catching each calf individually. Critical dimensions for the calf race are 410 mm (1 ft 4 in) internal width and 1.040 m (3 ft 6 in) to top rail. The shedder gate should be close-boarded to prevent visual contact between calves and cows in cow race. Calves will run into the calf race quickly if the shedder is operated from an overhead platform, but they tend to flinch at an operator working through the rails at head or shoulder level.

In addition to the cattle-handling facilities described above, it is useful to have a footbath suitable for cattle (see FOOT-BATHS FOR CATTLE), and loose-boxes for calving or isolation purposes. With a very large herd of, say, 500 cows, 15 loose-boxes would not be too many.

Veterinary Investigation Centres (VICs)

In April 2011 the Veterinary Laboratories Agency was merged with Animal Health forming the Animal Health and Veterinary Laboratories Agency (AHVLA) and in October 2014 it became the ANIMAL AND PLANT HEALTH AGENCY (APHA). Together with the Central Veterinary Laboratory, Weybridge, the VICs provide laboratory facilities and a consultative service for veterinary surgeons in private practice, assisting with the diagnosis of disease and herd problems. Their work includes autopsies, serological tests, biochemistry and parasitology. VIC staff carry out research into disease problems of local importance, and also provide a surveillance function for DEFRA in warning of local disease which might become important nationally. In Scotland similar VICs operate but are affiliated to the Scottish agricultural colleges.

Veterinary Medicines Directorate (VMD)

The government agency with responsibility for overseeing the evaluation and licensing of animal medicines, protecting the consumer from unacceptable or hazardous residues, and advising the Veterinary Products Committee. Address: Veterinary Medicines Directorate, Woodham Lane, New Haw, Addlestone, Surrey KT15 3LS. Telephone: 01932 336 911; email: postmaster@vmd.defra.gsi.gov.uk: website: www.vmd.gov.uk.

Veterinary Medicines Regulations

These regulations came into force in autumn 2005 and set out legal controls associated with veterinary medicinal products. They superseded the Medicines Act 1968 which had regulated veterinary medicines up to that time and in general is still the basis for the legal controls on such medicines. The regulations provide legal controls on medicinal products for human use when used for veterinary purposes. The regulations are reviewed and updated annually.

Veterinary medicines now fall into four different categories under these Regulations. The categories are:

1. AVM-GSL (Authorised Veterinary Medicine-General Sales List). These can be sold by anyone and were formerly designated GSL.
2. NFA-VPS (Non-Food Animal Medicine – Veterinarian, Pharmacist, Suitably Qualified Person). These must be prescribed by a veterinarian, pharmacist, or suitably qualified person for companion animals only (formerly this category was PML companion animal products and a few P products) and they involve a wide range of products but exclude most commonly use vaccines.
3. POM-VPS (Prescription Only Medicine – Veterinarian, Pharmacist, Suitably Qualified Person). This category is for medicines for food-producing animals (including horses), which are only to supplied on veterinary prescription, and which must be prescribed by a veterinarian, pharmacist or SQP (either orally or in writing), and which must be supplied by one of these three groups of people in accordance with the prescription. Formerly these were PML livestock

products, MFSX products and a few P products), and they include wormers and many vaccines.

4. POM-V (Prescription Only Medicine – Veterinarian). A medicine which must only be prescribed on a veterinary prescription, which must be prescribed (either orally or in writing) by a veterinarian to animals under their care following a clinical assessment, and which may be supplied by a veterinarian or pharmacist in accordance with the prescription. (Formerly these were POM products and a few P products). These include antimicrobials, most hormone and steroid preparations and some vaccines.
   (See MEDICINES ACT 1968.)

Veterinary Nurses (VN)

A title restricted to those who have completed the course of instruction and passed the examinations authorised by the Royal College of Veterinary Surgeons. People wishing to train as veterinary nurses must first find employment for not less than 35 hours per week in a veterinary practice or other veterinary centre approved by the RCVS. There are 1,643 training practices which include branch surgeries and 44 for trainee equine nurses. The greater part of the training is given while working; VN training is now part of the NVQ scheme.

The practical training is supplemented by formal tuition to provide the necessary background knowledge. Residential courses are available.

All pre-enrolment queries about training are dealt with by the British Veterinary Nursing Association. Address: 82, Greenway Business Centre, Harlow Business Park, Harlow, Essex CM19 5QE. Telephone: 01279 408644; email: bvna@bvna.co.uk.

There are many training centres, approved by the RCVS, where student nurses can study for the two qualifying examinations.

An RCVS Level 3 Diploma in Veterinary Nursing, and a university degree in veterinary nursing, can also be obtained.

Veterinary Poisons Information Service (VPIS)

This provides a subscriber service of advice to veterinary surgeons. Address: National Poisons Information Service, National Poisons Unit, Guy's and St Thomas' Foundation Hospital Trust, Mary Sheridan House, Guy's Hospital, London SE1 9RY. Telephone: 0207 188 0200; website, www.vpisuk.co.uk Initial contact: vpis@gstt.nhs.uk.

Veterinary Practitioner

Someone on the Supplementary Veterinary Register; not an MRCVS. The SVR was closed to new entrants in 1967. Very few members still remain. It is now often used to describe veterinarians in veterinary practice.

Veterinary Products Committee (VPC)

This, under the Medicines Act 1968, and now the Veterinary Medicines Regulations, advise the Medicines Commission and, ultimately, the Licensing Authority, on the marketing of medicines for animals. Its approval is needed before an animal medicine may be licensed for sale. It has to consider the safety, quality and efficacy of any veterinary medicine in relation to the treated animal, the safety of consumers of produce derived from treated animals, and the safety of farmer, pet-owner and the environment. (See also SUSPECTED ADVERSE REACTION SURVEILLANCE SCHEME.)

Veterinary Profession

This comprises those engaged in private practice, in the Animal Health agency of DEFRA, the Royal Army Veterinary Corps, the Home Office, the overseas veterinary services, in research and teaching at the universities, and also at Institute of Animal Health research establishments, and those of the Food Standards Agency etc., in food inspection and other municipal services, in AI centres, in research and advisory appointments with, e.g. FAO, and in commercial undertakings. There are about 18,000 veterinary surgeons working in the UK and about 2,600 veterinary practices. The traditionally male-dominated profession now has a majority of female veterinary surgeons.

Veterinary Surgeons Act 1966

This relates to veterinary education, the management of the profession, and the registration and professional conduct of veterinary surgeons and practitioners. The practice of veterinary surgery continues to be limited to veterinary surgeons and practitioners whose names appear on the registers maintained by the Royal College of Veterinary Surgeons. Unregistered persons may carry out only the very limited treatments, tests, or operations specified in section 19 of the Act, any exemption orders made thereunder, or schedule 3.

The Amendment Order to the Act permits a veterinary nurse to carry out any medical treatment or any minor surgery to a companion animal, provided that the latter is under the care of a registered veterinary surgeon who has authorised the treatment.

Veterinary Surgery (Epidural Anaesthesia) Order 1992

(See under LAW.)

Vetrabutine

A specific uterine relaxant used in cows, sows ewes, and bitches. It must not be used in queens.

VetBooks.ir

VetBooks.ir

'Vetting'
A common name for examining an animal, and often done in the context of PRE-PURCHASE EXAMINATION.

Vial
(See AMPOULE.)

Vibices
Vibices are long tapering markings that sometimes occur on visible mucous membranes during certain diseases, such as purpura haemorrhagica and pernicious anaemia of horses.

Vibrio
Vibrio is a bacterium shaped like a boomerang. In stained smears they are often seen in pairs either in the form of an 'S' or of a flying seagull. Now known as *Campylobacter*.

Vibrio fetus Now *Campylobacter fetus fetus*. (See *Campylobacter* SPP. INFECTIONS.)

'Vibrionic scours' in pigs (See SWINE DYSENTERY.)

Vibrio parahaemolyticus An organism found in warm brackish seawater. It is a human food-borne infection ingested with undercooked or raw seafood such as seafish, crabs, lobsters, oysters and clams. Symptoms are of an explosive gastroenteritis 24 hours after eating and last up to three days. In the USA it is estimated that there are 142 human cases undiagnosed for every one reported.

Vibriosis
Vibriosis caused by infection with *Vibrio anguillilarum* is a serious disease in marine fish farms. Affected fish suddenly lose appetite and turn dark in colour. Post-mortem examination reveals haemorrhagic internal organs; the kidney may be liquefied. Surviving fish may have ulcers that erode the back muscles and the base of the fins. Prompt treatment with antibiotics in the feed may save those still eating. The infection has also been found in eels transported live in inadequate conditions.

Vibrissae
The thick, stiff hairs or whiskers which project from the faces of cats, dogs, and other animals. They are minor sense organs. (See SKIN.)

'Vices' and Viciousness
A definition comprehensive enough to include bad habits. (See TAIL-BITING (in pigs), SUCKING (in calves); and FEATHER PICKING, CANNIBALISM (in poultry).) The following concern the horse.

Bad habits, mild vices, or whims in horses Horses that are shut in stables without exercise or work frequently learn vices and tricks which not only may be harmful to the animals themselves, but may be dangerous to persons who attend them. Perhaps the most objectionable is the habit of kicking when being approached. (See below, under 'Kicking'.)

Eating the bedding may be merely an endeavour on the part of the horse to acquire a sufficiency of coarse bulky food when the ration is too concentrated, or it may be a bad habit. It can be prevented by supplying sawdust instead of straw, or peat moss litter.

Refusing to lie is often due to fear, nervousness, or physical inability, such as ankylosis of the spinal column. Horses may lie when housed in a loose-box instead of a stall; a stout rope from one heel post across to the other may allow the horse to obtain some amount of rest. (See SLEEP (HORSES), etc.) Gnawing the walls is usually a sign of the presence of worms, bots, a mineral or other deficiency, or indigestion, and appropriate measures should be taken to determine which condition is present, and to treat it accordingly.

Pawing in the stable may be a sign of impatience or loneliness; then it is not important, but sometimes it develops into a vice of such persistency that it entails great wear of the shoes, and may result in the production of holes in the stable floor. It should be remembered that pawing is sometimes a sign of abdominal pain (colic).

(See CRIB-BITING AND WIND-SUCKING; WEAVING.)

Aggressiveness may be due to pain (see HORSES, BACK TROUBLES IN); and, in countries where the disease is present, to RABIES. (See also BRAIN DISEASES.)

When an animal shows an ungovernable temper under the pressure of sexual disturbances, it is unfair to consider it vicious. Cruel treatment in the past may also be an underlying factor (and see also the effect of EQUINE VERMINOUS ARTERITIS).

Kicking (a) Rearing and striking with the fore-feet is a dangerous vice that is more common among the light horses than among the heavy draught. Sometimes the animal merely rears from a desire to get started with his work; sometimes he will not allow himself to be held by the head when in harness, but rears and strikes out at anyone approaching him; at other times he may strike out without rearing. A saddle horse, when rearing, may with his head strike the face or chest of his rider and unseat him, and may so lose his balance that he falls over backwards and perhaps crush the rider.

VetBooks.ir

(b) Kicking with the hind-feet. 'With a kicking horse, pass in front' is a proverb that it is well to remember when dealing with the horse that uses his hind-feet for kicking. The hind-feet can be used to strike an object within a radius of from 1.2 m to 1.8 m (4 ft to 6 ft) all around them. It is a well-known fact that a mule can deliver a kick with his hind-feet to a person standing at its shoulder, and there are many horses able to do likewise. Two methods of kicking with the hind-limbs are commonly employed: in the first, which is the horse's natural method of defence and offence, the head is lowered, the body is lifted from the withers backwards, and both the hind-limbs are suddenly extended as far backwards as possible with tremendous force; in the second, the horse lifts one hind-foot and deals a short vicious backward or sideways kick without always fully extending the limb.

In addition to these there are 'cow kickers', which project one hind-limb forwards, outwards and backwards, so that they may reach a person standing as far forward as the shoulder. These are especially dangerous.

Biting is commonest among stallions. It is well to take precautionary measures, such as muzzling while grooming, tying up short, using double head ropes, one to either side of the stall, etc.

Shying In many cases where horses suddenly stop, plunge to one side, snort, tremble, attempt to turn in the opposite direction and run away, when confronted by some unusual sight, sound, or smell, the same causes as occasion bolting are operative. The horse does not trust his eyesight, is unable to interpret an unusual sound or smell, and consequently takes fright. Among the many objects at which horses are liable to shy may be mentioned the following: pools of water shining in the sunlight, fluttering pieces of paper, clothes hung out to dry, dogs, cats, fowls and other small animals darting into the roadway. The odour of wild beasts, and the smell of blood and offal, that an animal perceives when passing a menagerie or a knackery or abattoir, are also likely to frighten it and cause it to shy.

Aversion to special objects Occasionally a horse is encountered which has an absolute horror of some special, usually quite harmless, common object, e.g. pieces of white or coloured paper or rag, cock turkeys, pigs, goats, donkeys, small white inanimate objects of any nature, etc. Grey horses have been known to attack bay horses, and a brown-bay horse, light grey horses.

Vicunas, Vicugas

A member of the Family CAMELIDAE (*Vicugna vicugna*) found in South America. The ALPACA was developed from the wild vicuna about 6,000 years ago. It has very fine mainly brown hair, and as it can only be shorn every three years the fibre is very expensive. They are smaller than llamas being about 75 cm to 85 cm (about 3 ft) at the shoulder and weigh 35 kg to 65 kg (75 lb to 45 lb).

Vietnamese Pot-Bellied Pigs

(See POT-BELLIED PIGS.)

Villus
(plural, Villi)

Villus is the name given to one of the millions of minute finger-like processes which are present on the free surface of a membrane. The most common are on the surface of the small intestine. The cells can have microvilli on their surfaces. These are structures increasing the surface area for absorption and concerned in the taking up of sugars, amino acids, fatty acids, minerals, etc. Villi also occur in the SYNOVIAL MEMBRANES of joints, in the DURA MATER and the placental CHORION. (See DIGESTION, ABSORPTION AND ASSIMILATION; INTESTINES.)

Vincristine

An alkaloid CYTOTOXIC DRUG derived from the Madagascar periwinkle (*Catharanthus roseus*) and used in treating canine LYMPHOMA. It used to be called leurocristine.

Vipers

(See ADDER; SNAKE BITES; SNAKES.)

Viraemia

The presence of large amounts of infecting virus in the blood.

Viral

Relating to viruses.

Viral Haemorrhagic Disease of Rabbits

(See RABBIT HAEMORRHAGIC DISEASE.)

Viral Hepatitis in Dogs

(See CANINE VIRAL HEPATITIS.)

Viral Hepatitis of Ducklings

Viral hepatitis of ducklings is a disease which attacks ducklings under three weeks of age. There are usually no clinical signs before death except general malaise. On post-mortem examination, the liver shows enlargement and haemorrhaging. It can be prevented by vaccination at one day old.

Viral Infections of Cows' Teats

These include cowpox. Nowadays, true cowpox is (in the UK) considered to be a rare disease.

VetBooks.ir

Another infection common to man and cattle is pseudo-cowpox or milkers' nodules. The skin disease in herdsmen is indistinguishable from that in shepherds who have been handling sheep suffering from orf. It is now thought that the milkers' nodules virus very closely resembles the orf virus, but that they are two distinct entities.

Two doctors in Dorset who had seven patients with milkers' nodules found, with the aid of a veterinary colleague, that the six dairy herds in which the men worked all had some cows with pseudo-cowpox (or milkers' nodules) lesions on the teats. There are two types of this infection: one is described as benign or chronic – this lasts for months, it is painless throughout, and starts with a mild redness of the teats, followed by the formation of many scabs which get rubbed off at milking. The second, or acute, form involves pain before scabbing begins, but not afterwards. First there is reddening, then blisters which burst, then very large scabs form. So-called proud flesh is formed beneath the scabs. When these drop off, a characteristic horseshoe-shaped ring of minute scabs at the circumference is left. All this takes 7 to 10 days. What looks like a wart remains for several months.

This pseudo-cowpox differs from true cowpox in that the latter infection is associated with more pain, fewer scabs, quicker development of them and recovery within three weeks.

The virus which causes pseudo-cowpox or milkers' nodules may be identical with, or closely related to, that of bovine papular stomatitis (BPS).

Raised, roughened, brownish plaques are seen on the muzzle, and lesions on the lips and inside the mouth.

An ulcerative infection of the teats of dairy cows has been described in Scotland and many other parts of the world, and given the name BOVINE HERPES MAMMILLITIS. It is caused by a herpesvirus.

The disease is usually seen in early winter, and lasts for up to 15 weeks. It affects cows in milk and heifers are more severely affected. In severe cases it is of sudden onset, often appearing between milkings; the whole teat being swollen and very painful. Blue discoloration is common. The resultant ulcer covers most, if not all, the teat. Milking of affected animals may become difficult or impossible and suckling prevented. In a less severe form vivid red discoloration was noted.

Mastitis often follows, and some animals may have to be slaughtered. There is no specific treatment. Affected animals should be isolated and milked last.

Probably the disease is endemic in the cattle population and produces lesions only under conditions which result in devitalising of the tissues. Another possibility is that biting flies transmit the infection. (See also under FOOT-AND-MOUTH DISEASE.)

Viral Pneumonia of Cattle

(See infections listed under CALF PNEUMONIA.)

Virginiamycin

An antibiotic used as a growth promoter which may be included in livestock rations in some countries, but it is banned from use in the EU. It has an adverse effect on the normal (and beneficial) population of *Lactobacillus* spp. within the intestine. The antibiotic was imported from Australia for use in preventing LAMINITIS in horses, but a complete ban occurred from 30 September 2014.

Virino

A low-molecular-weight nucleic acid and a host-derived protein. (See SCRAPIE for a possible example.)

Virion

A mature virus; the ultimate phase in viral development.

Virology

The study of viruses.

Virulence-Blocking Agents

This is a class of antimicrobials being developed and they are unlike antibiotics. These agents do not kill bacteria but block the secretion of virulence factors. The bacteria are disarmed and these agents are showing promise in the control of *Salmonella* spp.

Virus Diarrhoea of Cattle

(See BOVINE VIRAL DIARRHOEA/MUCOSAL DISEASE.)

Viruses

These are minute entities which carry their genetic information in one type of nucleic acid. They use the energy system of the host cell for their own biosynthetic needs, and can be differentiated from bacteria by their size and by their inability to multiply except in living cells.

Most viruses produce disease in man, animals and plants. They can be transmitted from one animal to another and stimulate the production of antibodies in infected animals.

Viruses are mostly invisible under the light microscope, although some of the larger examples (e.g. the pox viruses) can be seen readily under the light microscope. Most viruses can only be visualised in the electron microscope. There is considerable variation in size. FOOT-AND-MOUTH DISEASE virus is about 25 nm in diameter, whereas AFRICAN SWINE FEVER virus is about 10 times that size. (See NANOMETRE.)

Many pathogenic viruses are capable of altering their antigenic structure, or their pathogenicity, or

both, in response to pressures put upon them by, for example, vaccination.

The classical example is provided by influenza viruses, which are able to change from harmless to extremely virulent forms very quickly within the same species.

The nomenclature and classification of viruses has in recent years undergone many changes, and further changes are likely as new viruses are discovered and new information on the properties of viruses accrues.

VetBooks.ir

Some viruses of veterinary importance

Group	*Diseases caused*	*Animals affected*
Adenoviruses	Canine viral hepatitis	Dogs
	Fox encephalitis	Foxes
	(See also KENNEL COUGH.)	
Alphaviruses	Equine encephalitis	Horses, birds, man
Aphthoviruses	Foot-and-mouth disease	Cattle, sheep, goats, pigs, deer, hedgehogs; (very rarely) man
Arboviruses	(See Togaviruses below.)	
Arenaviruses	Lymphocytic choriomeningitis	Mice, hamsters, man
	(See also LASSA FEVER.)	(Man)
Bunyaviruses	Rift Valley fever	Sheep, cattle, goats, buffaloes, camels, man
	Nairobi sheep disease	Sheep, goats
	Gumboro disease (infectious bursal disease)	Poultry
Caliciviruses	Feline calicivirus disease	Cats
	Vesicular exanthema	Pigs; (rarely) horses
Circoviruses	Anaemia	Chickens
	Dermatitis and nephrosis syndrome	Pigs
	Post-weaning multisystemic wasting syndrome	Pigs
Coronaviruses	Transmissible gastroenteritis	Pigs
	Feline infectious peritonitis	Cats
	Infectious bronchitis	Chickens
	Enteritis	Calves, foals, dogs, cats
Enteroviruses	Swine vesicular disease	Pigs; (rarely) man
	Teschen/Talfan disease	Pigs
	Duck virus hepatitis	Ducklings
	Avian encephalomyelitis	Chickens
Flaviviruses	Louping-ill	Sheep, cattle, deer, dog, man
	Wesselbron disease	Sheep, man
	Japanese B encephalitis	Horses, man, pigs, birds
	Tick-borne encephalitis	Rodents, goats, cattle, man
	Kyasanur forest disease	Monkeys, rodents, man
	Omsk haemorrhagic fever	Rodents, man
	Murray Valley encephalitis	Wild birds, children
	St Louis encephalitis	Wild birds, bats, horses, man
Herpesviruses	(See table under HERPESVIRUSES.)	Horses, cattle, pigs, dogs, cats, man
Iridoviruses	African swine fever	Pigs, African wart-hog
Lentiviruses	Maedi/visna	Sheep
	Caprine arthritis-encephalitis	Goats
Morbilliviruses	Canine distemper	Dogs, ferrets, mink
	Cattle plague (rinderpest)	Cattle, sheep, goats
Oncoviruses	Leukaemia, leukosis, cancer	Mammals, birds
Orbiviruses	Bluetongue	Cattle, sheep
	African horse sickness	Horses (but not donkeys)
Orthobunyaviruses	Schmallenberg Disease	Cattle, sheep, goats, llamas
Orthomyxoviruses	Influenza	Horses, pigs, birds
Orthopoxviruses	Cowpox	Cattle, man
Papillomaviruses	Warts/papillomas/cancer/sarcoids	Cattle, horses, dogs, man
Paramyxoviruses	Newcastle disease	Poultry, pigeons
Parainfluenza	Cattle, dogs (see KENNEL COUGH.)	

VetBooks.ir

Some viruses of veterinary importance (contd)

Parapoxviruses	Pseudo-cowpox	Cattle, man
Group	*Diseases caused*	*Animals affected*
	Orf	Sheep, cattle, goats, dogs
	Bovine papular stomatitis	Calves
Pestiviruses	Bovine virus diarrhoea	Cattle
	Border disease	Sheep
	Swine fever	Pigs
	Equine viral arteritis	Horses
Picornaviruses	(This group includes Aphthoviruses and Enteroviruses (see above) and Rhinoviruses.)	
Poxviruses	(See Orthopoxviruses and Parapoxviruses, above.)	
Reoviruses	Respiratory disease, enteritis	Calves, pigs, dogs, cats, rabbits, man
Retroviruses	(See Lentiviruses and Oncoviruses above.)	
Rhabdoviruses	Rabies (See LYSSA; DUVENHAGE; MOKOLA VIRUS; LAGOS BAT VIRUS.)	
	Vesicular stomatitis	Horses
Togaviruses	(See Alphaviruses, Flaviviruses and Pestiviruses above.)	

Anti-viral agents Since viral infections are not controllable by antibiotics, there has been a long search for other compounds which might achieve anti-viral activity. Much hope was pinned on INTERFERON, but at present its use is very limited, and research has switched to attempts to stimulate natural production of interferon, or to find drugs effective against viruses.

Aciclovir may be used for ophthalmic infections by herpesviruses. Zidurodine alleviates clinical signs in cases of feline immunodeficiency virus (FIV). However, anti-viral drugs have to be used with great care as the margin between an effective dose and the toxic one (the therapeutic index) is narrow.

Vaccines are available against a number of viral infections, e.g. equine herpesvirus, canine distemper, and feline leukaemia.

(See also ROTAVIRUS; ASTROVIRUS; ONCOGENIC; DNA; RIBONUCLEIC ACID; CANCER.)

Viruses, Plant

Some of these can, by means of DNA technology, be adapted to produce 'potentially safe and inexpensive vaccines for use against disease in animals'. AFRC research workers have, for example, produced a harmless plant virus carrying a fragment of foot-and-mouth disease virus.

Viscera

Viscera is the name given to the larger organs lying within the chest and abdominal cavities. The term 'viscus' is applied to each of these individually.

'Visceral Gout'

A disease characterised by the deposit of urates over the internal organs; it is found in birds and reptiles. (See GOUT.)

Visceral Larva Migrans

A syndrome produced in man by the larvae of *Toxocara canis*. Occasionally it is the cause of death. (See *Toxocara*.)

Viscus

Any large organ in any of the body cavities. It is often associated with those organs in the ABDOMEN. (See also VISCERA.)

Vision

Rays of light pass, in the first place, through the CORNEA, then through the AQUEOUS HUMOUR that fills the anterior chamber of the eye. The light then enters the hinder part of the eye, through the PUPIL – a round, slit-like, or elliptical opening in the IRIS, which can be automatically narrowed according to the strength of the light rays that are passing through it. Immediately behind the iris lies the crystalline LENS, a clear structure arranged in concentric layers somewhat like an onion, which by alterations in its convexity, brings the rays to a focus upon the RETINA after they pass through a second clear jelly-like humour – the VITREOUS HUMOUR. The retina is the innermost of the three coats of the eyeball, and consists of the specialised terminations of the fibres of the optic nerve. (See also EYE.)

Monocular and binocular vision In animals whose eyes are laterally placed in the head it is impossible for both eyes to look at an object directly in front of them. One eye can be focused upon an object at any one time, while the other eye sees a completely different picture. This is called 'monocular vision'. When the eyes are placed towards the front of the head so that they can both be concentrated upon an object, as in man, horse and dog, each eye sees a slightly different picture,

VetBooks.ir

but the two ranges of vision overlap. This is called 'binocular vision': each eye sees slightly 'round the corner' of the object, and a sense of depth and distance is conveyed to the higher brain centres. The two pictures are not quite superimposed, and the previous experience of the animal enables it to judge distance by this difference in superimposition. This is technically known as 'stereoscopic vision'.

A striking point in connection with the eyesight of animals is that, although many of them have their visual powers obviously very highly developed, they seldom trust their eyes in matters of emergency. The visual images alone do not convey to the mind the reality of the external world. It becomes necessary for the animal to verify its visual impression by tactile or olfactory impressions. In practically every case the fear of a harmless object may be immediately or shortly dispelled by allowing the animal to smell and examine it by touching it with the nose.

In rabbits, the eyes are set on the side of the head and focus above and at a distance in front of the face so that the animal can scan the sky and horizon, rather than the ground directly in front of it. Food is located by means of the tactile hairs ('whiskers').

In birds, the central part of the lens has a magnifying power of up to eightfold. As a result (stereoscopic) vision is very accurate, enabling birds to locate food easily. Birds, reptiles, amphibia and insects can 'see' ultraviolet light.

Visna

A meningoencephalitis of sheep caused by a lentivirus. (See MAEDI/VISNA.)

Vitamins

Vitamins are substances present in natural foods, essential for health, and which exercise an influence in nutrition out of all proportion to the amounts consumed. The concept was developed by Polish-born chemist Casimir Funk in 1912 and he named the first one B1. Several vitamins are synthesised in the animal body, some being thus available independent of the diet, but it is important to note that a vitamin synthesised in the lower part of the alimentary canal may be available to an animal only if it eats its own droppings. (Nocturnal coprophagy is a regular practice in rabbits.)

Vitamin supplements now form an essential part of farm livestock feeding.

Animals, when feeding under natural conditions, with a free choice from a wide range of food-stuffs, consume, as a rule, all the vitamins they require. But under the influence of domestication, and especially of intensive rearing, animals often have no choice in the matter and suffer from vitamin deficiencies, either because their artificial diet is too restricted, or because vitamins naturally present have been destroyed in the preparation of the food.

Vitamin A is formed from yellow carotene found in carrots, green vegetables, egg-yolk, fish roe, liver, cod-liver oil, kidney and milk.

This vitamin is necessary for the growth and general well-being of the young animal in particular. Vitamin A is also necessary for healthy skin and teeth. It is essential for maintaining the cellularity of the lymphoid organs and epithelial tissues. It maintains the mucous membranes of natural orifices in a healthy condition to inhibit the invasion of microorganisms. Deficiency reduces phagocytosis. Cats are unable to synthesise vitamin A and obtain it from fish and liver.

Too little or too much vitamin A can be harmful. In excess, it can adversely affect growth and bone development and it can interfere with the effectiveness of vitamins D and E. Deficiency in birds is seen as pustules in the oesophagus. It may be seen in juvenile terrapins, where the signs of deficiency are focal white areas in the mouth, periorbital swelling and lethargy.

Vitamin B complex, water-soluble, includes riboflavin, nicotinic acid, pantothenic acid, choline, biotin, and thiamin. (See also CHOLINE; FOLIC ACID.) Most of these are present in yeast and liver. (For nicotinic acid, see NIACIN.)

Vitamin B_1 (thiamin, aneurine) is present in the husks of cereal grains, yolk of egg, yeast and liver. A deficiency can be caused by overheating the food of pet animals, or by the enzyme present in some fish. Horse and cattle which eat bracken are affected by the thiaminase in that plant. (See BRACKEN POISONING.)

Female birds fed a vitamin B_1-deficient diet produce chicks (or poults) that are 'star-gazers' because they hold their head back between their shoulders and the beak points directly upwards. Thiaminase in the diet of certain snakes (fed on fish) results in deficiency, characterised by twitching, incoordination, apparent blindness, torticollis, spinning and cycling. It can also occur in CHELONIANS. In aquatic species thiamine can be added to the water, otherwise it has to be administered orally.

Vitamin B_2 (riboflavin) is present in milk (and is not destroyed by pasteurisation), as well as in foods mentioned under B_1.

Riboflavin is a constituent of the flavoproteins – hydrogen-transporting enzymes concerned with the animal's energy metabolism.

Biotin, formerly known as vitamin H, is another of the B group of vitamins. It is necessary for the health of skin and hoof. It is referred to below under 'Vitamin deficiencies'.

Vitamin B_3 (pantothenic acid). Necessary for skin health, and growth.

VetBooks.ir

Vitamin B_6 (pyridoxine), present in liver, yeast and cereals, is important for growth and protein metabolism.

Vitamin B_{12} is the anti-pernicious anaemia factor of importance in human medicine, and contains cobalt. It is also known as cobalamin.

Vitamin C This is ascorbic acid; it is found in the juices of most fruits and vegetables. Most animals can produce sufficient vitamin C for their own requirements, with the exception of primates, guinea pigs and the bulbul family of birds. In hot weather and other stressful situations, additional vitamin C may be needed for all animals. It is essential for maintaining leukocyte membranes and the optimal functioning of neutrophils and granulocytes. In guinea pigs the signs of deficiency include a stiffness of gait with a shuffling action, petechiation of mucous membranes, articular and costo-chondral swelling (false rickets), rough hair coat, ptyalism and poor wound healing. Ascorbic acid given parenterally may be needed before the effect of dietary correction can take effect. The use of vitamin C on poultry can reduce the effect of heat stress.

Vitamin D, or calciferol, is the anti-rachitic principle found in cod-liver oil, meat juice, cow's milk, and egg-yolk. The absence of this vitamin causes rickets. There is an intimate association between the presence of this vitamin, the action of sunlight or the artificial irradiation by ultra-violet rays, and the mineral balance in the body. The active form is 1, 25 dihydroxy Vitamin D (or 1, 25 dihydroxy cholecalciferol).

With its help, salts of calcium and phosphorus, instead of being eliminated from the intestinal canal, are absorbed into the system and made use of in the calcification of bone. (See COD-LIVER OIL.) It has been found to control and reduce the severity of bovine MASTITIS. Vitamin D levels are often low in humans and cats with TUBERCULOSIS. Too much vitamin D is harmful. (See RODENTS - RODENTICIDES.)

Vitamin E (tocopherol) (fat-soluble). This vitamin is found in red meat, oil of seeds, milk and egg-yolk. It is necessary for fertility, and its absence from a diet has been shown to cause sterility in rats by inducing firstly the death, and later the absorption, of the embryos.

Vitamin K complex – mostly fat-soluble vitamins concerned with the formation of PROTHROMBIN, and hence regarded as 'the anti-internal-haemorrhage factor'. Present in alfalfa. Synthetic preparations are available for therapy.

Vitamin excess (hypervitaminosis) may result in serious disease. (For an example, chronic hypervitaminosis A occurs in cats fed almost exclusively on liver.)

An excess of yeast, fed to pigs as a vitamin B supplement, has resulted in severe rickets.

Vitamin deficiencies These may occur as the result of a vitamin-deficient diet, or a failure – in some instances – to synthesise a particular vitamin within the body. 'Secondary' or 'conditioned' deficiencies may also arise from any disease which impairs absorption from the alimentary tract, injuries to the liver, infections (which increase the consumption of vitamins), metallic poisoning, and as the result of some enzyme which destroys or inactivates a vitamin. (For examples of the last-mentioned cause, see 'CHASTEK PARALYSIS'.)

Biotin-producing bacteria live in intestines and contribute a variable amount. But biotin deficiency is not rare – except in adult ruminants. Signs of deficiency are: dermatitis on ears, neck, shoulder and tail of the pig, together with cracking of the walls and sole of the hoof; retarded growth and brittle feathering, foot dermatitis, swollen eyelids, eruptions on mouth and beak, perosis, leg weakness, poor hatchability and embryonic malformations in birds.

A report from Finland stated that bleeding from the navel, which was a serious problem in a breeding herd of 85 Finnish Landrace and 85 Large White sows, could be successfully controlled by vitamin C (not vitamin K as might have been expected). An ascorbic acid supplement was given to the sows for from eight to two days before farrowing. Piglets from the treated sows were also 5.5 per cent heavier than those from untreated controls at three weeks of age.

Vitamin E (tocopherol) could with advantage be added to all compound feeds as a precautionary measure, particularly if the feed contains polyunsaturated fatty acids. Less vitamin E is absorbed from the intestine if the latter are present. Some feeds contain vitamin E antagonists – present in lucerne and beans. The activity of vitamin E may be reduced by a high nitrate content in feed or drinking water. Animals which do not receive an adequate supply of the trace element selenium need extra vitamin E, because selenium has a vitamin E sparing effect. Application of fertilisers rich in sulphates inhibits the absorption of selenium by plants from the soil, and in these circumstances grazing animals will require extra vitamin E.

Vitamin E contents of feeds as well as crops may be reduced to a dangerous level on storage. (See also Muscular dystrophy under MUSCLES, DISEASES OF.) Anti-vitamin E factor may be present in barley as well as fats of animal origin.

Despite a current tendency to increase vitamin levels in animal feeds, cases of vitamin E deficiency appear to be becoming more prevalent in all classes

VetBooks.ir

of farm livestock, resulting in mulberry heart in pigs, muscular dystrophy in calves, and 'crazy chick' disease in poultry. Perhaps this has something to do with the faster growth-rates expected of animals nowadays. Certainly the low vitamin E content of some cereals is important. This is especially the case with some samples of barley grown on selenium-deficient soil but fed on a farm where selenium is no problem, and where the possibility of such a deficiency might well be overlooked.

It is generally accepted that the daily requirement of vitamin E is, for cows, 1 g; for calves, 150 mg; for ewes, 7 mg; and for lambs, 25 mg.

Vitamin E deficiency leads to white muscle disease or muscular dystrophy; and a supplement of this vitamin has been shown to reduce the incidence of retained placenta, metritis, and ovarian cysts when given with SELENIUM.

Horses Vitamin A deficiency is unlikely to occur except in town horses denied adequate green food. Deficiency signs are stated to include night-blindness, hoof lesions, corneal lesions, respiratory signs, and reproductive difficulties. Some of the B vitamins are synthesised by adult horses, but backward foals may benefit from vitamin supplements. Infertility in the mare may sometimes be associated with a vitamin C deficiency. It has been suggested that splints, sidebones, ringbones and spavins may be associated with a vitamin D deficiency.

Cattle Vitamin A deficiency in cattle denied adequate green food leads to abortion or the birth of weak, blind calves, or of those suffering from diarrhoea which die within a few days. Corneal lesions and blindness may also result in growing cattle. For example, Hereford bulls on a diet of beet-pulp nuts, high-protein nuts and barley straw went blind owing to a lack of vitamin A. (See also HYPERKERATOSIS.) Vitamins of the B complex are mostly synthesised in the rumen, but in the newborn calf a deficiency may occur. (See THIAMIN.) Vitamin C is apparently synthesised by adult cattle, but some cases of infertility may, it is believed, be due to a deficiency, and some cases of navel-ill benefit, it is said, from vitamin C treatment. In some parts of Britain pasture or fodder crops contain too little vitamin D, while sunlight during the winter months is insufficient to enable the shortage to be made good within the animal's body; the result is rickets. Vitamin E deficiency is associated with muscular dystrophy.

Pigs Vitamin A deficiency results in failure to grow in piglets and infertility in adult pigs, as well as paralysis of the hindquarters. A nicotinic acid deficiency gives rise to a condition simulating necrotic enteritis and poor growth. Yeast supplements will correct deficiencies of the B complex, but excess may result in rickets.

A vitamin E deficiency in newborn piglets can result in their sudden death after being given iron injections to prevent anaemia. It is advisable to delay the injection until the piglet is a week old, when it is more tolerant of iron. Gilts' rations low in vitamin E or high in fatty acid predispose to this condition in the offspring.

Biotin deficiency in pigs gives rise to signs which include dermatitis. Lameness can affect a whole herd where there is a biotin deficiency causing cracks in the sole or wall of the hooves.

Dog and cat Vitamin A has been used with success in the treatment of diarrhoea in kittens. Corneal lesions, even blindness in extreme cases, and sometimes deafness, have also been attributed to a vitamin A deficiency. Vitamin B (thiamin) deficiency results in fatigue and loss of appetite, and may be associated with cramp. Yeast may prove effective in cases of depraved appetite and chorea. 'Black tongue' in the dog and an ulcerative stomatitis in the dog are seen in the USA in naturally occurring cases of nicotinic acid deficiency. Lack of riboflavin is associated with eye lesions and skin disease. Rickets results from lack of vitamin D, especially in the larger breeds, but overdosage is harmful and can lead to deposits of calcium salts in or between muscles.

Poultry Vitamin A deficiency will occur only in birds deprived of adequate green food. Maize and cod-liver oil (which must not be rancid) are alternative sources of this vitamin. Lack of it leads, in chickens, to drowsiness, weakness, staggering, stunted growth, and often a discharge from the eyes and nostrils. The presence of pustular lesions in the oesophagus is diagnostic. Adult birds become dishevelled looking, weak and emaciated, and show a watery or cheesy discharge from eyes and nostrils. Deficiency of riboflavin (vitamin B_2) in the diet is not uncommon, particularly in wire-floor battery brooders, in which the chicks have no access to droppings. (On solid floors chicks may correct the deficiency by eating their droppings, which contain riboflavin synthesised by organisms in the lower part of the gut, but not otherwise available to the body.) Signs are leg weakness and a curling inwards of the toes in chicks; also decreased egg production and poor hatchability. (See also biotin under 'Vitamin B', above.) Thin shells, reduced hatchability, and sometimes a temporary paralysis after laying, are indications of a vitamin D deficiency. Chicks are unthrifty, walk with difficulty, and later show typical signs of RICKETS. Bone deformity and softening of the beak occur in adult birds. Sunlight, green food, and the judicious

use in winter of cod-liver oil overcome this deficiency. Vitamin E, necessary for hatchability, is present in whole grain and, to a lesser extent, in greenstuff. The latter also contains ample vitamin K, a deficiency of which leads to anaemia as a result of internal haemorrhage.

Vitellogenesis
The formation of a yolk. The term may be used to indicate PRE-OVULATORY OVARIAN STRESS (POOS) or EGG-BOUND in the ovary, seen in captive lizards and chelonians. The animals appear to be overweight and are inappetant and lethargic. Radiography will often reveal the presence of very many (often even 100) ova or yolks in the ovaries. Blood samples will reveal elevated calcium, lipids, albumin and AST levels. Treatment is by OVARIECTOMY and support of the liver, which has usually undergone extensive fatty change.

Vitreous Humour
The viscid, jelly-like, tenacious fluid found in the eyeball behind the lens.

VMD
(See VETERINARY MEDICINES DIRECTORATE.)

VMP
Veterinary Medicinal Product.

Vocal Cords
These are found within the LARYNX and are used to create a variety of sounds. There are two pairs present and consist of MUCOUS MEMBRANE folds which vibrate as air passes across them. The upper pair are the false vocal cords and the lower pair are the true vocal cords.

Vocalisation
Making sounds, noises, often as part of communication.

Voice
Voice is the sound produced as the result of the vibration of a column of air forced through the larynx in mammals (or SYRINX in birds) by contraction of the respiratory muscles. The means by which this is produced are analogous to those by which sound is produced in a reed instrument, except that in the living animal the pitch of the voice can be altered at will. This is accomplished by the amount of tension exerted by muscular action upon the vocal cords; the more tense these are the higher is the pitch of the voice. In the majority of mammals the vibrations are produced when a blast of air is expelled from the chest, but in the donkey the higher notes of the bray result from inspiration of air, and the lower notes from expiration.

The character of the voice can be altered to some extent by changes in the resonating chambers of the nose, mouth, pharynx, etc.; thus, the false nostrils of the horse are used to produce the snort of fear or excitement, the nasal cavities transmit the whinny and neigh of pleasure, and the mouth and pharynx furnish the character of the neigh of impatience, loneliness and, sometimes, the challenge of anger of the jealous stallion.

Neighing or whinnying in the horse is an expiratory act produced partly through the mouth and partly through the nose; the bray of the ass is expiratory for the low notes and inspiratory for the high; bellowing in the ox, bleating in the sheep, barking in the dog and the mew of the cat are all produced by expiratory efforts.

Animals use their voices upon widely different occasions. It seems probable that they make the greatest use of this faculty for the purposes of enabling the young to recognise their dams from a distance, and to maintain cohesion of herds or flocks. Stragglers getting left behind, or separated from their special companions, can be heard calling for long distances. Male animals of many species will give a warning upon the approach of newcomers or danger. Females may produce little cries or screams when attended by males during periods of oestrus, or when bonding with their newly born progeny. Almost all the domestic animals emit cries when suffering pain. In the horse tribe the sounds are often merely grunts or groans, especially when the pain is abdominal. In other cases horses will scream when they are suddenly subjected to acute pain, or to very great fright. Cattle and sheep in agony behave similarly to horses; they usually groan, but cows, ewes, and heifers may issue a long drawn-out bellow or bleat during difficult parturition. The pig has a range of notes from the satisfied grunt of suckling a sow, to the frightened squeals and screams of those that are being handled by man. The dog has a note for all occasions, expressing all the emotions of which he is capable by differences in his bark. (See also LARYNX and MUTING OF DOGS.)

In RABIES the character of the voice may be changed. In the 'dumb' form, barking is suppressed.

Voice Box
(See LARYNX.)

Volar
Refers to the back of the fore-limb.

Volatile Fatty Acids
Short chain water-soluble fatty acids such as ACETIC ACID, BUTYRIC ACID and PROPIONIC ACID. They are some of the products of carbohydrate digestion in ruminates.

Volcanic Gases
Typically these comprise water vapour, carbon dioxide, sulphur dioxide, hydrogen sulphide, hydrochloric acid, hydrogen fluoride, and carbon monoxide.

Volvulus
An intestinal obstruction is produced by the twisting of a loop of bowel round itself. It is usually due to some spasmodic contraction of the muscular coat, or to the presence of gas, and is very dangerous owing to the great risk of strangulation of the blood supply and consequent necrosis. Excessive gas formation in the caecum and colon of whey-fed pigs may lead to volvulus. (See HAEMORRHAGIC GASTROENTERITIS OF PIGS and INTESTINES, DISEASES OF.)

Vomeronasal Organ
(See JACOBSON'S ORGAN.)

Vomica
A cavity in the lung tissue produced by disease. Vomicae are most commonly met with in cattle suffering from either tuberculosis or contagious pleuro-pneumonia.

Vomiting
Vomiting involves not merely a contraction of the stomach walls and a dilatation of the gullet, but is a complex act in which the abdominal muscles, the diaphragm, the muscles of the chest and larynx, and those of the lower part of the neck all play a part.

Before the act there is usually a profuse secretion of watery saliva which serves to lubricate the passage of the stomach contents. The animal appears uneasy, and will usually seek a secluded spot. Soon rhythmic contractions of the abdominal muscles commence and culminate in the ejection of a quantity of frothy material. The diaphragm is generally fixed, and there is a powerful closing of the glottis to prevent any fluids from gaining access into the trachea.

The dog and cat vomit with relative ease. They are able to induce vomiting by eating portions of the green shoots of couch grass (*Triticum repens*), ingestion of which brings on vomiting within 5 to 10 minutes. In the pig, the process is more exacting than in the carnivores. Cattle and sheep may vomit occasionally, but it is not common and may be related to a serious stomach disorder or to rhododendron poisoning. Vomiting in the horse is rare, and often is associated with a rupture of the stomach; when it occurs it should be considered a very grave sign indeed. The material always escapes through the nostrils in the horse. In rabbits, vomiting is impossible in this species being prevented by a valve at the junction of the oesophagus and the stomach.

Causes Vomiting includes:
Travel sickness.
Stress.
Simple indigestion. In dogs, cats and other carnivores, when the stomach has received either a quality or a quantity of foodstuff with which it is unable to deal, the process of digestion does not proceed, or only proceeds up to a point. The material brought up is recognisable as food, but it is mixed with quantities of frothy mucus, water, and perhaps may be stained brownish from bile. It has a faintly sour smell which is greater the longer the process of digestion has been enabled to proceed. The ejecta is generally easily brought up, and the animal soon settles down and becomes normal.

Indigestion from foreign bodies. (See 'CHOKING'; IMPACTION; FOREIGN BODY.)

Gastritis. When the walls of the stomach are inflamed and thickened, the mucous membrane is swollen and painful, and the nervous system is in an irritable state. Whenever food or water enters the organ, vomiting immediately takes place. The VOMITUS consists of the solid material swallowed, coated on the outside with mucus and froth. If liquids have been taken they are returned almost unchanged. When the inflammatory condition is very severe there are quantities of blood that have undergone partial digestion and have an appearance not unlike coffee-grounds, seen in the vomit. In such animals there will be a very offensive smell both from the ejecta and from the mouth of the patient.

Pyloric stenosis, which may be congenital in dogs, is said to give rise to projectile vomiting.

Enteritis is associated with vomiting but there is diarrhoea as well.

Impaction of the rectum, whether from particles of undigested bone, or hair, hard faeces, etc., generally induces vomiting in which not only does the stomach expel its contents, but masses of bowel content as well.

Acute nephritis is an extremely common cause of thirst and vomiting in the dog.

Pyometra in the bitch, cat and sow is frequently accompanied by vomiting.

Accidents. The shock of a severe burn or accident will cause vomiting, although the injuries have not been inflicted upon the stomach itself. In other cases, where the head has been injured, the area in the case of the brain which control the act of vomiting becomes disturbed and the animal evacuates its stomach.

Poisons. Many irritant substances will produce vomiting. Of the commonest may be mentioned tartar emetic, mustard, salt, carbolic acid, arecanut, castor oil, etc.; and of substances less common, but more drastic, the following are examples: strychnine, arsenic, phosphorus, apomorphine, croton oil, ibuprofen, zinc and copper sulphates, and many of the metallic salts. Some of these have special characteristics; for example, phosphorus vomit is luminous in the dark.

VetBooks.ir

Diseases. The sign of vomiting is common to many other diseases – meningitis, peritonitis, nephritis, leptospirosis, rabies, vomiting and wasting syndrome in pigs, etc.

Treatment In the dog and cat the use of normal saline by injection is frequently indicated as an alternative to oral administration during an illness (such as nephritis, uraemia, and enteritis) in which vomiting is persistent.

Vomiting and Wasting Syndrome
This occurs in piglets five days old and upwards, and is characterised by vomiting, depression, loss of appetite, constipation, emaciation and a hairy appearance. It is caused by a coronavirus, haemagglutinating encephalomyelitis virus (HEV). (See also 'ONTARIO ENCEPHALITIS'.)

Vomitus
The material expelled by the action of vomiting.

Von Perthes Disease
(See LEGG-CALVÉ-PERTHES DISEASE.)

Von Willebrand's Disease
An inherited bleeding disorder found in some 25 breeds of dogs including CORGIS (Pembroke), DOBERMANN PINSCHERS, GERMAN SHEPHERD DOGS, GERMAN SHORT-HAIRED POINTERS, GERMAN WIRE-HAIRED POINTERS, KOOIKERHONDJE DOGS, MINIATURE SCHNAUZERS, PAPILLONS, SCOTTISH TERRIERS, SHETLAND SHEEPDOGS (DNA tests available), and associated with an autosomal trait causing a high morbidity but a low mortality. Signs may include epistaxis, haematuria, lameness, bleeding from genital mucosa, and prolonged bleeding from cut nails, etc.

VPIS
(See VETERINARY POISONS INFORMATION SERVICE.)

VS
1. Abbreviation of VESICULAR STOMATITIS.
2. Abbreviation of Veterinary Surgeon.

VT
(See VEROTOXIN.)

Vulpine
Of, related to or characteristic of foxes.

Vultures
Ingestion of livestock treated with DICLOFENAC resulted in very high mortalities in the Indian subcontinent due to KIDNEY toxicity. (See TROPICS, LIVESTOCK PRODUCTION IN THE; CARCASES, DISPOSAL OF.)

Vulva
It domesticated animals it has only simple, single labia or lips.

Diseases of the vulva In Kenya, squamous cell carcinoma of the vulva is common in cattle of the AYRSHIRE CATTLE breed. Cryosurgery has given good results when treatment has not been delayed until the tumour becomes too large. In 62 cases, 55 were successfully treated.

(For persistent bleeding from the vulva, see VAGINA.)

In the tropics, especially, a thick purulent discharge from the vagina may be a sign of tuberculosis involving the uterus/vagina.

Vulvovaginitis
(See under RHINOTRACHEITIS, INFECTIOUS BOVINE and VULVOVAGINITIS, GRANULAR.)

Vulvovaginitis, Granular
A venereal disease of cattle caused by *Mycoplasma bovigenitalium* and Ureaplasmas, affecting vulva and vagina or seminal vesicles and skin of the penis. The lesions are nodules.

VetBooks.ir

W

W
Abbreviation for TRYPTOPHAN.

Wakefulness
A daily recurring state of the brain. It results in the state of consciousness in animals and man. This is seen as coherent cognitive and behavioural responses to the external world including movement, communication, food ingestion and reproducing. The opposite state is being asleep, when most inputs to the brain are excluded.

'Walkabout Disease'
(See KIMBERLEY HORSE DISEASE.)

'Walking Dandruff'
An infection of the skin with *Cheyletiella* mites in dogs and cats. (See MITES, PARASITIC - OTHER MITES - CHEYLETIELLA.)

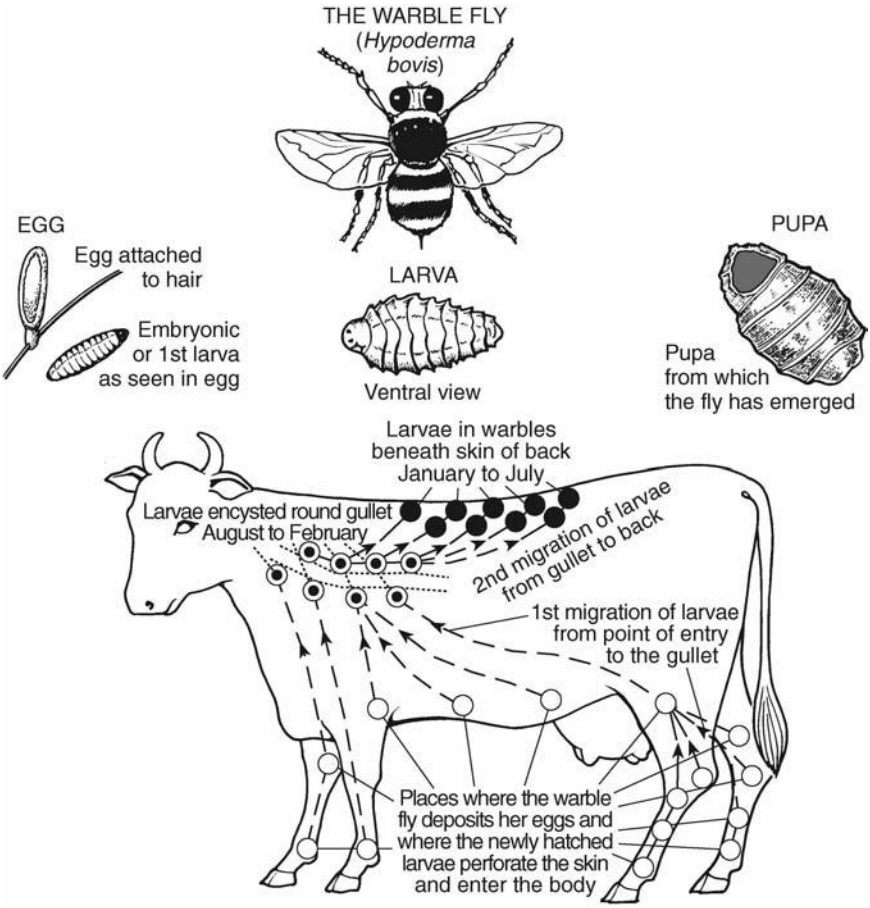
Wallabies
Smaller than kangaroos, these native Australian marsupials are a source of human HYDATID DISEASE in the southern tablelands of New South Wales. Lumpy jaw is a common finding. They may sometimes be found as feral animals in parts of England.

Wall Eye, Leukoma
Wall eye (leukoma) is a condition in which the brown pigment of the iris is lacking, giving the iris a steely blue appearance. In dogs, it is usually unilateral and is not a problem. In the horse, wall eyes may occur when the greater part of the face, or that portion around the eyes, is white. The pupil of the eye appears to be encircled by a ring of bluish or greyish white, and the expression of the horse's face is consequently unusual. It is not a serious defect except in tropical countries. (See also BLUE EYES.)

Walpole's Buffer Irrigation Solution
An aqueous solution of glacial acetic acid and sodium acetate used to alleviate urethral obstruction in male cats only. It is introduced via a catheter to relieve the obstruction and then to add to the bladder.

Warble Fly Order
The Warble Fly Order came into force in 1989. The presence of warble fly lesions in cattle is a NOTIFIABLE DISEASE in Britain. Where a blood test indicates that an infestation may be present, treatment under the supervision of an officer of the State Veterinary Service is required. Every herd and every bovine animal within 3 km of an infestation must be treated (the fly is able to travel only short distances). As warble flies are present in other countries, all cattle imported into Britain must be treated for possible infestation within 24 hours of arrival. The treatment must be supervised by a State Veterinary Service officer.

Warbles
Warbles are swellings about the size of a marble or small walnut occurring upon the backs of cattle in spring and early summer, caused by the presence in them of the larvae of one of the warble flies – *Hypoderma bovis* or *H. lineatum*. These are of very great economic importance. The adults – especially *H. bovis* – cause great annoyance to stock during the period when eggs are being laid. Not only does this result in injuries, animals rushing around ('gadding') to avoid the attacks, but the milk yield is reduced, sometimes by as much as 25 per cent, and condition is impaired.



H. lineatum in its migration through the body irritates the gullet; and both species may injure the spinal cord. The warbles on the back are really so many small abscesses which not only reduce condition very considerably but may, when many are present, result in the death of young animals. The accidental crushing of a number of the larvae in these cavities may cause the death of the animal from anaphylactic shock.

In the carcases there is considerable destruction of valuable meat around the warbles; 'butcher's jelly' or 'LICKED BEEF' is an oedematous, straw-coloured, jelly-like substance, which infiltrates the tissue near the larvae. The holes which the larvae produce in the hides reduce their value; heavily infected hides are often useless for leather.

Warbles are most common in young animals, in which loss of condition is most serious; but they have been found in small numbers in animals up to 15 years old. They are sometimes found in young horses. The larvae occasionally enter the spinal canal and produce very serious lesions. Horses are attacked mostly by *H. bovis* larvae, which affect the area of the saddle chiefly; but brain involvement has been reported in the horse.

Methods of control Satisfactory control depends upon artificial interference with the life-cycle. (See IVERMECTIN.) A systemic insecticide will kill a high percentage of larvae before they complete their migration and penetrate the back.

In Britain in 1978, 40 per cent of cattle in England and Wales, and 20 per cent in Scotland, were affected with warbles. (See FLIES – Fly

The life-cycle of the warble fly.

Dressing against warbles.

VetBooks.ir

control measures.) In that year, a compulsory eradication campaign was introduced in UK. Following the introduction of the Warble Fly Order 1985, infestation by warbles was virtually eradicated by 1995. It is a NOTIFIABLE DISEASE.

Autumn is the more effective time for treatment, even though infestation cannot be visually detected then, and cattle-owners in warble-affected areas are advised to treat their herds accordingly.

Pour-on warblecide compounds include PHOSMET and IVERMECTIN. Parenteral preparations of ABAMECTIN, DORAMECTIN and MOXIDECTIN are also effective.

Deer The main deer warble fly, seen in red deer, is *Hypoderma diana*.

Reindeer In Canada they are attacked by the warble fly *Edo Ede magana tarandi*. IVERMECTIN has been used for control.

Goats IVERMECTIN has been used also against the goat warble *Przhevalskiana silenus*.

The tropical warble fly of Central America is *Dermatobia hominis*, which lays its eggs on an intermediary vector – fly or mosquito – which it catches for the purpose. (See also under FLIES, and IVERMECTIN.)

Warfarin

An anticoagulant drug used in human medicine; its veterinary use is mainly as a rat poison. It causes death of rats and mice from internal haemorrhage. In the strengths used, 0.005 per cent and 0.025 per cent, it is considered that properly prepared baits will not prove dangerous to livestock if used with ordinary care. Cases of accidental poisoning have occurred, however, in domestic animals; and food contaminated by rodents' urine may be dangerous where warfarin is used.

Therapeutically, warfarin is used in the treatment of NAVICULAR DISEASE.

Treatment of warfarin poisoning Vitamin K_1 (phytomenadione) by intramuscular injection. Blood transfusion may be necessary.

Once signs have appeared, use of glucose saline, or blood transfusion, is indicated. The poisoned animal must be handled very gently, or further internal bleeding may occur. (See also NAVICULAR DISEASE.)

Warm Blood Horses

These large riding horses originate from Mainland Europe and they usually take on the name of the country of origin, i.e. Dutch Warmblood, Belgium Warmblood, etc. They are normally bay in colour with clean (non-feathered) legs. They are valued as dressage horses.

Warts, Papillomas

Warts (papillomas) are small growths which appear on skin or mucous membrane, and occur in all farm and domestic animals. Papillomas are benign, but an individual wart can become malignant, especially through the action of activating factors such as that found in bracken, resulting in UPPER ALIMENTARY SQUAMOUS CELL CARCINOMA and BLADDER CANCER in suckler cattle. (See PAPILLOMA.) Warts may be congenital or acquired. They are viral in origin and tend to be SPECIES-SPECIFIC and to be most common in young animals. Trauma is important in spread, as is abrasion from inanimate objects such as bars, barriers and barbed wire.

Warts occur in connection with the eyelids comparatively frequently in horses, cattle, and dogs; sometimes they become malignant, spreading rapidly and causing interference with sight or eyelid movements. Owing to the malformation that they may cause when numerous, warts should always be removed (except possibly in horses) before they attain a large size or before they have time to spread.

Around the mouth they may interfere with feeding, and when occurring about the nostrils they may obstruct the breathing. Soft warts in the oesophagus sometimes make swallowing difficult, and upon the penis or in the urethra they may hinder the passage of urine. (See also EYE.)

Horses The commonest situations are the skin of the udder or sheath, the lips and nostrils, the eyelids, outer and inner skin of the ears, the region of the breast, and the insides of the limbs.

Cattle The commonest seats of warts are the teats of cows. Young cows in winter are frequently affected about the skin of the eyelids and along the lower line of the abdomen, but the growths often drop off spontaneously from these positions when the young animals are turned out to grass in the early spring. Otherwise warty growths are found as in the horse.

Dogs and cats In the dog especially, less so in the cat, warts are common. Single small warts with a cauliflower-like extremity or with a rounded top are commonly found about the eyelids, lips, ears, paws, etc., as well as upon the general surface of the body. They usually grow very slowly and may be present for years without causing any pain or inconvenience. In other cases warts appear in connection with the gums, tongue and insides of the cheeks; in these positions they arise in clusters and grow very rapidly. Cases such as these are

usually accompanied by a great amount of salivation and a fetid discharge from the mouth.

Removal Of Warts Multiple warts in cattle have been treated by a variety of chemicals, including injections of lithium antimony tartrate, with varying degrees of success. Autogenous and other vaccines have also been used where there is a herd problem, and surgical removal may be resorted to. Removal should not be attempted in horses as they will self-cure if under six years of age. If seen in older horses the diagnosis must be questioned. (For warts in other species see PAPILLOMATOSIS)

Washing of Animals

(See BATHS.)

Washing Soda

Sodium carbonate (Na_2CO_3) is the sodium salt of carbonic acid and is used as an alkalising agent. It is also used as a water softener. Crystalline washing soda, placed over the back of the tongue, can be used in an emergency as an EMETIC (to elicit vomiting in animals), but is not recommended for routine use.

Wasp Stings

(See under BITES, STINGS AND POISONED WOUNDS.)

Waste (England and Wales) Regulations 2011

(See HANDLING VETERINARY WASTE.)

Waste Food

(See BAKERY WASTE; SWILL; CHOCOLATE POISONING.)

Wasting

(See ATROPHY.)

Water, Loss of

Loss of water from the tissues – a serious condition – is referred to under DEHYDRATION. It occurs especially during the course of diarrhoea.

Water and Watering of Animals

Amounts required The quantity of water needed per day by the various domestic animals depends upon the nature of the food, the climate, the temperature, and the size and the activity of the animals themselves. When very dry food is given, such as hay, bran, oats, etc., more water is required than when roots or growing grass is eaten.

Drinking water should be freely available to animals, so that they can drink as and when they choose. (See below under 'Water supply') Stress may occur in an animal deprived of the chance to drink sufficient water, and actual dehydration (which can lead to death) may be caused. Production of milk, etc., will obviously be adversely affected.

With an *ad lib* water supply, the amount of water required by various animals under various conditions is of mainly theoretical interest, apart from practical aspects of planning adequate supplies of piped water, trough space, etc. Water requirement figures can be taken only as approximate guidelines, and authorities differ to some extent.

Cattle Dry cows of the larger breeds require between 36.5 45 litres (8 to 10 gallons) per day. Those in milk need in addition about five times as much water as the volume of milk produced, while for the last four months of pregnancy, the daily consumption may rise to about 70 litres (approximately 15 gallons).

As the air temperature increases above 10° C (50° F), the water requirement rises rapidly.

Calves require much more water after they are weaned than before. A common mistake is to ignore this fact, with the result that the calves receive a check to their growth from which they may never fully recover.

Pigs are highly susceptible to water deprivation. (See SALT POISONING.) Approximate quantities required have been suggested to be 1.1 litres to 3.5 litres/day for a weaned pig, 3 litres to 4 litres/day for a 30 kg piglet, 6 litres to 8 litres/day for a 70 kg pig, 5 litres to 10 litres for a breeding gilt, 12 litres to 20 litres/day for a gestating sow and 25 litres to 40 litres/day (or more) for a lactating sow. The benefits of creep feeding may be lost if the piglets are denied water.

Quality of water This is obviously of prime importance. Animals may suffer thirst and stress if the only drinking water available to them is disagreeable in taste. Where piped water is not available, and rainwater has to be stored in tanks, it is important to clean out gutters and the tanks themselves. Galvanised iron tanks should not be allowed to get rusty. Well-water may contain an excess of one or more minerals which may make it unpalatable or be harmful to the animal, so that sampling and analysis should be carried out.

Poisoning by water may result from the use of lead pipes or tanks. (See LEAD POISONING) The use of lead paints in storage tanks is also a danger. (See also ZINC POISONING) Stored rainwater containing decaying organic matter (leaves, bird droppings, etc.) has led to the death of pigs from nitrite poisoning.

VetBooks.ir

Diseases spread by water Apart from illness caused by some inorganic substance dissolved in the water, such as lead from lead pipes or tanks, or arsenic from contamination with sheep-dip, water-borne infection may cause disease.

Among diseases that can be distributed in this manner are the following: anthrax, from water used in tanneries or wool-washing premises, or when a carcase has been buried near a stream; Johne's disease, salmonellosis and coccidiosis in cattle, from contamination of streams, ditches and ponds. Liver fluke can be spread via infected mud snails, *Lymnaea truncatula*. *Leptospira hardjo* infection is eight times more likely where cattle have access to a water course.

Washing water and water-tanks have been contaminated with, for example, *Bacillus subtilis*, leading to MASTITIS.

Water supply A good stockman will ensure that the animals in his care are never short of water; that all automatic drinking bowls or nipple drinkers are in working order; that frost has not cut off the supply of piped water (lagging of exposed pipes is obviously necessary in winter); and that the water has not been allowed to freeze in troughs, tanks, etc. It is also necessary to ensure that the levers of automatic drinking bowls are not too stiff for young animals to operate, and that young stock are shown working nipple drinkers – not left to find them for themselves. (See also ALGAE.)

In one incident, newly weaned pigs were put into a yard having automatic water-bowls fitted, but as the yard had been mucked out the bowls were out of reach of the young pigs.

Pigs deprived of water show nervous signs. They may walk in circles, or backwards, press their heads against a wall, champ their jaws, collapse and have convulsions. Of course, some pigs may be found dead without signs having been observed.

Sheep have shown signs suggestive of twin-lamb disease, and died, after being removed from a field where they had access to a stream and placed on pasture where the ball-valve of a drinking trough had been tied up. Sheep prefer to drink running water, and those of some breeds are so reluctant to drink anything else that, when housed, a running water supply must be arranged indoors.

A drop in milk yield may occur in dairy herds where the cows are moved periodically to a field too far from a water-trough; or where the water pressure is too low to ensure adequate supply.

Dogs, cats, and poultry should always be allowed an unlimited supply of water so arranged that they are unable to foul or upset the drinking vessels.

(See also DEHYDRATION.)

Designed for field use, this CemFil glass fibre-reinforced cement drinking trough is obtainable in sizes of up to 2000-litre capacity. The water supply is, of course, piped.

Horses Wherever possible, **water should be given before the food**, or not for one to two hours after feeding. The horse's stomach is small, and cannot contain a full feed and several litres/gallons of water simultaneously. Water in excess of requirements should be offered when horses are at rest, and they should be allowed to drink frequently when working.

Poultry When nipple drinkers are introduced the water pressure needs to gradually increase. Too high water pressure results in wet litter and can lead to respiratory diseases, BREAST BLISTERS and PODODERMATITIS IN POULTRY.

Water intoxication This may occur in farm livestock when, as a result of bad management, they have been deprived of adequate drinking water and then suddenly find themselves in circumstances which enable them to drink as much as they want.

One sign may be a red discoloration of the urine. Convulsions, recumbency, hyperaesthesia, aimless wandering and death have been seen in calves.

'Waterbag'

This is the common name given to the AMNION, which is a thick opaque sac containing the amniotic fluid, and it is the first membrane to appear in normal parturition. (See PARTURITION.)

Water Buffaloes

Water buffaloes (*Bos bubalis*) are regarded by many as an under-utilised form of livestock. It is common practice in the tropics to immerse them in water during the heat of the day as they have very few sweat glands and are prone to heatstroke. However, they can be reared away from water if

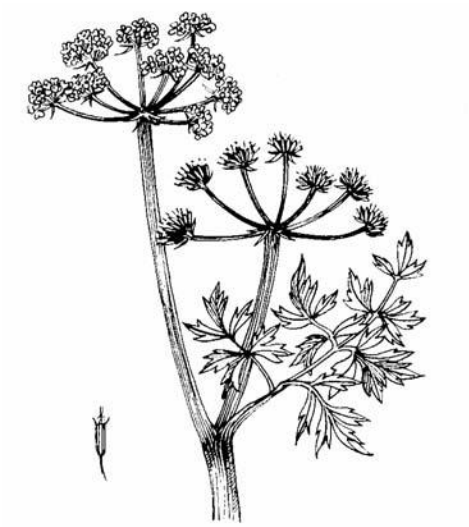
shade is available. They are widely used as a draught animal in warmer countries, including the poorer parts of Italy. They are farmed in Britain to produce mozzarella cheese. Studies in the USA, Papua New Guinea, Trinidad and Australia have shown water buffalo perform well as regards growth rates, health and production of meat and milk. They are able to digest rougher material than cattle or sheep.

Water buffalo meat is similar in taste to beef; the milk is richer in butterfat and solids-not-fat than cows' milk. There is a general low incidence of mastitis, probably because on ceasing milking, the teat canal closes very rapidly. Water buffalo are generally quite docile unless severely stressed or in pain.

Some of the steps needed to permit greater exploitation of this valuable animal are:

1. Trials to compare growth rate, feeding, nutrition and other characteristics of water buffalo with those of cattle.
2. Selective breeding and protection of outstanding buffalo specimens, especially in Southeast Asia.
3. Replacement of the 1,500-year-old inefficient wooden yoke (in rural Asia, where the water buffalo is the small farmer's 'tractor', improved harnesses could increase pulling power by up to 25 per cent).

The limitation of water buffaloes must be taken into account. For instance, the animals suffer if forced to remain, even for a few hours, in direct sunlight. They cannot be worked for long periods during the heat of the day, and they are also susceptible to extreme cold. (*The Water Buffalo: New Prospects for an Underutilized Animal,* US National Academy of Sciences).



HAEMORRHAGIC SEPTICAEMIA caused by *Pasteurella multocida* is one of the most economically important diseases of buffaloes in Asia and America. An important roundworm of the water buffalo (*Bubalus bubalis*) is *Paracooperia nodulosa*. This causes development of nodules in the intestine, and diarrhoea, anaemia, emaciation and sometimes death. (See LIVESTOCK PRODUCTION.)

Watercress, *Nasturtium officinale*

This is included in a herbal preparation for the relief of arthritis, skin and kidney disorders in dogs and cats. It is a rich source of beta-carotene and vitamin E.

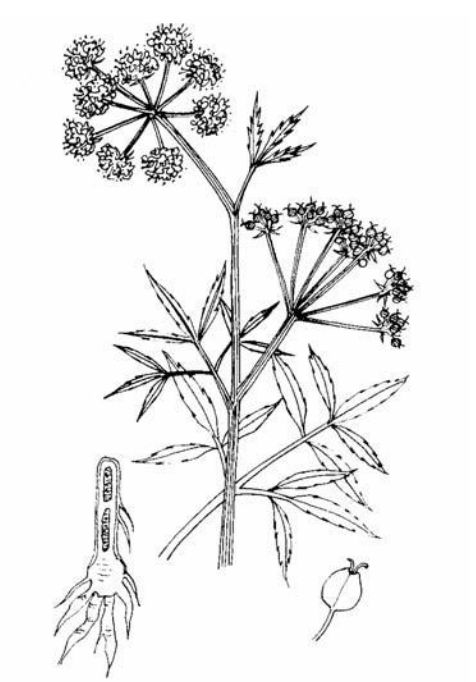
Water-Dropwort

This is *Oenanthe fistulosa*, and while it and parsley water-dropwort (*O. lachenalii* and also *O. aquatica*) are all poisonous, they are less so than hemlock water-dropwort (*O. crocata*) – a weed of marshy places, ditches and other wet locations. This is considered to be one of the most dangerous and poisonous of the commoner plants found in Britain, and many cases of poisoning, not only among animals but also among human beings, have been recorded. It is a member of the same botanical class as cowbane, hemlock, and fool's parsley, and like them the poisonous principle is found in all parts of the plant. In its leaves it has a great similarity to celery, and its rootstock has been mistaken for parsnip. The active toxic principle is called oenanthotoxin, and is most abundant in the root. Hemlock water-dropwort often causes problems when roots of the plant are exposed following hedging and ditching, and canal bank and stream clearances.

Water-dropwort (*Oenanthe crocata*). This should strictly be called hemlock water-dropwort. The roots are the most poisonous part of the plant, and are often dislodged during severe floods or ditching or drainage work. Height: about 1.3 m (4 ft).

Signs The signs appear very quickly after the plant has been eaten, and death follows within one to four hours when large amounts have been taken. Cattle become very depressed in general appearance, and their respiration is fast and laboured. The mucous membranes become congested, the eye rolls, the pulse is weak and fast, and there is a certain amount of foaming at the mouth. Convulsions follow.

In some cases that are not fatal, one or more of the limbs may remain paralysed. In the horse the appearance of signs and the course of the illness are much more rapid and the nervous signs are exaggerated.



Treatment Barbiturates may save life.

Water-Fleas
Daphnia pulex, a brown water-flea found in British ponds, is the intermediate host of the roundworms of ducks, e.g. *Acuaria uncinata*.

Waterhammer Pulse
The peculiarly sudden pulse that is associated with incompetence of the aortic valves of the left side of the heart.

Water Hemlock
Water hemlock, a common plant of damp marshy places in all parts of the Northern Hemisphere, has a short, stout hollow rootstock, and large much-divided leaves set on strong stems. Water hemlock (*Cicuta virosa*) is also known as cowbane.

The root in springtime contains the greatest amount of the poisonous principles, which are three in number, viz. an alkaloid, cicutine; an oil, oil of cicuta; and a bitter resinous substance, cicutoxin.

Water hemlock or cowbane (*Cicuta virosa*), showing the dahlia-like roots attached to the enlarged base of the stem, seed capsule, leaves and greenish-white inflorescence. The flowering stem may be 1.6 to 2.5 m (5 to 10 ft) tall.

Signs Salivation, dullness, vomiting in pigs; colic in horses; bloat in cattle; together with diarrhoea, a staggering gait. Sudden death or a few hours' illness.

First Aid Owing to the rapidity of the appearance of signs it is not often that treatment can be successfully carried out. Strong black coffee or tea may be given. Veterinary help should be sought.

Watery Mouth
An often fatal disease of newborn lambs in the UK. It results from the ingestion of various Gram negative bacteria, especially *E. coli*, from the bedding, fleece, teats and udder, together with inadequate colostrum uptake. The lambs appear strong and healthy but on taking milk from the ewe they soon show signs of abdominal pain, and a watery fluid drips from the mouth. There may be scouring. Death soon follows as a rule.

In a summary of the clinical features of 102 cases of watery mouth in lambs, the majority of cases were observed in ram lambs (73 per cent) and within the first three days of life (80 per cent). The results suggest that the incidence of watery mouth may be reduced by delaying castration until lambs are at least three days old. Treatment involves feeding colostrum, antibiotics, corticosteroids or NSAIDs and an enema to remove the meconium. Control is to ensure clean lambing conditions and removing hair from ewe's underbelly. A similar condition occurs in calves, also due to *E. coli*.

Wattles
Long appendages, sometimes fleshy, present under the jaw in some goats and pigs including KUNE KUNE PIGS. In goats they are called TASSELS and, if left, they can become cystic. Wattles are also present in many types of chickens. They tend to be called caruncles and are usually in the cock. In some species they can be erectile.

WBC
White blood cells.

Weals
They are often incorrectly spelt WHEALS. Weals are raised white areas of the skin which possess reddened margins. They may result from sharp blows or from continued pressure against some hard object. They are only visible upon the skins of pigs, as the hair of the other domestic animals hides the actual skin surface. (See URTICARIA.)

The term 'weal' is also used in surgery in connection with the use of local anaesthetic solution. A primary weal is made, and when the local anaesthetic has taken effect, the needle of the syringe may be reintroduced into the now insensitive area and further injections made painlessly in order to anaesthetise a given area.

Weaning
Weaning is a critical period in the life of the young animal unless carried out with care. Generally

VetBooks.ir

speaking, it is necessary to accustom the young growing animal to a diet in which its dam's milk takes a more and more secondary place for some time before actual separation occurs. In the case of dairy cattle there is an exception to this rule, in that newly born calves are often taken away from their mothers as soon as they have had some colostrum, and are then reared from a pail. Sudden changes in the diet are to be avoided in all species at all times, and the changes from a milk to a herbivorous or omnivorous diet should be gradual. In modern pig husbandry, creep-feeding is practised before weaning. (See CREEP-FEEDING; COLOSTRUM.)

Early weaning of calves Most calves in the dairy herd are taken from their mothers within a day or two of birth, after they have received colostrum. They are then introduced to milk or milk-substitute feeding from a bucket, a teated container or an automatic machine feeder. The amount of liquid the calf receives with the first two methods is restricted, usually, to about two litres of milk or substitute containing 12.5 per cent solids. This does not completely satisfy the appetite of the growing calf, so it is introduced to roughage, in the form of creep feed and water. They continue on a fixed quantity of the liquid feed and gradually increase the amount of other feed consumed. This allows them to be completely weaned at a younger age than would otherwise be possible. Calves can be weaned when they are consuming 0.7 kg (1½ lb) daily if in single pens, or 1 kg (2 lb) on average if in group pens, for three consecutive days. It has, however, been suggested that calves should not be weaned until they double their birth-weight or are at least 80 kg (175 lb), whichever is the heavier.

Early weaning of piglets Most piglets are weaned at three to four weeks. Earlier weaning is only permissible if the health and/or welfare of the sow or the litter would be adversely affected by the normal weaning age.

Piglets suckled to eight weeks can cause marked loss of condition in the sow. Weaning at four weeks allows quicker turnaround in the farrowing house, and consequently less accommodation is needed – as well as the attainment of more than four litters in two years. Food-costs per piglet are higher by this method, but weight at eight weeks can be appreciably higher. The sow must be taken from the piglets, not vice versa, and housed out of earshot, as she will fret. (See also under SOWS' MILK.)

Early weaning of lambs (See SHEEP BREEDING AND MANAGEMENT.)

Weaning of puppies This is usually performed at three weeks of age, the puppies being encouraged to suck on a paste of a proprietary food and then to lick the food from a saucer.

Weaning of kittens This occurs at about three weeks old and is undertaken in the same way as puppies. Feral cats will allow the kittens to feed off prey – usually the offal such as liver, kidneys and gut content.

Weaning of rabbits This is a complex process; it is the time when the young rabbit has to seed its hind-gut with AUTOCHTHONOUS flora. The process usually begins at two-and-a-half weeks old, when the kits start to ingest their mother's CAECOTROPHS. After three weeks, wild kits venture out of the burrow and nibble on grass shoots. This should be mimicked in pet rabbits by the provision of good quality hay. (See TIMOTHY GRASS.)

Weatings

This is a by-product of milling consisting of brans of varying sizes and varying amounts of attached endosperm. The particles finer than bran of the husk of wheat, containing not more than about 6 per cent fibre. They are also known as offals and middlings, and much confusion exists between these various terms. It can also be spelt wheatings. (See BRAN.)

Weaving

Weaving was thought to be a vice of horses and a form of stereotypical behaviour, but this is open to doubt. Affected animals swing the head and neck and the anterior parts of the body backwards and forwards; sometimes the affected animal appears not to be able to stand still on all four feet and lifts each foot in turn. The behaviour shown is thought to indicate pain. It has been postulated that the affected horse is suffering from trigeminal neuralgia, a recognised condition in man that causes excruciating pain. In some cases, a degree of relief has been obtained by tracheotomy; it appears that the mere passage of air through the nose is enough to cause the clinical signs.

Wedder, Wether

A castrated male lamb, after weaning. (See under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC.)

Wedge Osteotomy

An operation for treating an angular deformity of the horse's fetlock of 8° or more.

Weedkillers

Weedkillers used in agriculture include: DNOC, DNP, PARAQUAT, DIQUAT. Hormone weedkillers: MCPA, Agroxone 4, and 2, 4-D. MCPA, it is

VetBooks.ir

claimed, renders pasture more palatable and has no ill-effects upon cattle or their milk. Ragwort and buttercups also become more palatable, due to a temporary increase in their sugar content, and poisoning may consequently arise. (See also HERBICIDES.)

Weighband

An easy device which allows an assessment of cattle, sheep and pigs. They are reasonably accurate and if used correctly and regularly on an individual animal can indicate changes in weight.

Weighbridge

A platform weighing scale. A static apparatus which can be used for large animals; mobile weighbridges are available and collapsible; portable types are available for horses and ponies.

Weights of Cattle

At birth, calves of the larger breeds weigh 36 kg to 54 kg (80 lb to 120 lb) – 77 kg (170 lb) has been recorded. The averages for heifer calves are about: British Friesian, 39 kg (86 lb); Dairy Shorthorn, 36 kg (80 lb); Jersey, 25 kg (56 lb). Bull calves weigh about 2.25 kg (5 lb) more.

Weights of Horses

At birth, a Shire or Clydesdale foal averages 90 kg or 100 kg (1½ cwt or 2 cwt).

Weights of Pigs

Averages in Britain are as follows: at birth, 0.9 kg or 1.4 kg (2 lb or 3 lb); at three weeks, 5.4 kg or 5.9 kg (12 lb or 13 lb); at eight weeks, 16 kg or 16.6 kg (36 kg or 37 lb).

Weil's Disease

A severe disease of humans caused by *Leptospira icterohaemorrhagiae* resulting in severe malaise, jaundice and with a relatively high mortality. It is often contracted from rats or water contaminated by them or other rodents. (See LEPTOSPIROSIS.)

Weimaraner Dogs

A German breed of dog, medium to large, with long neck, pendulous ears and a smooth silvery coat. Originally used as a pointer and retriever. Close to extinction at the end of the 1939–45 war, it was saved by British troops. Distortion of the nictitating membrane may be found, as well as SPINAL DYSRAPHISM (an abnormal dilation of the central canal of the spinal cord). CUTANEOUS ASTHENIA and ununited ANCONEAL PROCESS may be inherited, as may HAEMOPHILIA, SYRINGOMYELIA and CANINE DILATED CARDIOMYOPATHY are also inherited conditions seen in the breed. They are susceptible to INFLAMMATORY BOWEL DISEASE.

Welfare Codes for Animals

Welfare Codes for Animals produced under the Agriculture (Miscellaneous Provisions) Act 1968, make recommendations as to how animals should be kept. There are codes covering cattle, domestic fowl, ducks, farmed deer, goats, pigs, rabbits, sheep and turkeys. Anyone keeping any of those species must have, and have read, a copy of the appropriate code; staff looking after the animals must also have read it. They are amended as required under the ANIMAL WELFARE ACT 2006 and 2011. The codes are produced and updated from time to time but probably in future by the species organisation. While the codes are advisory only (but *see* below), if the recommendations are ignored and animals suffer in consequence, the code can be used in evidence in a court of law.

Regulations The regulations relating to cattle, poultry, pigs and rabbits (Welfare of Farmed Animal Regulations 2000) have converted some of the recommendations of the codes of practice into mandatory requirements (e.g. stocking densities for pigs). The regulations also prevent the routine tail-docking and tooth-clipping of pigs except where this is necessary (a case for performing such operations must be made). Tail-docking of cattle, surgical castration of poultry and interference with the vision of birds are also prohibited. (See also under FARM ANIMAL WELFARE COUNCIL; LAW.)

Welfare of Animals Act (Northern Ireland) 2011

The 2011 Act succeeds the Welfare of Animals (Northern Ireland) Act 1972. This is the Act under which prosecutions for causing unnecessary suffering by cruelty or neglect are carried out in Northern Ireland. Unlike the British equivalent, this Act covers every animal in every circumstance.

Welfare of Animals at the Time of Killing Regulations 2012

This is the implementation of the European Council Regulation 1099/2009 and was implemented from 1st January 2013. It replaces the WELFARE OF ANIMALS (SLAUGHTER OR KILLING) REGULATIONS 1995. Probably the largest change from the previous legislation was that the new legislation is outcome-based and introduced a degree of flexibility for business operators in implementing the Regulation. The flexibility is implemented by using Standard Operating Procedures (SOPs) which all operators are required to develop and implement and these place the animal welfare responsibilities firmly with the business operator. Slaughter licences were replaced by Certificates of Competence for all personnel involved in restraining animals (including in lairages), stunning, slaughtering, pithing,

VetBooks.ir

shackling or hoisting and bleeding. An Animal Welfare Officer had to be employed by all slaughterhouses killing over 1,000 livestock units/year. Electrical stunning equipment must have monitoring displays and visible and audible warnings if the current used is insufficient. Poultry will require breast comforters and chickens must not be shackled and suspended conscious for more than 60 seconds (120 seconds for ducks, geese and turkeys). On farms neck dislocation or killing by a blow to the head can only occur in animals under 5kg liveweight and then not routinely.

Welfare of Animals (Slaughter or Killing) Regulations 1995

This succeeds the Acts of 1974 and 1980, and covers the formal training, examination and licensing of slaughtermen including the handling of animals at abattoirs; codes of practice relating to welfare, in both slaughterhouses and knackers' yards. They detail the (only) methods by which animals may be slaughtered or killed. There have been Amendments in 1999, 2000, 2001, 2003, 2004 and 2007. These refer to the banning of pithing, changes in the use of gaseous mixtures, recognition that mink are no longer slaughtered in the UK, and permitting the use of gaseous mixtures for killing spent hens. This Regulation was replaced on 1 January 2013 by the WELFARE OF ANIMALS AT THE TIME OF KILLING REGULATIONS 2012.

Welfare of Farmed Animal Regulations 2007

Welfare of Farmed Animal Regulations 2007 replaces the Regulations of 2000. These specify the minimum standards under which farmed animals are to be kept. There are special provisions for battery hens, calves, pigs and rabbits. The regulations incorporate many of the guidelines in the WELFARE CODES FOR ANIMALS. Backyard chickens are a very common companion animal and a 2010 Greater London Urban Area survey were found people to have generally provided them with living conditions that allowed expression of natural behaviour. (See also BACKYARD CHICKENS.)

Wells, Well Water

(See WATER AND WATERING OF ANIMALS.)

Welsh Black Cattle

They originated in South West Wales and were originally dual purpose (milk and meat), now mainly used for meat. They are black, with a long coat in winter, and white horns with black tips. They are hardy and have a habit of browsing rather than grazing, meaning they can be used on rough grazing and also in some nature reserves.

Welsh Cobs

(See Section D of WELSH MOUNTAIN PONIES.)

Welsh Collie Dogs

(See WELSH SHEEPDOGS; COLLIE DOGS.)

Welsh Corgi Dogs

(See CORGI.)

Welsh Government

This has the responsibility for matters concerning animal health and welfare in the Principality. It can pass its own Statutory Instruments.

Welsh Mountain Ponies

The breed is divided into four sections. Section A ponies are the smallest and should not exceed 12.2 HANDS. They can be any colour except piebald or skewbald and have pretty, dished faces. Section B are similar to Section A except they are larger, but should not exceed 13.2 HANDS. Section C are of a similar height to Section B but contain COB blood and so they are more thickset and may have some FEATHERING to their legs. Section D are called WELSH COBS and they should exceed 13.2 HANDS, but there is no upper limit for their height.

Welsh Mountain Sheep

A small tidy hardy sheep capable of living on mountains and hills. The males have horns; females are polled. There are several varieties: White Welsh Mountain, Badger Faced Welsh Mountain, Balwen Welsh Mountain, Black Welsh Mountain and South Wales Mountain.

Welsh Pigs

White, lop-eared pigs with long backs native to Wales. The male is often used to crossbreed with other breeds for hybrids to produce a good bacon pig.

Welsh Sheepdogs

These are also called WELSH COLLIE DOGS. They are working dogs used for gathering sheep and cattle. They are bred for their herding abilities and not for size, build or colour. They are of collie-type and black and white, brown and white, or tricoloured, and merle markings can occur. They have prick ears often with a fold at the tip and with short or longish hair. They are longer legged, broader chested and wider muzzled than BORDER COLLIES. They are prone to COLLIE EYE ANOMALY and SUPERFICIAL PYODERMA.

Welsh Springer Spaniel Dogs

A breed thought to be similar to the old land Spaniel and resemble the ENGLISH SPRINGER SPANIEL. They are working dogs, bred for hunting

and are not common. They may suffer defects including GLAUCOMA and HIP DYSPLASIA.

Welsh Terrier

A small breed of dog with a black and tan wiry coat and the hair is longer on the muzzle and legs. The medium length tail is held upright and folded ears. GONIODYSGENESIS as been recorded.

Welsummer Chickens

A breed originating from Welsum in the Netherlands; it was developed at the beginning of the 20th century. They are a light docile breed of a rustic red or orange colour, with the hens having gold, hair-like feathers on their neck and the cocks rusty red necks. The cockerels look classic in appearance. The eggs are brown and spotted. The cocks weigh about 3.2 kg (7 lb) and the hens 2.7 kg (6 lb). There is a bantam variety.

Wensleydale Sheep

A white dual-purpose (meat and wool) longwool breed, with the breed association being formed in 1890. It began in North Yorkshire from a very dark blue-faced Dishley Leicester named 'Bluecap' born in 1839, and is now found in UK, Europe and USA. It has a deep blue head, legs and ears, with no wool on the head except a well-developed feather of wool. Both sexes are polled. The rams are used for crossing with hill ewes (SWALEDALE, SCOTTISH BLACKFACE, CHEVIOT, Rough Fell, Dalesbred) to produce prolific, hardy sheep. Their lambing percentage is up to 250 per cent, and they have genetic resistance to scrapie. Rams weigh 136 kg (300 lb) and ewes 113 kg (250 lb).

Wesselsbron Disease

Cause A FLAVIVIRUS. Transmitted by mosquitoes, and communicable to man, this infection was first reported in South Africa in 1955. It caused death of lambs, abortion, and some deaths of ewes; persistent muscular pain in man. It resembles Rift Valley fever.

Wessex Saddleback Pigs

The old breed which is black except for a continuous white belt over the shoulders and forelegs. It has now been combined with the ESSEX SADDLEBACK breed to form the BRITISH SADDLEBACK.

West Highland White Terrier

A small, rough-haired breed, with pointed ears and black nose. The breed is prone to CRANIOMANDIBULAR OSTEOPATHY, INGUINAL HERNIA, GLOBOID CELL LEUKODYSTROPHY (DNA test available), KERATOCONJUNCTIVITIS SICCA and LEGG-CALVÉ-PERTHES DISEASE. They are susceptible to ATOPIC DERMATITIS, CRUCIATE LIGAMENT RUPTURE. PERSISTENT PUPILLARY MEMBRANE, PERSISTENT and PYRUVATE KINASE DEFICIENCY (DNA test available) have been recorded.

West Nile Fever

Caused by the WEST NILE VIRUS. It was first detected in Uganda in 1937. The disease is now seen in temperate and tropical climates and countries.

West Nile Virus

Cause of an infection, mainly in wild birds; corvids (crows, magpies, jays) are particularly susceptible, with dead birds literally falling out of the sky. The house sparrow is resistant. It can infect horses, primates and human beings. The disease was transported from Israel to the USA in 1998 and spread rapidly, reaching Canada. In 2001 about 3,200 humans showed clinical signs and 177 died. Virus is transmitted by mosquitoes; horses, humans and other primates can be infected, but a mosquito biting an infected human is unable to transmit the disease to another person. In humans, most of those infected show no signs, but in a relatively small number of cases show meningitis, vomiting and generalised fever. There is evidence that the infection is present in British wild birds. The FLAVIVIRUS is related to yellow fever and Japanese encephalitis viruses. (See USUTU VIRUS.)

In horses it is a NOTIFIABLE DISEASE with an encephalitis seven to 10 days after infection. There may be pyrexia and neurological signs which include ataxia, weakness, muzzle twitching, dullness and recumbency.

Wether

A castrated male sheep after weaning. (See under SHEEP, NAMES GIVEN ACCORDING TO AGE, SEX, ETC.)

'Wet Tail' in Hamsters

A serious condition of pet hamsters in which profuse diarrhoea and severe soiling of the hindquarters causes the animal to walk with its hindquarters elevated. It is also called TERMINAL ILEITIS IN HAMSTERS and the stress of captivity is thought to predispose to its occurrence. Sometimes INTUSSUSCEPTION and rectal PROLAPSE are sequelae.

Wetting Agents

Substances which lower the surface tension of water, so that the latter spreads out over the surface rather than remaining in the form of drops. Good wetting ability is a characteristic of detergents, which play an essential part in the disinfection of vessels, pipes, glassware used for milking equipment, etc.

VetBooks.ir

VetBooks.ir

Wharton's Duct
Wharton's duct is the name of the tube by which saliva secreted by the submaxillary gland reaches the cavity of the mouth.

Wharton's Jelly
Wharton's jelly is the embryonic connective tissue that forms the basis of the umbilical cord in the fetus. In its substance are found the umbilical vessels and the other structures that constitute the umbilical cord.

Wheal
The incorrect spelling of WEAL.

Wheat, *Triticum* species
An ingredient of animal diets especially farm livestock. The commonest plant on earth and a hybrid of three different species. It is a high energy cereal (higher than BARLEY, MAIZE, OATS) and relatively low in protein except for the WHEAT GERM. It is mainly used in human foods, but the by-products are often included in animal feeds such as wheat bran and wheat feed, which are both lower in energy and protein than wheat grain

Wheat Germ
An important source of vitamin E.

Wheat Gluten
For the adverse effect of this in some instances in calves, see under SOYA BEANS.

Wheezing
(See BRONCHITIS; also 'BROKEN WIND'.)

Whelping
(See under PARTURITION, in the bitch.)

Whey
Whey is the liquid residue left after the separation of the curds in cheese-making. Used as a food, particularly for pigs. Can be a source of infection if made from unpasteurised milk.

Whippet
A medium-sized dog of the greyhound type. The breed is prone to alopecia and suffers from CANINE MULTIDRUG SENSITIVITY and COLLIE EYE ANOMALY (DNA tests available).

Whipworm
Whipworm is the popular name for the Genus *Trichuris* found in the caecum. (See ROUNDWORMS.)

Whirling Disease
A parasitic disease of fish caused by the protozoan *Myxobolus* (formerly *Myxosoma*) *cerebralis*. The parasite spends part of its life-cycle in mud; after swallowing by the fish it migrates and penetrates the cartilage of the skull. Affected fish swim erratically. There is no treatment but the disease can be prevented by rearing young fish in plastic or concrete-lined ponds until the skull is ossified – the parasite cannot penetrate bone. It was formerly a notifiable disease.

Whistling
Whistling is a defect affecting the respiratory system of the horse. In many respects it is similar to 'ROARING', but the note emitted is higher pitched. It constitutes an unsoundness.

White Beige Fat
(See FAT.)

White Blood Cells
(See LEUKOCYTES; BLOOD.)

White Cells
(See under BLOOD. For white cells in milk, see under MASTITIS.)

White Diarrhoea, Bacillary
(See under PULLORUM DISEASE OF CHICKS.)

White Fat
(See FAT.)

'White Heifer Disease'
The name given to defects in the genitalia most commonly found in Shorthorn cattle. The defects can vary from the presence of fibrous tissue across the posterior part of the vagina ('persistent hymen') that may be corrected surgically, to the absence of all or part of the uterus.

White Line
White line is the margin of horn that runs round the outside of the sole, between it and the wall, in the horse's hoof. It acts as a slightly pliable cementing material between wall and sole. It is important as a guide to the shoeing smith, since it forms a line inside which it is unsafe to drive a nail without risk of pricking the sensitive parts of the foot.

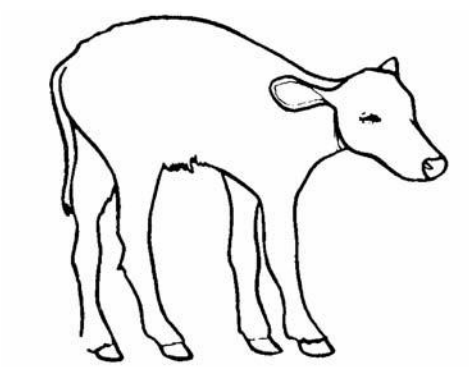
White Liver Disease in Sheep
This can be seen in sheep with poor growth, PARESIS, RECUMBENCY and marked tear production (EPIPHORA). It is seen in COBALT or Vitamin B_{12} deficiency.

White Muscle Disease
White muscle disease is another name for the result of vitamin E and/or selenium deficiency. (See MUSCLES, DISEASES OF - NUTRITIONAL MUSCULAR DYSTROPHY.)

White-Nosed Syndrome

A disease of bats first discovered in New England in 2006, since when it has become widespread in the USA and Canada with between 5.7 million to 6.7 millions bats dying by the end of 2011. The name derives from the white fungal growth (*Geomyces* spp.), occurring mainly on the nose but also on the ears and wings. Affected bats may show abnormal behaviour and leave their places of hibernation to die of hypothermia. There is a very high mortality and, one State is reportedly totally devoid of bats. In view of the severity of the syndrome, monitoring of hibernating bats is taking place in the UK and the European mainland. The fungus may be the primary cause or a secondary invader.

White Park Cattle



These include Ancient White Park, White Forest, White Horned, Wild White. They are relatively rare and are white with black points (ears, nose, eye, feet, hooves, teats). The cow weighs 650 kg (1430 lb) and bulls 950 kg (2090 lb). There are horned and polled breeds recorded back to the 1200s. Several of the herds were confined to parks such as those of the wild Chillingham herd (Northumberland), and have not been crossed. Many others in different parts of Britain have in the past been crossed with breeds including HIGHLAND, LONGHORN or WELSH BLACK. They can be used for meat.

'Whites'

'Whites' is another name for leukorrhoea, and is a term popularly used in connection with *Trueperella pyogenes* infection in cows. (See LEUKORRHOEA; UTERUS, DISEASES OF; VAGINITIS.)

White Scour in Calves

White scour in calves is a disease affecting calves within the first three weeks of life. The disease is usually a rapid one. In the acute case the calf may be found dead or dying; in other cases death occurs within three to 10 days after signs are first noticed.

An arched back is characteristic of white scour, also a dejected appearance.

Cause is usually *E. coli,* but other organisms may be involved, including *Proteus vulgaris* and *Pseudomonas pyocyanea*, *Salmonella* spp., cryptosporidia, rotavirus and coronavirus.

Predisposing causes include: exposure to cold and damp; deprivation of colostrum; sudden changes in diet; feeding with unsound milk or mouldy calf-meals from unclean utensils; overcrowding; and housing healthy calves in pens or boxes that have previously contained cases of the disease and have not been carefully disinfected afterwards.

White scour is uncommon in beef cattle at pasture.

Calving-boxes should be disinfected and well littered before the pregnant cattle occupy them. A protective serum has been used with encouraging results. Where bucket-feeding is adopted, colostrum must not be withheld.

Treatment It is essential to overcome the dehydration resulting from the diarrhoea. (For details, see DEHYDRATION.)

Other treatment comprises the use of sulfamezathine or one of the other sulfa drugs, or antibiotics if bacterial in origin, and in some cases the inclusion of yeast in the diet. Serum from the dam has been given by subcutaneous injection in default of colostrum. (See also DIARRHOEA.)

Whiteside Test

This has been used for the detection of subclinical mastitis, by indicating an abnormally high white-cell count of the milk. A modified version consists of placing one drop of 4 per cent caustic soda (NaOH) and five drops of the milk on a glass plate, and stirring with a glass rod for 20 seconds or so. The presence of flakes indicates a positive result; a viscous mass at the end of the rod suggests a strong positive result. It is a laboratory version of the CALIFORNIA MASTITIS TEST.

White Spot Disease of Crustaceans

This is due to a virus and is widespread over shrimp farms on the American Pacific Ocean coastline. Currently there are no vaccines or medicines to tackle the disease although there are encouraging developments in formulating feed. Fish and animal protein solubles, yeast extracts and single-cell proteins have been used with some success. All of these have a high content of nucleic acids, and as these are the building blocks for DNA, they may be significant in that respect.

White Spot of Fish

White spot is a parasitic disease of fish in which white cysts are formed all over the surface of the

VetBooks.ir

fish, including the gills. It is more common in the carp family, including goldfish. The cause is *Icthyophthirius multifiliis*. Part of its life-cycle is spent at the bottom of ponds, from where the infective stage is released into the water and makes for the fish. It is only at this stage that the parasite can be treated. Zinc-free malachite green is used to create a very dilute solution in the pond (0.1 ppm), as the parasite will continue to be released until eradicated. Treatment instructions must be followed carefully if toxicity is to be avoided.

White Wyandotte Chickens
These are a popular breed of backyard or pet poultry. (See WYANDOTTE CHICKENS.)

WHO
(See WORLD HEALTH ORGANIZATION.)

Whorls
These, as well as colour markings, assist in the identification of horses. A whorl is a pattern of hairs, often about 2.5 cm (1 in) across and may be circular or linear. Occasionally they are irregular in shape.

WHW
(See WORLD HORSE WELFARE.)

Wild Birds
For unintended poisoning of these, see under GAME BIRDS, MORTALITY; also TEM.

Wild Dogs
Wild dogs are an important source of human hydatid infection in New South Wales, where a sylvatic strain of *Echinococcus granulosus* circulates predominantly between them and wallabies. The incidence of infection in domestic dogs, however, is much lower.

Wildlife Information Network (WIN)
A charity aiming to disseminate information on the health and management of free-ranging and captive animals and their environments, and emerging infectious diseases, to wildlife and veterinary professionals worldwide, by producing the Wildpro® Multimedia Electronic Encyclopaedia. In 2010, WIN became part of Twycross Zoo – East Midland Zoological Society.

Wildlife Rehabilitation
Young wild animals with no or minor clinical problems are often successfully released. Adult animals are often difficult to return to the wild, especially those which have had major surgery or long periods in care.

Wildpro® Multimedia
This is a referenced, peer-reviewed electronic encyclopaedia on the health and management of captive and free-living wild animals, and emerging infectious diseases. It is designed to assist veterinary and wildlife professionals worldwide with logical decision-making based on consideration of animal, pathogen and environmental factors. It is freely available on www.wildlifeinformation.org.

Wilting
Wilting of sugar-beet tops is highly desirable before feeding in order to avoid poisoning, and with a lush crop of grass on a new ley, cutting and allowing to wilt may obviate bloat.

Wiltshire Horn Sheep
The breed is an old native breed, founded in 1829. It is a large breed with a Roman nose. The rams weigh 150 kg and ewes weigh 100 kg (220 lb) with wool weighing 2.5 kg to 4.5 kg. It is used for meat and has a short fleece which it sheds; it is a 'self-shedder'.

WIN
(See WILDLIFE INFORMATION NETWORK.)

Wind-Borne Infection
Under favourable conditions, viruses, including the virus of foot-and-mouth disease, may be carried from country to country, even where a long sea passage is involved.

Windbreaks
(See under EXPOSURE.)

Wind Galls
Distensions of the joint capsules, or of tendon sheaths, in the region of the fetlock. (See SYNOVITIS.)

Windpipe
The common name for the TRACHEA.

Wind Puffs
A popular term for the rupture of one or more air sacs in birds, with escape of air under the skin. The birds appear very fat, until handled. The condition usually resolves without treatment.

Wind-Sucking
(See CRIB-BITING AND WIND-SUCKING.)

Wing Tip Oedema
A condition affecting the wing tip of birds of prey, manifested by the presence of a fluid-filled swelling. (See ISOXSUPRINE.)

Winter Cough
An allergic non-infectious disease in goats mainly affecting the lower airways of the respiratory system.

Winter Diet
It is often wise to incorporate 5 per cent of animal protein in the winter rations of dairy cattle, which otherwise may be getting too little protein and give milk low in solids-not-fat. Succulent food such as silage or kale forms a high proportion of the winter diet for cattle, which may be receiving too little carbohydrate. On self-fed silage the NIRD have recorded a 33 per cent reduction in dry-matter intake, compared with a diet of hay and concentrates.

Winter Dysentery
This is an explosive outbreak of diarrhoea, and occasionally dysentery, mainly seen in autumn and winter affecting adult cows, usually dairy cows, mainly milking animals. There may be a marked reduction in milk yield and also appetite. Most of the herd is usually affected to a varying degree. The outbreak lasts for a few days and then most animals rapidly recover. The cause is normally considered to be a CORONAVIRUS and CAMPYLOBACTER INFECTIONS; have also been implicated.

Winter Infertility
(See INFERTILITY.)

Winter Scours
(See WINTER DYSENTERY.)

Wire
(See STOMACH, DISEASES OF - FOREIGN BODIES IN THE RETICULUM; TRAUMATIC PERICARDITIS; TRAUMATIC RETICULITIS.) So-called 'wire' or 'hardware disease' results from a piece of hard sharp material, usually metal, penetrating the wall of the reticulum and possibly the peritoneum, diaphragm and pericardial sac. Barbed wire is responsible for many small wounds of the cow's udder which predispose to mastitis, and for accidents in the hunting field.

Wire-Haired Fox Terriers
A small sturdy dog, mainly white with brown on face and ears and black patch on body, it is larger than the BORDER TERRIER. Although originally thought to be related to the SMOOTH-HAIRED FOX TERRIER this is probably not the case. They suffer DEAFNESS, LENS LUXATION and PULMONARY STENOSIS (See FOX TERRIERS). A breed of terriers which is less popular than in the past.

Wisents
Another name for the European Bison or European wood bison (*Bison bonasus*). (See BISON.)

'Witch's Milk'
An old name for abnormal secretion, in rare instances, of milk by the newborn of either sex.

Withdrawal Period, Withdrawal Time
The length of time that must elapse after treatment with a medicinal product before an animal can be slaughtered for food, or its milk or eggs used for human consumption.

Withers
The region over the backbone where the neck joins the thorax. It is where the spinous processes of the thoracic vertebrae are present, and the scapulae are just below the skin. It is the highest point of the back and the place where the height of a horse or pony is measured.

Withhold Period, Withhold Time
Used for the time from when a medicine is administered before the milk can again be used for human consumption. With INTRAMAMMARY tubes it is often given in hours or milkings.

'Wobbler' Syndrome
A colloquialism for a horse which evinces a slight swaying action of its hindquarters and a tendency to stumble. The condition is likely to progress to a form of ataxia in which the horse cannot trot without swaying from side to side and falling.

Cause Pressure on the spinal cord in the neck region blocking nerve transmission to the hindlegs. The pressure may be caused by subluxation of the vertebrae of the neck, arthritis, or osteochondritis. Surgery to relieve the pressure may be a possibility.

The 'wobbler' syndrome in the dog is referred to under SPINE AND SPINAL CORD, DISEASES AND INJURIES OF - CERVICAL SPONDYLOPATHY.

Womb
(See UTERUS.)

Wood-Ash, Eating of, by Cattle
This is suggestive of a diet deficient in salt, calcium or magnesium.

Wooden Tongue
(See ACTINOBACILLOSIS.)

Wood Preservatives
Some of these are a source of arsenical poisoning; others, containing chlorinated naphthalene compounds, of hyperkeratosis. Creosote and pentachlorophenol are liable to cause poisoning in young pigs; the latter has caused fatal poisoning in cats bedded on sawdust from treated timber. Cats

have been killed also by DIELDRIN used for treating floorboards, etc., against woodworm.

Wood's Lamp
A source of ultra-violet radiation, it is used in the diagnosis of ringworm – diseased hairs, etc.

Whorls appearing fluorescent in the case of *Microsporum canis* infection. It is a useful screening method. The fluorescence is of an apple-green colour.

Wool
This is the dense coat of woolly or waxy hair covering the body of sheep. The coarseness of the hair of some ancient breeds has been developed by selective breeding over many centuries. It is used in clothing, carpets, insulation, sound dampeners etc. Some sheep breeds were bred specifically for their fleece such as DEVON LONGWOOL, LINCOLN LONGWOOL and MERINO. The wool price, unless for a specialised type, usually makes it uneconomic to rear sheep just for this purpose. The staple is the clustering of the fibres, and in longwool sheep they are called locks, the wool rather than hair is crimped (bends) and elastic. The quality depends on the crimp (number of bends per unit length) and micron (micrometre – the fibre diameter). The term is also often used for cashmere and mohair from goats, angora from rabbits and qiviut from alpacas, camels muskoxen and vicunas.

Wool Balls in Lambs
On opening a lamb's stomach after death from some unknown disease, if a mass of wool and greyish or greenish softer material is found in the reticulum or abomasum and no other readily obvious signs are noticed, the shepherd or owner is prone to reach the conclusion that the cause of death was this mass of wool. In some districts, so-called 'wool balls' have in the past been held to account for a high mortality among lambs, when the real cause was often LAMB DYSENTERY.

While wool balls can kill it is much more likely to be an indication of inadequate milk supply from the dam. The hungry lamb withdraws all the milk available, but when it reaches the age of two to four weeks or so, this proves insufficient to satisfy its needs. When searching for a further supply it finds a small tag of wool on the udder or near to it and sucks at it because of its somewhat salty taste. The tuft of wool may come away and be swallowed and starts a trend.

The mass of wool which accumulates may occasionally result in blockage of the outlet from stomach to small intestine (PYLORUS).

Prevention The removal of shed wool from the pastures, and 'udder-locking' (clipping all wool from the udder before or at lambing). The nutrition of the ewes should be improved and creep feed provided to the lambs.

Wool-Eating by Cats
Sucking wool (garments and/or knitted yarn) is common in cats and may occur as continuation of the sucking reflex from kittenhood. It is often accompanied by treading and drooling. Usually it is more irritating to owners than being associated with digestive disturbance in the cat. It can also result from boredom (e.g. in Siamese); very uncommonly it can cause an obstruction of the pylorus or bowel.

Wool-Eating by Sheep
This occurs, as a result of boredom, in sheep confined in winter and may not be associated with any clinical signs. It should be distinguished from biting and gnawing due to parasitism or other causes.

Wool Rot
(See LUMPY WOOL.)

Wool Slip
Alopecia occurring in housed ewes shorn during the winter, reducing wool yield by up to 25 per cent. It is thought to be stress induced.

In order to avoid this alopecia, it has been suggested that sheep should be sheared at the same time as they are housed, to reduce the number of periods of stress, and that a better-quality diet should be provided after shearing. The diet should be introduced before housing.

Working Horses
These horses are used to help man to carry out certain tasks. They are in a different category from race-horses and pleasure horses. They are normally called draught horses (draft horses – America) and are usually from one of the breeds of HEAVY HORSES e.g. CLYDESDALE, PERCHERON, SHIRE, SUFFOLK PUNCH. (Source: 'Veterinary Treatments of Working Horses' by Graham Duncanson, CABI International, Wallingford).

Works Chimneys
(See FACTORY CHIMNEYS.)

World Health Organization (WHO)
The United Nations authority for co-ordinating and directing human health. Address: Avenue Apperia 20, 1211 Geneva 27, Switzerland; Telephone: +41 22 791 21 11; Fax: +41 22 791 31 11.

(See OFFICE INTERNATIONAL DES EPIZOOTIES [OIE].)

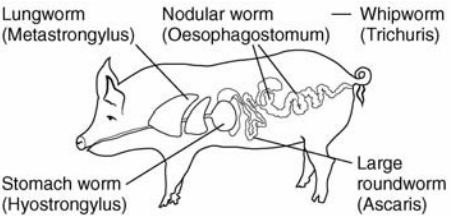
Worm Egg Counts

The use of faecal egg counts as a means of estimating the degree of infestation can be misleading. With *Ostertagia* worms in calves, for example, the pattern of faecal egg counts tends to be the same whether the worm burden is large or small, increasing or decreasing. Counts increase fairly rapidly to an early peak, from which they decrease according to a logarithmic curve. This means that the egg count at any one point in time bears a constant relation to the egg count a given number of days before. The limit to total egg output evidently depends on the host's degree of immunity.

Worms

(See ROUNDWORMS; TAPEWORMS; LIVER-FLUKES; RUMEN FLUKES; SCHISTOSOMIASIS for 'blood flukes'; HEARTWORM; also EARTH-WORMS.)

In cattle and sheep, parasitic gastroenteritis and bronchitis (husk) are important diseases caused by worms. (See also LIVER-FLUKES; NEMATODIRUS, STEPHANOFILARIASIS; and WORMS, FARM TREATMENT AGAINST.)



In horses, strongyle worm larvae may cause a verminous arteritis with fatal results. (See HORSES, WORMS IN; EQUINE VERMINOUS ARTERITIS; DIARRHOEA; FOALS, DISEASES OF; HYDATID DISEASE.)

In dogs in Britain, the worms usually encountered comprise ascarids, hookworms, whipworms, and tapeworms. (See also ANTHELMINTICS; *Toxocara*; TRACHEAL WORMS; HEARTWORM; KIDNEY WORM; FLUKES AND FLUKE DISEASE.)

In pigs *Ascaris* worms in the intestine reduce growth rate, while their larvae, migrating through the lungs, may give rise to pneumonia and the sign known as 'thumps'. Metastrongylus lungworms cause bronchitis and sometimes pneumonia. (See also THIN SOW SYNDROME and WORMS, FARM TREATMENT AGAINST.)

Worms, Farm Treatment Against

Much effort has been concentrated on the development of effective and safe anthelmintic drugs to control infestation of farm livestock by parasitic worms (endoparasites). There are many on the market, but often they derive from a relatively small group of chemical compounds. There is confusion among many users about which drugs to use in particular cases. A wide range of worms may be present in the gut (intestine), stomach or abomasum, lungs or liver; some endoparasites such as tapeworms and liver-flukes are found in other parts of the body during migratory stages of their development.

The principal parasitic worms of the pig, and their habitat.

No wormer is completely effective against all worms, and one which may eradicate adult worms may not be effective against the larvae or eggs.

Thus the choice of which product to use depends both on knowing which worms are to be treated and the stage in their life-cycle at which they are to be destroyed.

Some anthelmintics act by killing the parasite, which may then be expelled in the faeces, broken down in the body or coughed up, depending on the site of infestation. Others work by immobilising the worm, thus allowing it to be expelled from the body.

Whatever worming procedures are used, they must be integrated with other animal-husbandry and grass-land-management procedures to prevent or reduce reinfection.

Wormers may be formulated to be given by mouth as a suspension, liquid, paste, in the feed or as a bolus; they may be given by injection; or as a 'pour-on' to be absorbed through the hide. Most have a wide margin of safety, but the effect of the medication on sick animals must always be considered. The effect of accidental contact, or ingestion, on the person administering the wormer must also be considered; the manufacturer's precautions and dosage instructions must be carefully read before use. Many products have a long duration of activity, and milk-withdrawal and meat-withholding times must be observed.

Administration The method of administering an anthelmintic is worth consideration. No method is perfect – each having some disadvantage. Drenching can, if not done with care, lead to 'drenching pneumonia', and the necessary restraint may be undesirable with yarded cattle or in-lamb ewes. The smaller dosages now required

VetBooks.ir

make drenching less hazardous, but see under DRENCHING.

Injection usually involves less restraint than drenching, but with any injection there is the slight risk of broken-off needles and an abscess at the site. Neither of these disadvantages applies to anthelmintics which can be given in the feed – a most convenient method which normally should not involve extra cost.

Long-acting boluses which lodge in the reticulorumen, and contain anthelmintics released over a period, are available for cattle. One containing morantel tartrate introduced by Pfizer provides several months' activity, depending on the type of roundworm present. The bolus was presented in the form of a cylinder made from a laminated sheet that unrolls to release the drug. Schering-Plough use a 'pulse' system which releases a dose of the anthelmintic oxfendazole at intervals of about three weeks. Other slow-release boluses contain fenbendazole and ivermectin. Such boluses are usually for use only in animals over a certain weight and age.

To reduce the possibility of anthelmintic resistance, anthelmintics should only be used when infection has been shown to be present. This is particularly important in sheep, goats and horses. Principles have been laid down by Sustainable Control of Parasites in Sheep (SCOPS) and Control of Worms Sustainably (COWS).

Husk – drugs or vaccine? Parasitic bronchitis or verminous pneumonia (known colloquially as husk or hoose) is mainly thought of as a disease of young stock in their first season at grass. Recovery from an attack can be expected to result in a useful degree of immunity to the lungworm.

While the disease is a virtually permanent problem on many farms, and a risk on most others except where zero-grazing is practised, some farms do escape it altogether – at any rate for a time; but then one day it may suddenly appear out of the blue with devastating results. When this happens it may be cows in milk which suffer, losses to the farmer arising mainly as a result of a lowered milk yield but also of the extra feed needed for recuperation. There may be deaths, too, following signs common to those of an allergic condition. Indeed one shocked farmer, in his first encounter with husk, lost several dairy cows from oedema of the lungs – and his bull as well!

Especially on farms where the disease is a perennial problem, the farmer's own veterinary surgeon should be consulted concerning the use of vaccine as a preventative.

The vaccine consists of third-stage larvae of the lungworm *Dictyocaulus viviparus* treated by exposure to a specified level of radiation by X-rays. This type of vaccine, the first anti-worm vaccine commercially available, was developed at the University of Glasgow.

The irradiated larvae are left with the ability to stimulate antibody production in the host animal, but are deprived of their power to cause disease. The vaccine is administered in two doses (each containing 1000 irradiated larvae) with a four-week interval.

Certain precautions are necessary in using this vaccine. For example, calves should not be less than two months old when vaccinated, and should be healthy. They should not be exposed to natural infestation with lungworms until two weeks after their second dose; and should be introduced gradually to heavily infested pasture. Vaccinated and non-vaccinated calves should not be mixed.

Where the vaccine is not used, reliance must be placed on anthelmintics. It will be readily appreciated, however, that once severe signs of husk have appeared, the most that any drug can do is rid the animal of its lungworms. A drug cannot undo the lung damage, clear the blocked airways, or neutralise any subsequent infection; and the coughing will persist after the worms are gone. Vaccine can prevent such a situation from arising. Drugs, however, are a valuable means of lungworm control. If long-acting anthelmintics are to be used as well as vaccine, it is advisable to take veterinary advice.

Liver-flukes Years ago the problem with drugs intended to kill liver-flukes was their toxicity. The margin between an effective medicinal dose and a lethal dose was sometimes very small, especially in an already seriously ill sheep.

The introduction of safer drugs still left the problem of resistance to them shown by immature flukes which, by their massive invasion of the liver, cause 'liver rot' and a high mortality in affected flocks. Later developments brought drugs effective against both immature and mature stages of the fluke. CLOSANTEL (Flukiver; Janssen) has a claimed activity of over 97 per cent on adult flukes, 91 per cent of five-week-old and up to 73 per cent on three to four-week-old flukes. TRICLABENDAZOLE (Fasinex; Novartis), at the appropriate dose level, is claimed effective against flukes from two weeks old. NITROXYNIL (Trodax; Merial) and RAFOXANIDE are also claimed active against immature and mature flukes.

Other drugs with specific action on adult liver-flukes include OXICLOZANIDE (Zanil) and ALBENDAZOLE.

Drugs in use include the following:

Against PGE worms in cattle and sheep*	*Against liver-flukes in cattle and sheep*
albamectin	albendazole
albendazole	closantel
doramectin	clorsunol

VetBooks.ir

febantel	oxyclonazide
fenbendazole	nitroxynil
ivermectin	triclabendazole
levamisole	
mebendazole	
moxidectin	
netobimin	
oxfendazole	
thiabenzadole	
thiophanate	
morantel tartrate†	

Against lungworms in cattle and sheep	*Against worms in pigs‡*
albamectin	flubendazole
albendazole	ivermectin
doramectin	levamisole
febantel	oxibendazole
fenbendazole	parbendazole
ivermectin	piperazine (ascarids only)
levamisole	tetramisole
mebendazole	thiophanate
moxidectin	thiabendazole
oxfendazole	
thiophanate	

*parasitic gastroenteritis
†a bolus, given by balling gun, for cattle only
‡given in the feed

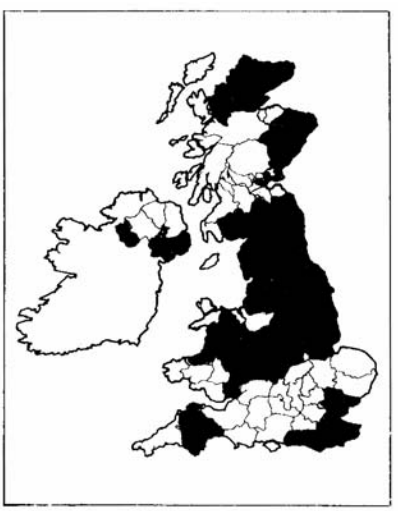
(See also IVERMECTIN, for use against PGE worms and lungworms, in cattle and sheep; and against parasites of pigs.)

Dual-purpose and multi-purpose anthelmintics are available.

Parasitic Gastroenteritis For control of the parasites causing gastroenteritis, it is advised that calves should be dosed once with an efficient anthelmintic in mid-July and moved to pasture which has not been grazed that season by other cattle. The first pasture may then be grazed by animals not susceptible to parasitic gastroenteritis, such as adults.

The second essential dose is in the autumn when cattle come in from grass. At housing, the wormer selected should be active against inhibited larvae, as well as maturing larvae.

Ostertagia worms, which are of considerable economic importance, are peculiar in that while most infective larvae living in the abomasum moult twice to become adults, some – especially perhaps those ingested by the calf during late summer and autumn – moult only once and remain as fourth-stage larvae in a dormant state. The larvae are resistant to many anthelmintics, but FENBENDAZOLE and ALBENDAZOLE are often effective. Later, they develop into adults causing a winter outbreak of gastroenteritis, with scouring and other digestive disturbance. Accordingly, it is usually recommended that calves be dosed in September and moved to 'clean' land.



IVERMECTIN (Ivomec) is effective against immature and even inhibited *Ostertagia* larvae; it can be given to both beef and dairy cattle, but not within 21 days of slaughter, or to dairy cows in milk, or within 28 days prior to calving. Three doses a year – in spring, summer, and autumn – are recommended to make the best use of this multi-purpose anthelmintic.

IVERMECTIN has no action against flukes or tapeworms, but is highly effective against all the important roundworms, both adult and larval forms.

Nematodirus in Lambs Lambs four to six weeks old and upwards may become severely ill as a result of infestation with *Nematodirus* worms. A well-recognised condition, it may show itself with dramatic suddenness in lowland flocks in spring, but – depending on locality and weather – the main period of incidence is probably the end of May until the second week in July. Recently a second syndrome has occurred in older lambs from August to September.

The worms, each about 1.70 cm (⅔ in) long, cause unthriftiness and poor liveweight gains; they may also cause a high mortality following four to five days' scouring resulting in a lethal loss of body fluids, i.e. dehydration. Where recovery does take place, it is usually long-drawn-out and the animal may remain stunted.

These worms differ from others infesting the stomach/intestine of sheep in Britain in that their life-cycle takes about 12 months to complete, and the eggs require exposure to cold to initiate development; as infective larvae, they remain viable for only a few weeks. This fortunate fact offers an obvious method of control – the well-known rule, 'Never put lambs on the same pasture

Areas where *Nematodirus* may be a problem. (With acknowledgements to ICI.)

VetBooks.ir

two years running.' On farms where it is impracticable to observe this rule, dosing three or four times with an appropriate anthelmintic has been advised but should not be necessary if pasture management is good and the epidemiology of the infestation is understood. (See also 'CLEAN' PASTURE.)

Worms in Pigs Anthelmintics, complemented by good hygiene, play an essential part in maintaining health in the intensively managed pig unit. Pigs kept outdoors are vulnerable to worm infections.

Infestation by parasitic worms is best regarded as a herd problem, and the fact that anthelmintics are available in a palatable pellet form, or as a powder to mix in a meal, is a great help to the pig farmer. These are usually broad-spectrum drugs which will act against most of the species of worm normally found in the pig. Where a particular species has led to a severe health problem, an anthelmintic most effective against that species can be selected.

The main wormers used in pigs are FEBANTEL, FENBENDAZOLE, FLUBENDAZOLE, IVERMECTIN, MOXIDECTIN and THIOPHANATE.

Steering a middle course The farmer should, where necessary, seek veterinary advice on the spot, and aim to steer a middle course between inconveniently frequent dosing and high drug bills on the one hand, and tolerating poor liveweight gains, unthriftiness and even several deaths among his stock on the other hand. Internal parasites steal feed intended for their hosts, and often cause physical injury – sometimes very severe – as well.

Wounds

A wound may be defined as a breach of the continuity of the tissues of the body produced by violence. (See also under BRUISES.)

Varieties Wounds may be classified according to the nature of the effect produced, viz. incised, punctured, lacerated, and contused, and whether they are infected or contaminated.

Incised wounds are usually inflicted by some sharp instrument which leaves a clean cut; the tissues are simply divided without extensive damage to the surrounding parts.

Any one of these forms of wounds may become infected with pus-forming organisms, and develop into a suppurating, septic wound. (For other information, see under ACCIDENTS; FRACTURES; etc.)

Bleeding from wounds **Bleeding from an incised wound** is apt to be very profuse for a time, but it soon stops and is easily controlled.

Punctured wounds or stabs are inflicted with a pointed instrument or another animal's incisor or canine teeth. (A dose of tetanus antitoxin or toxoid is indicated in punctured wounds, especially in the horse, cow, sheep, goat, dog and man.)

Lacerated wounds are those in which much tearing occurs. They are usually very painful for a few days, and suppurate before they heal. They are usually followed by disfiguring scars when extensive.

Contused wounds are those accompanied by much bruising of the surrounding tissues, as in the case of blows from heavy sticks, kicks from shod horses, and from road accidents. There is usually little bleeding from the wound itself, but blood may be extravasated into the tissues. (See HAEMATOMA.)

First-aid treatment With a serious wound involving much haemorrhage, the first consideration must obviously be to stop the bleeding. (See BLEEDING, external: first aid for.)

With all wounds it is advisable to clip away the hair – preferably using blunt-pointed surgical scissors – first inserting a piece of cotton-wool moistened in antiseptic into the cavity of the wound (if large enough), so that the cut hair does not fall into the wound. This is especially important if mechanical or electrical devices are used to remove the surrounding hair.

If the hair is not cut away, it is apt to become matted by blood or oozing serum, and the wound may later be found to be suppurating instead of healing. (What may look to the animal-owner or attendant like a normal healthy scab may be, in fact, a crust of blood, matted hair and dirt.)

The surface of the wound may be cleaned by gentle application of a piece of cotton-wool soaked in warm antiseptic such as diluted POVIDONE IODINE or Cetrimide, etc., or KY Jelly.

The wound may be covered in order to prevent contamination and infection by flies – in the case of farmyard animals – or to prevent excessive licking by dogs and cats.

The covering of a wound cleaned and dressed as described should be removed every one to five days depending on the amount of healing and granulation so that the progress of healing can be observed, and cleaning repeated if necessary. An open, granulating wound should have a clean, pink appearance.

Large, gaping wounds may require suturing, which should be done by a veterinary surgeon, who should also always be consulted concerning the treatment of punctured and lacerated wounds.

Other points that should be noted are: (1) that stitches should be removed if they commence to suppurate, and in any case after the wound has healed, after which they serve no useful purpose;

VetBooks.ir

(2) that if pus gathers under the skin surrounding a wound, it must be given drainage by incision below the level of the most dependent swelling or by drainage tubes; (3) that if the granulation tissue (i.e. 'proud flesh') rises to a higher level than the skin around, it may need professional treatment; and (4) that in cases of injury to parts such as the eyes, nostrils, lips, genital organs, feet, etc., it is essential to seek skilled advice rather than to persist in rule-of-thumb methods which often lead the enthusiastic amateur astray, and cause the animal unnecessary distress. (See also FRACTURES; GRANULATIONS; ULCER; ANTISEPTICS; ANTIBIOTICS; SULFONAMIDES; and under ACCIDENTS, INJURIES.)

Wounds, How They Heal

The blood forms clots; these consist of minute threads of fibrin, in which are enmeshed red blood cells and white blood cells. The threads of fibrin bridge the gap between the cut surfaces of the wound, at its base, forming a matrix, and hardening into a scab under which tissue repair can take place. (See CLOTTING OF BLOOD.)

From the neighbouring blood capillaries come white cells (especially neutrophils) which engulf dirt, bacteria, etc. (See PHAGOCYTOSIS.) Monocytes arrive later, especially if the wound has become infected. They become macrophages which remove any disintegrated neutrophils and also bacteria. Meanwhile, the cells of the epidermis begin to multiply in order to restore the skin covering. (See LYMPHOCYTES.)

Healing of wounds may be delayed if the animal is being treated with corticosteroids. First aid or professional attention must not hinder any of these processes so that healing is not delayed. (See also INTENTION.)

Wry-Neck, Torticollis

Wry-neck (torticollis), which occurs particularly in foals, sheep, poultry (NEWCASTLE DISEASE) and pigeons (PARAMYXOVIRUS), is a lateral deviation of the head and neck to the right or left side of the body, usually so marked as to hinder or prevent foaling. The bones of the skull and neck are frequently distorted, and the ligaments, tendons, and muscles on the inside of the curve are shorter than those on the outside.

The condition may also be encountered in cattle.

When seen in rabbits, the cause may be middle ear infection with *Encephalitozoon cuniculi*.

In poultry it is seen in NEWCASTLE DISEASE and PARAMYXOVIRUS infection in pigeons.

Wyandotte Chickens

These originated in the USA in the 1870s. They are dual purpose (brown eggs and meat), producing 200 eggs per year. Usually, there is a white ring of feathers around the neck; they are of medium size, with clean legs, white skin and a rose comb which is almost flat and has two rows of digital protrusions along the comb length. The male weighs 3.9 kg (8.5 lb) and the hen 2.7 kg (6 lb). There are eight usually recognised colours (golden laced, silver laced, white, black, buff, Columbia, partridge, silver pencilled). In the USA there has been added white laced red and buff laced; in Britain, there are overall 17 colours.

X

Xanthine
A PURINE that is found in most living cells and fluids and can form URIC ACID. THEOPHYLLINE is a xanthine compound used as a DIURETIC.

Xanthomatosis
The accumulation in the body of excess lipid due to a disturbance of lipid function. It is marked in skin lesions (usually epidermoid cysts) by the formation of foam cells and Touton giant cells. It is seen in DIABETES MELLITUS in dogs and is quite common in humans and chickens.

Xanthosis
Xanthosis is a yellowish-brown pigmentation of meat, generally affecting the heart and the tongue. It gives the meat an objectionable colour, but is quite harmless.

Xenophthalmia
Inflammation of the eye caused by a foreign body.

Xenotransplants
These are transplant of tissues or organs from one species into the body of another species. Much work has been undertaken in pigs genetically modified by the insertion of human genes, with the aim of using the tissues of those pigs notably heart valves) for use in human surgery.

Xerophthalmia
A disease of the eye associated with a vitamin A deficiency. There is thickening and cloudiness of the conjunctiva and cornea; blindness may result.

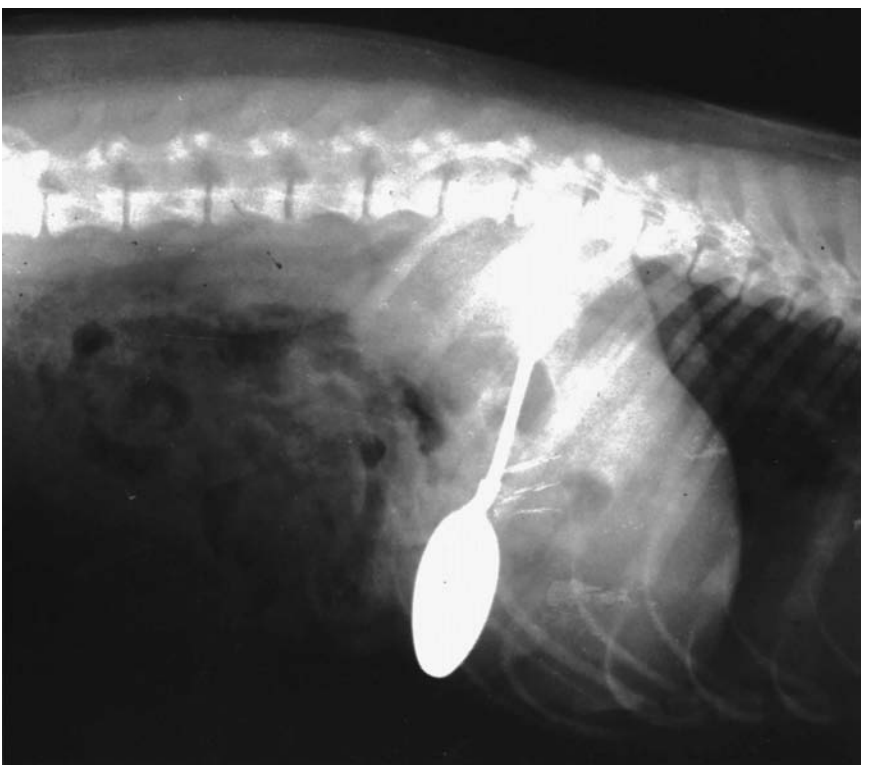
X-Rays
X-Rays are high-energy radiation capable of passing through considerable thicknesses of many substances which are opaque to ordinary light, without undergoing material absorption, but other substances, even in very small thicknesses, are able to absorb the great majority of the rays: thus, flesh is very transparent; healthy bone is fairly opaque. Widely used for diagnostic imaging of internal body structures and in human and animal medicine for radiotherapy.

Precautions Guard screens of lead glass, rubber impregnated with lead, or sheet lead, are used to protect the operators of radiographic apparatus, and precautions are necessary to shield the testes and ovaries of young persons and animals from the sterilising effects of the rays.

Detailed precautions are as follows:

1. Persons under 16 years must not take part in radiological procedures.
2. Fluoroscopy (imaging) or radiotherapy should not be carried out except under expert radiological guidance. Hand-held fluoroscopes must not be used in any circumstances.
3. Personnel radiation monitoring devices, such as film badges, must be worn by all persons who take part routinely in radiological procedures.
4. The animal should, if possible, be anaesthetised or tranquillised for radiography, and all persons should withdraw as far as practicable from the useful beam.
5. If it should be necessary to hold the animal for radiography, lead-protective gloves and aprons must be worn. Whenever possible, holding should be done by the owners, unless they are under 16 years or pregnant.
6. Persons should not expose any part of their bodies to the useful beam even when wearing protective clothing.
7. The useful beam should be restricted to the area being examined by means of a beam-limiting device, usually by a LIGHT BEAM DIAPHRAGM.

Notes on protection against radiation will also be found in the British Veterinary Association's guide to the Health and Safety at Work Act.



Regulations In the UK, the Ionising Regulations 1985 require veterinary surgeons using X-ray equipment to notify their local Health and Safety Executive. Many veterinary practices now employ a radiation protection adviser to ensure compliance with the requirements of the regulations.

Procedure of Radiography The production of a radiograph of the internal structure of a small animal is a comparatively simple matter once the difficulty of control is overcome. The animal is arranged upon the table in such a position as to allow the rays to pass down through the part and become registered upon a sensitive plate placed flat upon the table immediately below. The animal may lie upon its back, on one or the other side, or on its chest and abdomen with the legs pulled out from under it and secured by adhesive tape, ropes, webbing, bandages, sand bags, Velcro onto hooks or other fittings on the table. To maintain this position it is always advisable to administer an anaesthetic. The anode tube is best arranged immediately above the animal in such a position as to allow the rays to fall perpendicularly down through the body on to the plate. (For screening, the tube must be below the table, and the screen

held or supported above the animal.) The period of exposure to the passage of the rays varies according to the tissues, to the type and power of the equipment, to the distance of the tube from the plate, and to whether or not an intensifying screen is used.

There are many conditions in which the actual extent of injury or disease can be accurately discovered by the use of X-rays, but the most important are diseases and injuries of bones. Fractures of the limb-bones are well shown, and their extent is better realised than is possible by palpation. Exostoses (overgrowths of bone) can also be clearly indicated, while tumour formation (usually sarcomatous) shows as a thinning and enlargement of the bone tissue. OSTEOLYSIS shows as radiolucent (dark) shadows on a radiograph. Where only one limb is affected it is advisable to arrange the animal so as to include a picture of the normal limb for comparison. Foreign bodies – especially needles, pins, nails, and other metallic substances – which have been swallowed or have penetrated from the outside into the musculature or the nose, mouth, anus, bladder or body cavities are best shown by a profile view of the abdomen. Parts of or pieces of whole bones (which are specially dense and show up well) can also be seen in the stomach or intestines, and are very often surrounded by gas, which, in the negative radiograph, appears as a dark (RADIOPAQUE) shadow – the bone itself appearing light. Internal tumours can very often be diagnosed. They appear as more or less discrete pale areas in positions where a radiograph from a normal animal is denser under the same conditions of exposure, etc. Certain tumours can be made to show up well by giving the animal medicinal doses of a lead salt for a few days before taking the plate. Some of the lead becomes deposited in the tumour and intensifies the contrast. Where some displacement, stricture, or dilatation of the stomach or of part of the intestinal canal is suspected, the animal is given a feed or a draught containing an emulsion of bismuth or barium carbonate, or some other harmless metallic salt, or has some of the same material injected into the rectum. After waiting until the salt has become suitably distributed, a radiograph of the abdomen is taken, and the outlines of those organs to which the salt has been carried by peristalsis, can be made out as pale areas in the negatives.

Other conditions in which X-rays are useful are as follows: stones in the kidney, urinary or gall-

A teaspoon in the stomach of a cocker spaniel. The spoon was swallowed while the animal was being given cod-liver oil. (Reproduced by courtesy of Mr S. W. Douglas, University of Cambridge School of Veterinary Medicine.)

Radiography reveals that a painful swelling on the leg of a St Bernard is due to an osteosarcoma involving the radius. (Reproduced by courtesy of Mr S. W. Douglas, University of Cambridge School of Veterinary Medicine.)

bladder; dilatation of the heart; solidification of a portion of a lung; and pleurisy.

Portable X-ray apparatus is available for use in, for example, examining the lower limbs of a horse at the stable.

Computed tomography An effective method of visualising the interior of the body, this has revolutionised radiography and DIAGNOSTIC IMAGING. (See also ANGIOGRAPHY; COMPUTED TOMOGRAPHY.)

Radiotherapy X-ray therapy has been applied to a limited extent in specialist centres in the treatment of certain tumours in the dog and cat. (See also RADIOTHERAPY.)

Xylazine

A sedative used to render animals easier to handle, it is widely used in dogs, cats, horses, farm livestock, and zoo animals. It is also used for pre-anaesthetic medication and for general anaesthesia in combination with ketamine, especially in small animals, birds and reptiles when ISOFLURANE and SEVOFLURANE are not available for the same type of anaesthesia. (See ANAESTHESIA, LOCAL AND REGIONAL.) It can be used on its own or with LIDOCAINE or MORPHINE for caudal EPIDURAL ANAESTHESIA in horses, and on its own in sheep.

Xylazine increases blood glucose levels and urine output. Side-effects may include bradycardia, slower breathing, and lowered blood pressure. In cattle tolazoline has been used as a xylazine antagonist.

Xylitol

An artificial sweetener used to replace sugar. It can cause poisoning in dogs as the canine pancreas appears unable to distinguish it from sugar. Thus if a product containing xylitol is ingested there is an insulin surge resulting in hypoglycaemic coma and even death. Prolonged use in small doses results in liver damage.

Xylometazoline

(See IMIDAZOLINE COMPOUNDS.)

Y

Yarded Cattle

Before yarding cattle in the autumn, it is wise to make a gradual change from sugar-poor autumn pasture to things like roots; otherwise digestive upsets are likely to occur.

Similarly, in spring it is a mistake to turn calves straight out on to grass. This means a sudden change from protein-poor food to the rich protein of the early bite, and the resulting effect upon the rumen will set them back. It is best to get them out before there is much grass for a few hours each day; let them have hay and shelter at night to protect them from sudden changes of weather. Hypomagnesaemia, too, is far less likely under these circumstances. (See also HOUSING OF ANIMALS.)

Boss cows can be a nuisance in yards, but the provision of yokes for feeding overcomes the main difficulty.

When self-feeding of silage is practised, precautions are necessary in order to prevent foot troubles. (See SILAGE.)

Yarded animals fed on cereals, sugarbeet pulp, straw, and hay – but with little or no greenstuff – may suffer from xerophthalmia and go blind as a result of a vitamin A deficiency.

Yawning

Yawning is an important sign of KIMBERLEY HORSE DISEASE; it may also be seen in cases of LABURNUM POISONING and NARCOLEPSY.

Yeast

Yeast is a valuable source of vitamin B, but should not be fed in excessive amounts to pigs or it may give rise to rickets unless adequate vitamin D is simultaneously available. Yeast has proved successful in the treatment of tropical ulcers in humans, and success has been reported in a limited number of cases in horses in the tropics. The human patients were mostly those whose diet was deficient in vitamin B, a deficiency further increased by sweating. The yeast was applied directly to the ulcer, and a small quantity given internally also.

Yeasts release mannan-oligosaccharides that occupy intestinal receptors and prevent the entry of certain pathogens which then pass through the gut without colonisation. They also have anti-oxidant properties, can alleviate heat stress, increase trace mineral uptake and balance the intestinal flora. Whole yeast cells can bind aflatoxins. Live yeast *Saccharomyces cerevisiae* fed to adult dairy cows as a dietary supplement increases the digestibility of hemicellulose and crude protein and increases the number of cellulolytic bacteria in the rumen. In young calves supplementation increases dry matter intake and weight gain.

A sub-species, *S. cerevisiae boullardii* has been used for about 100 years in man and other monogastric animals as both a prevention and a treatment for a variety of pathogenic enteric bacteria, such as entero-haemorrhagic *E. coli* and *Salmonella typhimurium*. In the USA, adding the sub-species to milk replacer improved the health and performance of calves by reducing diarrhoea. Hydrolised brewers' yeast have been fed to piglets in Europe and resulted in reduced diarrhoea problems and enhancement of intestinal absorption.

Yeasts

Yeasts sometimes cause enteritis, and are important in some cases of refractory otitis in the dog. CANDIDIASIS usually infects the respiratory system. (See FUNGAL DISEASES.)

Yellow Fat Disease of Cats

(See STEATITIS.)

Yellow Fever

A viral disease affecting man and other vertebrates, principally monkeys, in large areas of tropical America and Africa. There are two known cycles of transmission, the urban and jungle cycles. In the urban cycle, man is the reservoir and *Aedes aegypti* probably the only vector. This cycle from man to *A. aegypti* to man is now virtually unknown in the Americas owing to efforts to eradicate the vector, but it is still common in Africa.

The jungle cycle has a primate reservoir maintained by various mosquitoes. Movement of virus from the monkey-mosquito-monkey cycle into man is accidental, and is the result of human penetration into jungle where the disease is endemic.

The causative organism is classified as a flavivirus.

Yelt

A female pig intended for breeding, up to the time that she has her first litter.

Yemane

A fast growing tree (*Gmelina arborea*), which is drought tolerant. It is mainly grown in the Philippines in commercial forest operations and parts of the tree are edible for humans and other animals. Yemane leaf meal can partially replace rice bran and copra in animal feeds.

Yersinia enterocolitica

Infection can cause diarrhoea in man, cattle and pigs. It is associated with food poisoning and can cause YERSINIOSIS.

VetBooks.ir

Yersiniosis

Infection with *Yersinia pseudotuberculosis* or with *Y. enterocolitica*.

Up to 1960, states WHO, only the former organism was regularly isolated in man and animals in Europe; but since then most of the isolations have been of *Y. enterocolitica*.

'Pseudotuberculosls' in the early 1990s was still occasionally found in rodents and birds, especially in France and the UK, and is a zoonosis. People may become infected through pets such as guinea pigs, hamsters, and cats, all of which may have a subclinical infection only but excrete *Y. pseudotuberculosis*.

An investigation in New Zealand, resulted in *Y. pseudotuberculosis* being isolated from 675 apparently healthy small mammals and birds. In descending order of prevalence were feral cats (27.8 per cent), Norway rats (8.6 per cent), mice, hares, rabbits, ducks, sparrows, seagulls and starlings.

In New Zealand, yersiniosis has also emerged as a serious disease of farmed red deer. It appears to be triggered off by stress, and most cases occur during the winter.

Cats (which are liable to become infected by their prey) may also show clinical signs: loss of appetite, vomiting and diarrhoea. Also loss of weight.

Pheasants Yersiniosis is an important cause of death of these birds in the UK.

***Yersinia enterocolitica* infection** in Europe was first found in hares, in outbreaks of disease on chinchilla farms, in monkeys in zoos, and in guinea pigs. There may be enteritis and other lesions, but symptomless carriers have been found among all the farmyard mammals and birds.

Occasionally *Y. enterocolitica* has been isolated from cases of mastitis in cows, endocarditis in bulls, and septicaemia in pigs. In cattle, the antibody produced may be difficult to differentiate from that produced by *Brucella abortus*.

Camels, foxes, and fleas may also carry the organism.

Public health *Yersinia enterocolitica* infection is not regarded as a genuine zoonosis by WHO. Person-to-person infection occurs, and also infection from soil-contaminated vegetables. The human illness is characterised by enteritis, and is a cause of diarrhoea, although less important than salmonella and campylobacter. Ileitis may be accompanied by acute pain, suggestive of appendicitis. A mesenteric adenitis is also seen, and sometimes polyarthritis, deep abscesses, eye lesions, and occasionally septicaemia.

In the UK in 1984, 250 cases were reported. Outbreaks in North America have been linked to raw milk. In the USA, it is estimated that there are 123 human cases undiagnosed for every one reported. (For *Y. pestis see* BUBONIC PLAGUE, which can occur in cats and dogs in subclinical form.)

Yew Poisoning

All varieties of the British yew trees are poisonous, but owing to its more frequent cultivation, the common yew (*Taxus baccata*) is most often responsible for outbreaks of poisoning among animals. The Irish yew (*T. baccata* var. *fastigiata*) and the yellow yew appear to contain less of the poisonous alkaloid, which is called taxine. The bark, leaves and seeds all contain it. The older dark leaves are more dangerous than the fresh green young shoots, which cattle have been known to eat in small amounts without harm. Cases of poisoning have been noted among horses, donkeys, mules, cattle, sheep, goats, pigs, deer, rabbits, and even pheasants, but the majority of cases occur in young store cattle and in dairy cows which have access to the shrubberies, graveyards, etc., where yew trees are most common.

Signs In many cases cattle drop dead without showing any preliminary signs at all. They may fall while cudding almost as suddenly as if shot. In other cases where less has been eaten, excitement and paresis may be seen.

Treatment Antidotes are as for alkaloids. If time allows, rumenotomy may be carried out.

Yohimbine

An alkaloid found naturally in the Yohimbe (*Pausinystalia yohimbe*) and in the Indian Snakeroot (*Rauwolfia serpentina*). It is used to reverse anaesthesia from XYLAZINE in small and large animals.

Yokohama Chickens

A show breed originating from Japan. It is a quiet breed and usually only the males are shown. The plumage is unusual with long elegant tail and tail coverts called saddle feathers. The heaviest birds weigh 1.8 kg to 2.3 kg (4 lb to 5 lb).

Yolk Sac Infection

(See OMPHALITIS OF BIRDS.)

Yorkshire Boarding

Vertically arranged boards with a gap between each, used for partial cladding of a livestock building. The boards are placed with gaps on either side of a timber frame so that the air is baffled before entering the building. It is a very useful means of improving ventilation and avoiding condensation, thereby reducing the risk or incidence of bronchitis and pneumonia in housed livestock.

Yorkshire Terrier

A long-haired, black-and-tan coloured toy dog. The breed is prone to TRACHEAL COLLAPSE caused by a cartilage defect that may or may not be inherited. ATOPIC DERMATITIS, PATELLAR LUXATION and PROGRESSIVE RETINAL ATROPHY (DNA test available) are inherited as recessive traits.

VetBooks.ir

Z

Zearalenone
An oestrogenic toxin from the fungus *Fusarium graminearum* of standing corn. The toxin has caused abortion in sows, and possibly a splayleg condition in piglets. It can result in udder development in farm animals and has been used in the past as a growth promoter, but is now banned in Europe.

Zebra Fish
Danio rerio is a tropical fish that has been kept in aquaria. It has a remarkable ability to repair its heart muscle. It is being studied to discover the mechanism with a view to developing treatments for other species.

Zebu
Bos indicus, the cattle of India, East and West Africa, and Southeast Asia. The American name is Brahman; in South Africa, the Afrikaner.

Zeolite
A natural reservoir rock containing loosely-held water. It includes aluminium silicates and three-dimensional macro-molecular structures. The elementary unit is a tetrahedron. It absorbs water, carbon dioxide, ammonia and mercury. It is used in some alimentary conditions and to prevent uptake of toxins including mercury.

Zero-Grazing
Taking cut fodder to yarded cattle, or to cattle in exercise paddocks. Zero-grazing has a place on heavy land, with high stocking rates and large herds. It obviates poaching and the spoiling of grass, and a given acreage zero-grazed can provide more grass than if grazed. It means, however, cutting grass every day, and mechanical failures can upset the system. It is not yet considered economic for sheep.

The term is now also used for cattle kept inside all the year round and normally fed conserved grass products rather than fresh grass. It allows more feed control and results in more consistent feed quality for the cattle. Many Danish herds are housed and it is increasing in Britain (two per cent of dairy herds in 2012).

Ziehl-Neelsen Stain
A stain used to demonstrate ACID-FAST staining. It is used to stain organisms which are difficult to stain with ordinary staining techniques e.g. GRAM'S STAINING. It is used in *Mycobacterium* species such as *M. bovis*, *M. tuberculosis*, *M. avium* subspecies *paratuberculosis*. Gram-positive micro-organisms stain bright red. A MODIFIED ZIEHL-NEELSEN STAIN can be used and stains various micro-organisms such as *Cryptosporidium* spp. (See CRYPTOSPORIDIOSIS.)

Zilpaterol Hydrochloride
A GROWTH PROMOTER used in North America improving growth and conformation in steers and heifers before slaughter. It was alleged that it might cause lameness and was voluntarily discontinued in 2013, although research did not find a link. It is not used in Europe.

Zinc (Zn)
Zinc (Zn) is a trace element, and a deficiency has occurred in pigs (see PARAKERATOSIS). It has a role in immunity and increases thymocyte and peripheral T-cell count, the activity of natural killer cells and neutrophils. It is important in the production of macrophages, antibodies and interferon. Deficiency of zinc impairs interleukin-2 production, which plays a role in cell-mediated immunity. A zinc supplement to prevent or correct this condition must be used with care, as 1000 parts per million can cause poisoning. It seems that a high calcium intake by pigs aggravates a zinc deficiency.

A zinc deficiency may also occur in dogs, especially in those fed largely on flaked maize or 'loose cereal-based diets'. Signs include a predisposition to skin infections, a poor coat, localised alopecia, and hardening of the skin in places. Response to a zinc supplement is usually quick. (See SHEEPDOGS.)

A zinc supplement has been used to protect sheep against facial eczema due to ingestion of the MYCOTOXIN SPORIDESMIN. Feeding 160 ppm of zinc sulphate and 140 ppm of zinc-amino acid complex in the diet of broiler breeders resulted in superior performance in some studies and improved feed conversion in their progeny in other trials. Zinc as acetate at 1 per cent of the diet can successfully induce moult in poultry, and is important as the traditional method of withholding feed for 24 hours is prohibited in the EU.

Zinc toxicity has been reported in dogs, with signs of vomiting, pigmenturia and haemolytic anaemia. Blood analysis shows hyperbilirubinaemia. Treatment is usually successful with hospitalisation for two days.

External uses Zinc oxide is an ingredient of ointments; the carbonate an ingredient of calamine lotion used for moist eczema, etc. The sulphate in weak solution has been used in wound treatment and in eye lotions; the chloride – a caustic – to repress granulations.

Zinc Bacitracin
An antibiotic formerly used as a feed additive to improve growth rate in most farm

animals and egg production in poultry. (See ADDITIVES.)

Zinc Poisoning

Chronic zinc poisoning has been reported in a dairy herd as a result of contaminated drinking water – caused by interaction between copper pipes and newly galvanised tanks, and from accidental incorporation of zinc oxide in the manufacture of dairy nuts. The main sign was chronic constipation throughout the herd, and a diminished yield from the cows in milk.

Fatalities of zinc poisoning have occurred in dairy cattle fed on dairy nuts to which zinc oxide has been added instead of magnesium oxide. The first deaths occurred after three weeks.

Zinc poisoning is quite common in psittacine birds kept in old or recently constructed aviaries in which new galvanised wire mesh has been added. The birds gnaw at the wire with their beaks and ingest particles of zinc from the galvanised coating. Neurological signs occur. In dogs it occurs orally from skin preparations or tablets and the main problem is HAEMOLYTIC ANAEMIA, with colic, anorexia, and vomiting.

Treatment is by CHELATING AGENTS. Prevention involves allowing the wire to 'weather' in normal rainfall or by the application of dilute acetic acid to remove excess zinc.

Zinc-responsive skin disease It has been seen in many species especially dogs, cattle and camelids. The most common cause of this is the feeding of soya or cereal-based diets – with little or no meat, which is rich in zinc. Some dogs may have an inherent defect which limits zinc absorption.

Signs A dull, harsh coat; sometimes with whitish crusts on the skin.

Zinc Protoporphyrin

A compound found in red blood cells when HAEM production is inhibited by LEAD POISONING and/or a lack of IRON.

Zondek-Ascheim Test

(See PREGNANCY DIAGNOSIS.)

Zoo Licensing Act 1981

The Zoo Licensing Act 1981 (amended 2002) is intended to promote animal welfare and public safety at zoos. It covers any collection of wild animals (including mammals, birds, reptiles, fish, and insects) in Britain to which the public has access for more than seven days in any 12-month period; but exempts pet shops and circuses, as these are covered by the Pet Animals Act 1951 and the Performing Animals (Registration) Act 1952.

Of 150 zoos inspected following the passing of the Act, only five were refused a licence; and in those cases it was public-safety considerations rather than the quality of animal care which brought about the refusal.

Zoonoses

(singular, Zoonosis; adjective, Zoonotic)

Diseases communicable between animals and human beings and which may have passed through intermediate hosts such as ticks, mosquitoes, midges etc. Information about them will be found under the following headings: ARIZONA INFECTION; BABESIA; Babesiosis; ANTHRAX; BAYLISASCARIOSIS; B VIRUS (from monkeys); BOVINE SPONGIFORM ENCEPHALOPATHY; BRUCELLOSIS; CAMPYLOBACTER SPP. INFECTIONS; CAT-SCRATCH FEVER; CHAGAS DISEASE; EQUINE ENCEPHALITIS; EQUINE INFECTIOUS ANAEMIA; FOOT-AND-MOUTH DISEASE (very rare in human beings); GLANDERS; HYDATID DISEASE; LEISHMANIASIS; LEPTOSPIROSIS; LISTERIOSIS; LIVER-FLUKES; LOUPING-ILL; LYME DISEASE; LYMPHOCYTIC CHORIOMENINGITIS (from mice); NEWCASTLE DISEASE; ORNITHOSIS; ORF; pasteurellosis; Q FEVER; RABIES; RAT-BITE FEVER; RIFT VALLEY FEVER; RINGWORM; ROCKY MOUNTAIN FEVER; RUSSIAN SPRING-SUMMER VIRUS; SALMONELLOSIS; SCABIES; SCHISTOSOMIASIS; TAPEWORMS; TICK-BITE FEVER OF MAN IN AFRICA; TICK PARALYSIS; *Toxocara*; TOXOPLASMOSIS; TRICHINOSIS; TUBERCULOSIS; TULARAEMIA; VESICULAR STOMATITIS; MARBURG DISEASE; WESSELSBRON DISEASE; YERSINIOSIS; YELLOW FEVER; SWINE VESICULAR DISEASE; PORCINE STREPTOCOCCAL MENINGITIS; ROTAVIRUS; LASSA FEVER; BOVINE ENCEPHALOMYELITIS; LEISHMANIASIS; BUBONIC PLAGUE; ENCEPHALOMYOCARDITIS VIRUS.)

Typhus and plague may be transmitted, by flea-bite, from rats; and, in jungle areas, yellow fever, by mosquito-bite, from monkeys. (See also under RODENTS; MONKEYS; INFLUENZA.)

Among skin diseases, the parasite of follicular mange may occasionally infest the human eyelid. Among eye infections, INFECTIOUS BOVINE KERATOCONJUNCTIVITIS should be mentioned. Human enteritis has followed contact with sheep affected with campylobacter abortion.

(See also BIRD-FANCIER'S LUNG; MELIOIDOSIS; CHLAMYDOPHILA; PSITTACOSIS; BOUTONNEUSE FEVER; LEISHMANIA; HANTAVIRUS; TICK-BORNE ENCEPHALITIS; *Ehrlichia canis*; ABORTION, ENZOOTIC.)

Zoonoses in UK Veterinarians

A questionnaire was distributed to 1,717 members of veterinary and support staff of the Ministry of Agriculture and the Institute for Research on

VetBooks.ir

VetBooks.ir

Animal Diseases; 1,625 (95 per cent) responded, comprising 563 veterinary surgeons, 690 scientific staff and 372 technical support staff. A total of 1,057 (61.5 per cent) had apparently not suffered any zoonotic infection. Animal RINGWORM was the commonest reported zoonosis. The incidences of ringworm, BRUCELLOSIS and NEWCASTLE DISEASE were higher in the veterinary and support staff than in the laboratory workers. In contrast, ORNITHOSIS, SALMONELLOSIS and Q FEVER occurred at least as often in the laboratory staff. Fourteen people developed TUBERCULOSIS during their employment, although only one was caused by *Mycobacterium bovis*. The veterinarians reported 441 injuries that resulted from accidents at work; 397 (71 per cent of all veterinarians) of these involved animal-handling. The comparable figures for laboratory workers and technical staff were 329 and 103 (15 per cent) and 198 and 179 (42 per cent) respectively.

Zoonoses Orders 1988 & 1989

These include measures intended to reduce the risk to humans of salmonella and brucella infections of animal origin. The 1989 Order recognises bovine spongiform encephalopathy as a zoonotic disease.

Zootechny

Animal management.

Zwartble Sheep

The sheep were developed at the start of the 20th century in Freisland, Holland, and were introduced in Britain in 1980s. They are a large black sheep with a white blaze on the face from nose to crown, the legs may be part white and a white tip to the undocked tail. The medium to fine fleece is chocolate brown to black and weighs about 4 kg (9 lb). The average mature ram weighs 100 kg (220 lb) and the ewe 85 kg (185 lb).

Zwitterion

A neutral molecule with both a positive and negative charge at different locations within the molecule but not at the poles. It is a characteristic of FLUOROQUINOLONES.

Zygodactyly

A congenital fusion of two or more digits (same as SYNDACTYLY).

Zygoma

Zygoma is the bridge of bone which runs from near the base of the ear to the lower posterior part of the eye-socket. It protects the side of the bony orbit, forms part of the support of the outside of the joint of the lower jaw with the rest of the head, and serves as a base of attachment for part of the strong masseter muscle which closes the mouth and is important in the chewing of the food. The zygomatic arch (another name for the zygoma) is formed by projections from the temporal, zygomatic, and maxillary bones.

Zygote

The body that results from the fertilisation of an egg cell by a sperm.
